A Reference Handbook

of

THE MEDICAL SCIENCES

EMBRACING THE ENTIRE RANGE OF

SCIENTIFIC AND PRACTICAL MEDICINE

AND

ALLIED SCIENCE

BY VARIOUS WRITERS

A NEW EDITION, COMPLETELY REVISED AND REWRITTEN

EDITED BY ALBERT H. BUCK, M.D.
NEW YORK CITY

VOLUME VII

ILLUSTRATED BY CHROMOLITHOGRAPHS AND SIX HUNDRED AND EIGHTY-EIGHT HALF-TONE AND WOOD ENGRAVINGS

NEW YORK
WILLIAM WOOD AND COMPANY
MDCCCCIV

PUBLISHERS' PRINTING COMPANY
32 AND 34 LAFAYETTE PLACE, NEW YORK

LIST OF CONTRIBUTORS TO VOLUME VII.

SAMUEL W. ABBOTT, M.D., NEWTON CENTRE, MASS.
Secretary of State Board of Health of Massachusetts.

CHARLES WARRENNE ALLEN, M.D., NEW YORK, N. Y.
Professor of Dermatology, New York Post-Graduate Medical School; Consulting Dermatologist to the Randall's Island Hospitals.

JAMES RAE ARNEILL, M.D....... DENVER, COL.
Associate Professor of Medicine, University of Colorado, Denver, Col.; formerly Instructor in Clinical Medicine, University of Michigan.

ISAAC E. ATKINSON, M.D.... ...BALTIMORE, MD.
Formerly Professor of Therapeutics and Clinical Medicine, Medical Department of the University of Maryland.

JAMES B. BAIRD, M.D.......... ...ATLANTA, GA.
Professor of Clinical Medicine, Southern Medical College; Attending Physician, Grady Hospital, Atlanta, Ga.

FRANK BAKER, M.D., PH.D....WASHINGTON, D. C.
Professor of Anatomy, Medical Department, Georgetown University, Washington, D. C.; Superintendent, National Zoological Park, Smithsonian Institution.

FREDERICK AMOS BALDWIN, M.D., ANN ARBOR, MICH.
Assistant in Pathology, Medical Department, University of Michigan.

CHARLES EDWARD BANKS, M.D...CHICAGO, ILL.
Surgeon and Medical Purveyor, United States Marine Hospital Service.

LEWELLYS FRANKLIN BARKER, M.B. (TORONTO), CHICAGO, ILL.
Professor of Anatomy, Medical Department, University of Chicago; formerly Associate Professor of Anatomy in the Johns Hopkins University.

DONALD McLEAN BARSTOW, M.D...NEW YORK, N. Y.
Clinical Assistant, Department of Medicine, Vanderbilt Clinic, College of Physicians and Surgeons, Columbia University.

WALTER ARTHUR BASTEDO, PH.G., M.D., NEW YORK, N. Y.
Instructor in Materia Medica and Therapeutics, College of Physicians and Surgeons, Columbia University; formerly Torrey Club Lecturer on Botany at the New York College of Pharmacy.

ROBERT RUSSEL BENSLEY, M.D. (TORONTO), CHICAGO, ILL.
Assistant Professor of Anatomy, University of Chicago.

HENRY W. BERG, M.D.........NEW YORK, N. Y.
Attending Physician to the Willard Parker and Riverside Hospitals; Adjunct Attending Physician to Mount Sinai Hospital.

HENRY WALD BETTMANN, M.D.....CINCINNATI, OHIO.
Pathologist, City Hospital of Cincinnati; formerly Professor of Medicine, Cincinnati College of Medicine and Surgery.

ROBERT PAYNE BIGELOW, PH.D., BOSTON, MASS.
Instructor in Biology, Massachusetts Institute of Technology.

W. P. BOLLES, M.D. ....BOSTON, MASS.
Professor of Materia Medica and Botany, Emeritus, Massachusetts College of Pharmacy; Attending Surgeon, Boston City Hospital.

DAVID BOVAIRD, JR., M.D......NEW YORK, N. Y.
Tutor in General Medicine, College of Physicians and Surgeons, Columbia University; Associate Physician to the Presbyterian Hospital; Pathologist to the Foundling Hospital.

L. DUNCAN BULKLEY, M.D....NEW YORK, N. Y.
Attending Physician, Skin and Cancer Hospital; Dermatologist, Randall's Is. and Hospitals.

WILLIAM NORTON BULLARD, M.D......BOSTON, MASS.
Physician, Department of Diseases of the Nervous System, Boston City Hospital; Consulting Neurologist, Carney Hospital; Neurologist, the Children's Hospital.

FRANK BULLER, M.D........MONTREAL, CANADA.
Professor of Ophthalmology and Otology, Medical Department, McGill University.

RICHARD CLARK CABOT, M.D....BOSTON, MASS.
Assistant in Clinical Medicine, Harvard University Medical School; Physician to Out-Patients, Massachusetts General Hospital.

WILLIAM JEPHTHA CALVERT, M.D., COLUMBIA, MO.
Assistant Professor of Internal Medicine, Missouri State University, Columbia, Mo.; formerly Assistant Surgeon, United States Army, Manila, Philippine Islands.

DONALD M. CAMMANN, M.D...NEW YORK, N. Y.

H. W. CLARK, ESQ....... ....BOSTON, MASS.
Chemist in Charge of Experimental Station and Laboratories at Lawrence, Mass.

SOLOMON SOLIS COHEN, M.D., PHILADELPHIA, PA.
Lecturer on Clinical Medicine, Jefferson Medical College; Attending Physician, Philadelphia and Rush Hospitals.

WILLIAM T. COUNCILMAN, M.D...BOSTON, MASS.
Shattuck Professor of Pathological Anatomy, Harvard University Medical School.

JOSEPH WILLIAM COURTNEY, M.D.. ..BOSTON, MASS.
Assistant Physician for Diseases of the Nervous System, Boston City Hospital.

DAVID MURRAY COWIE, M.D., ANN ARBOR, MICH.
First Assistant in Internal Medicine, Medical Department, University of Michigan.

JAMES K. CROOK, M.D....... .. NEW YORK, N. Y.
Adjunct Professor of Clinical Medicine and Physical Diagnosis, New York Post Graduate Medical School; Attending Physician, New York Post Graduate Hospital.

EDWARD CURTIS, M.D. .... NEW YORK, N. Y.
Emeritus Professor of Materia Medica and Therapeutics, College of Physicians and Surgeons, Columbia University.

JOHN CHALMERS DACOSTA, M.D., PHILADELPHIA, PA.
Professor of the Principles of Surgery and of Clinical Surgery, Jefferson Medical College; Attending Surgeon, Philadelphia Hospital; Consulting Surgeon, St. Joseph's Hospital, Philadelphia.

THOMAS DARLINGTON, M.D. KINGSBRIDGE, NEW YORK, N. Y.
Attending Physician, New York Foundling Hospital, New York, and St. John's Riverside Hospital, Yonkers, N. Y.

D. BRYSON DELAVAN, M.D..... NEW YORK, N. Y.
Professor of Laryngology, New York Polyclinic; Consulting Laryngologist, General Memorial Hospital and Hospital for Ruptured and Crippled, New York.

JOHN DOUGLAS, M.D.......... NEW YORK, N. Y.
Attending Surgeon, University and Bellevue Medical College Clinic; Assistant Attending Surgeon, St. Luke's Hospital, Out Patient Department.

THEODORE DUNHAM, M.D ..... NEW YORK, N. Y.
Adjunct Professor of Surgery, New York Post Graduate Medical School; Attending Surgeon, Post-Graduate Hospital (Babies' Wards).

WILLIAM A. EDWARDS, M.D..... CORONADO, CAL.
Attending Physician, Coronado Hospital.

J. HAVEN EMERSON, M.D ...... NEW YORK, N. Y.

MARTIN F. ENGMAN, M.D..... .. ST. LOUIS, MO.
Chief of Dermatological Clinic, Medical Department, Washington University, St. Louis, Mo.; Dermatologist, St. Louis City Hospital.

AUGUSTUS A. ESHNER, M.D., PHILADELPHIA, PA.
Professor of Clinical Medicine, Philadelphia Polyclinic; Attending Physician, Philadelphia Hospital; Attending Physician, Hospital for Diseases of the Lungs at Chestnut Hill.

PAUL F. EVE, M.D............. NASHVILLE, TENN.
Professor of Principles and Practice of Surgery and of Clinical Surgery, Medical Department, University of Tennessee.

WILLIAM HASTY FLINT, M.D. SANTA BARBARA, CAL.

EDWARD MILTON FOOTE, M.D ..... NEW YORK, N. Y.
Instructor in Minor Surgery, College of Physicians and Surgeons, Columbia University; Visiting Surgeon, City Hospital, New York.

EUGENE FOSTER, M.D........ .... AUGUSTA, GA.
Professor of Principles and Practice of Medicine and State Medicine, Medical Department, University of Georgia.

JOSEPH FRAENKEL, M.D... ... NEW YORK, N. Y.
Instructor in Nervous Diseases, Cornell University Medical School, Neurologist to the City Hospital; Physician to the Montefiore Home, New York.

ALBERT HENRY FREIBERG, M.D.... CINCINNATI, OHIO.
Professor of Orthopædic Surgery, Medical Department, University of Cincinnati; Orthopædic Surgeon to the Cincinnati, Presbyterian, and Jewish Hospitals, Cincinnati.

JAMES M. FRENCH, M.D....... CINCINNATI, OHIO.
Lecturer on the Theory and Practice of Medicine, Medical College of Ohio; Attending Physician, St. Mary's Hospital, Consulting Physician, St. Francis Hospital for Incurables.

F. MORLEY FRY, M.D... .... MONTREAL, CANADA.
Clinical Assistant, Royal Victoria Hospital; Assistant Physician, Montreal Foundling and Sick Baby Hospital.

FREDERIC R. GREEN, M.D......... CHICAGO, ILL.
Head Demonstrator of Anatomy and Instructor in Osteology, Northwestern University Medical School, Chicago.

JOHN GREEN, M.D............ .... ST. LOUIS, MO.
Special Professor of Ophthalmology, Medical Department, Washington University, St. Louis.

WILLIAM DAVID HAGGARD, M.D.... NASHVILLE, TENN.
Professor of Gynæcology and Diseases of Children, Medical Department, University of Tennessee; Gynæcologist to the Nashville Hospital.

WINFIELD SCOTT HALL, M.D..... CHICAGO, ILL.
Professor of Physiology, Northwestern University Medical School, Chicago.

ALICE HAMILTON, M.D............ CHICAGO, ILL.
Professor of Pathology, Women's Medical College of Northwestern University, Chicago.

HENRY FAUNTLEROY HARRIS, M.D.. ATLANTA, GA.
Professor of Pathology and Bacteriology, College of Physicians and Surgeons, Atlanta, Ga.

MILTON B. HARTZELL, M.D., PHILADELPHIA, PA.
Instructor in Dermatology, Medical Department, University of Pennsylvania; Dermatologist to the Methodist Hospital of Philadelphia and to the Philadelphia Hospital.

WILLIAM BARKER HILLS, M.D.... BOSTON, MASS.
Associate Professor of Chemistry, Harvard University Medical School.

OSCAR H. HOLDER, M.D....... NEW YORK, N. Y.
Instructor in Dermatology, the University and Bellevue Hospital Medical College; Attending Dermatologist, Out-Patient Department, Bellevue Hospital.

WILLIAM H. HOWELL, PH.D., M.D.... BALTIMORE, MD.
Professor of Physiology, Medical Department, Johns Hopkins University, Baltimore.

JAMES NEVINS HYDE, M.D....... CHICAGO, ILL.
Professor of Skin and Venereal Diseases, Rush Medical College; Attending Surgeon, Michael Reese, Presbyterian, and Augustana Hospitals, Chicago.

EDWARD JACKSON, M.D. .... DENVER, COL.
Emeritus Professor of Diseases of the Eye, Philadelphia Polyclinic; Ophthalmologist to the Mercy Hospital, Philadelphia.

GEORGE THOMAS JACKSON, M.D.... NEW YORK, N. Y.
Instructor in Dermatology and Chief of Clinic, College of Physicians and Surgeons, Columbia University; Consulting Dermatologist, the Presbyterian Hospital and the New York Infirmary for Women and Children.

GEORGE T. KEMP, PH.D., M.D.. .CHAMPAIGN, ILL.
Professor of Physiology, University of Illinois.

EDWARD L. KEYES, JR., PH.D., M.D.. NEW YORK, N. Y.
Lecturer on Genito-Urinary Surgery, New York Polyclinic Hospital; Special Lecturer on Genito-Urinary Diseases, Georgetown University, District of Columbia; Assistant Visiting Surgeon, St. Vincent's Hospital, New York.

CARL KOLLER, M.D............ NEW YORK, N. Y.

MAYNARD LADD, M.D. . . . . Boston, Mass.
Assistant in Diseases of Children, Harvard University Medical School; Assistant Physician to the Children's Hospital; Assistant Physician to the West End Nursery and Infants' Hospital, Boston.

DANIEL SMITH LAMB, M.D. . . Washington, D. C.
Pathologist, Army Medical Museum at Washington, D. C.; Professor of Anatomy, Medical Department, Howard University, Washington, D. C.

RALPH CLINTON LARRABEE, M.D. . . . . Boston, Mass.
Assistant in Histology, Harvard University Medical School; Physician to Out-Patients, Boston City Hospital.

HENRY LEFFMANN, M.D . . . . Philadelphia, Pa.
Professor of Chemistry and Toxicology, Women's Medical College of Pennsylvania; Pathological Chemist to Jefferson Medical College Hospital; Honorary Professor of Chemistry, Wagner Free Institute of Science.

WILLIAM M. LESZYNSKY, M.D. . New York, N. Y.
Neurologist to the Demilt Dispensary and the German Poliklinik; Consulting Neurologist to the Manhattan Eye and Ear Hospital.

ALFRED HAMILTON LEVINGS, M.D. . Milwaukee, Wis.
Professor of the Principles and Practice of Surgery and of Clinical Surgery, Wisconsin College of Physicians and Surgeons; Surgeon to Milwaukee County and St. Joseph's Hospitals; Consulting Surgeon to Emergency Hospital and to Milwaukee Hospital for Acute and Chronic Insane.

ROBERT W. LOVETT, M.D. . . . . Boston, Mass.
Assistant in Orthopaedic Surgery, Harvard University Medical School; Surgeon to Infants' Hospital; Surgeon to the Peabody Home for Crippled Children; Assistant Surgeon to Children's Hospital, Boston.

ALEXANDER GEORGE McADIE, M.A. . . . . San Francisco, Cal.
Professor of Meteorology, United States Weather Bureau.

ERNEST LEWIS McEWEN, M.S., M.D. . . . Chicago, Ill.
Associate Instructor in Dermatology, Rush Medical College, Chicago.

FRANKLIN P. MALL, M.D . . . . . . Baltimore, Md.
Professor of Anatomy, Johns Hopkins University.

FRANK BURR MALLORY, M.D. . . . . Boston, Mass.
Associate Professor of Pathology, Harvard University Medical School.

HARRY T. MARSHALL, M.D. . . . . . Baltimore, Md.
Instructor in Pathology, Johns Hopkins Hospital, Baltimore.

CHARLES F. MARTIN, M.D. . . Montreal, Canada.
Assistant Professor of Medicine and Clinical Medicine, McGill University; Assistant Physician, Royal Victoria Hospital, Montreal.

LAFAYETTE BENEDICT MENDEL, Ph.D. . . New Haven, Conn.
Professor of Physiological Chemistry, Yale University.

HERBERT C. MOFFITT, M.D., San Francisco, Cal.
Lecturer on Theory and Practice of Medicine, Medical Department, University of California.

BENJAMIN MOORE, M.A . . Liverpool, England.
Professor of Biochemistry, University College, Liverpool, England; Formerly Professor of Physiology, Yale University, New Haven, Conn.

WILLIAM S. MORROW, M.D. . Montreal, Canada.
Lecturer in Physiology, McGill University; Clinical Assistant in Medicine, Royal Victoria Hospital, Montreal.

ALBERT GEORGE NICHOLLS, M.D. . Montreal, Canada.
Lecturer in Pathology, McGill University; Assistant Pathologist to the Royal Victoria Hospital, Montreal.

SAMUEL NICKLES, M.D. . . . . . . Cincinnati, Ohio.
Emeritus Professor of Materia Medica and Therapeutics, Medical College of Ohio.

ALBERT P. OHLMACHER, M.D. Gallipolis, Ohio.
Superintendent of the Ohio Hospital for Epileptics and Director of the Pathological Laboratory.

WILLIAM OLDRIGHT, M.D . . . . Toronto, Canada.
Professor of Hygiene and Associate Professor of Clinical Surgery, University of Toronto; Surgeon to St. Michael's Hospital; Member of the Provincial Board of Health of Ontario.

B. ONUF (ONUFROWICZ), M.D. . . . Sonyea, N. Y.
Pathologist to the Sonyea Colony of Epileptics.

EDWARD OSGOOD OTIS, M.D. . . . . . Boston, Mass.
Professor of Pulmonary Diseases and Climatology, Tufts College Medical School; Visiting Physician, Free Home for Consumptives, Boston; Physician to the Department of Pulmonary Tuberculosis, Boston Dispensary.

ROSWELL PARK, M.D. . . . . Buffalo, N. Y.
Professor of Surgery, Medical Department, University of Buffalo; Surgeon to the Buffalo General Hospital.

WILLIAM H. PARK, M.D. . . . . . . New York, N. Y.
Associate Professor of Bacteriology and Hygiene, The University and Bellevue Hospital Medical College.

GEORGE A. PIERSOL, M.D . . . . Philadelphia, Pa.
Professor of Anatomy, Medical Department, University of Pennsylvania.

LEWIS STEPHEN PILCHER, M.D., LL.D. Brooklyn, N. Y.
Surgeon to the Methodist Episcopal Hospital and to the German Hospital in Brooklyn.

PAUL MONROE PILCHER, M.D. Brooklyn, N. Y.
Assistant Attending Surgeon to the Methodist Episcopal Hospital, Brooklyn, N. Y.

N. J. PONCE de LÉON, M.D . . . . . Havana, Cuba.
Deputy Health Officer of the Port of Havana, Cuba; formerly Instructor in Medicine, New York Post-Graduate Medical School.

WILLIAM HENRY POTTER, Esq. . . . Boston, Mass.
Assistant Professor of Operative Dentistry, Harvard University.

WILLIAM ALLEN PUSEY, M.D. . . . Chicago, Ill.
Professor of Dermatology, Medical Department, University of Illinois.

LEOPOLD PUTZEL, M.D . . . . . . New York, N. Y.

MAJOR CHARLES RICHARD. . Zamboanga, Mindanao, Philippine Islands.
Surgeon, United States Army.

HENRY H. RUSBY, M.D . . . . Newark, N. J.
Professor of Botany, Physiology, and Materia Medica, New York College of Pharmacy; Professor of Materia Medica, University and Bellevue Hospital Medical College, New York.

BERNHARD SACHS, M.D . . . . . . New York, N. Y.
Consulting Surgeon, Mount Sinai Hospital, New York.

EDWARD WILLIAM SCHAUFFLER, M.D..KANSAS CITY, MO.
Professor of Principles and Practice of Medicine and of Clinical Medicine, Kansas City Medical College.

R. J. E. SCOTT, M.D............NEW YORK, N. Y.
Attending Physician, Bellevue Hospital. Out Patient Department; Gynaecologist, Demilt Dispensary, New York.

GEORGE B. SHATTUCK, M.D. .... BOSTON, MASS.
Visiting Physician, the Boston City Hospital.

FRANCIS J. SHEPHERD, M.D..MONTREAL, CANADA.
Professor of Anatomy and Lecturer on Operative Surgery, McGill University; Senior Surgeon to the Montreal General Hospital.

DANIEL KERFOOT SHUTE, M.D....WASHINGTON, D. C.
Professor of Anatomy, Medical Department of the Columbian University, Washington, D. C.

BEAUMONT SMALL, M.D. ......OTTAWA, CANADA.
Attending Physician, St. Luke's General Hospital, Ottawa; Consulting Physician, The Children's Hospital, Ottawa; Late Examiner in Materia Medica, College of Physicians and Surgeons, Ontario.

ERNEST ELLSWORTH SMITH, M.D., PH.D..NEW YORK, N. Y.
Pathologist to Trinity Hospital, New York City, and St. John's Riverside Hospital, Yonkers, N. Y.; Consulting Pathologist to the Somerset Hospital, Somerville, N. J.

M. ALLEN STARR, M.D..........NEW YORK, N. Y.
Professor of Diseases of the Mind and Nervous System, College of Physicians and Surgeons, Columbia University; Consulting Physician, Presbyterian, St. Vincent's and St. Mary's Hospitals and the New York Eye and Ear Infirmary.

BRIG.-GEN. GEORGE M. STERNBERG . WASHINGTON, D. C.
Late Surgeon-General, United States Army.

ISRAEL STRAUSS, M.D...........NEW YORK, N. Y.
Assistant in Neuro-Histology, Cornell University Medical School; Adjunct Attending Physician, Hospital for Incurables, Almshouse, Blackwell's Island.

MERVIN T. SUDLER, M.D., PH.D...ITHACA, N. Y.
Instructor in Anatomy in Johns Hopkins University, Baltimore, and in the Cornell University Medical College, Ithaca, N. Y.

EDWARD W. TAYLOR, M.D.........BOSTON, MASS.
Instructor in Neuropathology, Harvard University Medical School.

AUGUSTUS THORNDIKE, M.D.....BOSTON, MASS.
Visiting Surgeon, Good Samaritan Hospital and West End Infant Hospital; Junior Assistant Surgeon, Children's Hospital, Boston.

BENJAMIN T. TILTON, M.D....NEW YORK, N. Y.
Instructor in Surgery, Cornell University Medical College; Assistant Visiting Surgeon, Bellevue Hospital; Visiting Surgeon, Lincoln Hospital, New York City.

ERNEST EDWARD TYZZER, M.D..BOSTON, MASS.
Austin Teaching Fellow in Histology and Embryology, Harvard University Medical School.

HENRY SWIFT UPSON, M.D...CLEVELAND, OHIO.
Professor of Diseases of the Nervous System, Western Reserve Medical School; Attending Physician to the Lakeside Hospital.

FERD. C. VALENTINE, M.D. ...NEW YORK, N. Y.

FREDERICK H. VERHOEFF, M.D...BOSTON, MASS.
Pathologist, Massachusetts Charitable Eye and Ear Infirmary; Assistant in Pathology, Harvard University Medical School; Assistant Ophthalmic Surgeon, Carney Hospital, Boston.

JAMES J. WALSH, M.D., PH.D., LL.D..NEW YORK, N. Y.
Lecturer on General Medicine, New York Polyclinic.

HENRY BALDWIN WARD, PH.D...LINCOLN, NEB.
Dean of the College of Medicine and Professor of Zoology, The University of Nebraska.

ALDRED SCOTT WARTHIN, M.D.....ANN ARBOR, MICH.
Professor of Pathology and Director of the Pathological Laboratory in the University of Michigan, Ann Arbor, Mich.

HARRY GIDEON WELLS, M.D..... CHICAGO, ILL.
Associate in Pathology, University of Chicago.

ROYAL WHITMAN, M.D.........NEW YORK, N. Y.
Chief of Clinic and Instructor in Orthopaedic Surgery, College of Physicians and Surgeons, Columbia University.

CHARLES F. WITHINGTON, M.D...BOSTON, MASS.
Instructor in Clinical Medicine, Harvard University Medical School.

RUDOLPH A. WITTHAUS, M.D..NEW YORK, N. Y.
Professor of Chemistry, Physics, and Toxicology, Cornell University Medical College in New York City.

EDWARD S. WOOD, M.D........... BOSTON, MASS.
Professor of Chemistry, Harvard University Medical School.

PHILIP ZENNER, M.D...........CINCINNATI, OHIO.
Clinical Lecturer on Diseases of the Nervous System, Medical College of Ohio.

A REFERENCE HANDBOOK

OF

THE MEDICAL SCIENCES.

SACCHARIN or **GLUSIDE**—(*Benzoyl-sulphonimide*). A coal-tar product, a derivative of toluene, with the formula $C_6H_4(CO)(SO_2)NH$. It occurs as a light, white powder, odorless but with an intensely sweet taste. It is very slightly soluble in cold water, more so in boiling water, alcohol, and glycerin. Its solution gives an acid reaction, and it forms sweet salts with alkaloids and metals. Its property of combining with alkaloids is taken advantage of to supply quinine and other bitter substances in a more palatable form. The insolubility of gluside is overcome by combining it with soda to form a soda salt which is very soluble. It may be prepared by dissolving one hundred parts in water and neutralizing the solution with bicarbonate of soda and evaporating to dryness; this forms one hundred and thirteen parts of soluble gluside or saccharin. It has been placed in the British Pharmacopœia under the title of Glucidum.

Excepting in its sweetening power, gluside is not allied to sugar in any way. It does not affect polarized light, it lacks the essential character of sugar to produce alcohol by fermentation, and when administered does not increase the production of sugar in the system. It is this latter quality that renders it of value in the treatment of diabetes, where it is desired to avoid the use of sugar as far as possible.

Gluside is two hundred and eighty times as sweet as sugar, and if it is remembered that an ordinary lump of sugar ranges from 150 to 300 grains, it is very evident that one-half to one grain will be an equivalent. Its disadvantages are the distaste that the patients are liable to have for it after using it for a time, and the dry, acrid sensation which it produces in the pharynx. In medicines, it may also be used to replace sugar and syrup for the purpose of rendering them palatable, one grain with a six-ounce mixture furnishing sweetness equal to one ounce of ordinary syrup. To facilitate dispensing, the following solutions are prepared:

Liquor Glusidi.—From the "National Formulary" of the American Pharmaceutical Association. Gluside, 512 grains; bicarbonate of sodium, 240 grains; alcohol, 4 fluidounces; water, sufficient to produce 16 fluidounces. Each drachm represents four grains of gluside.

Elixir Glusidi.—From the "Unofficial Formulary" of the British Pharmaceutical Conference. Gluside, 480 grains; bicarbonate of sodium, 240 grains; rectified spirit, 2½ fluidounces; distilled water, a sufficiency. Rub the gluside and the bicarbonate of sodium in a mortar, with half a pint of distilled water gradually added. When dissolved, add the spirit, filter and wash the filter with sufficient distilled water to make one pint. Each drachm represents three grains. Saccharin may be given freely, as it is devoid of toxic action. In some cases reported its prolonged use has produced symptoms of gastric disturbance with indigestion, but this rarely occurs. As much as seventy-five grains have been given at one dose without producing any ill effect. It is, however, advisable that not more than twenty-five grains daily be administered.

Gluside possesses antiseptic properties in common with other coal-tar derivatives, and for this reason it has been suggested as a remedy in many diseases. It has been used in pulmonary phthisis, acute articular rheumatism, scarlatina, intestinal catarrh, cystitis, and a number of other disorders in which its antiseptic action might prove of service. Of these, cystitis is the only one in which any satisfactory results have been obtained. In this condition it is administered internally and renders the urine antiseptic during its excretion. When there are pus and an alkaline reaction, this is rapidly overcome, and the urine becomes clear and normal in character; the change in the urine being accompanied by a corresponding improvement in the mucous membrane of the bladder. Three grains, in divided doses, daily, is the quantity recommended, and this is to be continued for a prolonged period. The bladder may also be irrigated at the same time.

Beaumont Small.

SACCHAROMYCOSIS.—Our knowledge of pathogenic yeasts and of the pathological conditions produced by them is at present but slight; and the unsatisfactory state of the classification and terminology of the blastomycetes has led to much confusion. Inasmuch as the blastomycetes are usually divided into various genera, *Saccharomyces*, *Oïdium*, *Monilia*, etc., the term *saccharomycosis* should be limited to the pathological conditions produced by the yeasts which are included under the *Saccharomycetes*, viz., those characterized by their power to ferment sugar and form alcohol, of which *Saccharomyces cerevisiæ* may be taken as the type. But few observations of such pathogenic yeasts have been made. The most important contributions to this subject are those of Busse and Curtis.

In 1895 Busse obtained pathogenic yeasts from a woman suffering with a peculiar cystic tumor of the tibia, which on microscopical examination presented the appearance of a sarcomatous-like granulation tissue containing giant cells. From the viscid fluid obtained from the tumor yeast-like fungi were cultivated. Pure cultures of the yeast were pathogenic for mice and rabbits, giving rise, when injected into the animal, to nodules of chronic granulation tissue, and leading to the formation of metastatic miliary nodules in the brain, kidneys, and lungs. The organism grew well on ordinary media, at ordinary and incubator temperatures, forming white, non-characteristic growths, which did not liquefy gelatin. On special media to which malt extract was added the growth was more abundant, and on potato and other media, grayish or black cultures were obtained. Acid media seemed especially to favor its growth. Glucose media were fermented with the production of alcohol and carbonic dioxide. Reproduction took place by budding exclusively. The patient died thirteen months after the appearance of the tibial tumor, and at autopsy numerous foci of disease, containing the yeast in great abundance, were found in the lungs, kidney, and spleen, some reaching the size of an apple. The yeasts were also found in a small corneal vesicle. Microscopically these lesions resembled those of a chronic inflammatory process with caseous and fatty degeneration; in these lesions the yeasts were found in great numbers, lying singly or in colonies.

In the next year a similar case was reported by Curtis, who obtained a yeast, *Saccharomyces subcutaneus tumefaciens*, from myxomatous tumors appearing in a young man, beneath the skin of the neck and thigh, and also from a large ulcer of the loin. Microscopically these tumors resembled myxosarcoma. Both in and between the tumor cells yeasts were found in large numbers. These were easily cultivated, and caused sugar to ferment with the production of alcohol. Dogs, rabbits, rats, and mice were susceptible to inoculation, a chronic inflammation and proliferation being produced at the site of injection. In old cultures endosporous division was seen.

Corselli and Frisco report a case of saccharomycosis in which "sarcomatous" nodules were found in the omentum and mesentery. The chylous ascitic fluid obtained by exploratory puncture during life contained the yeast fungi, which were cultivated and found to be pathogenic for dogs, rabbits, and guinea pigs.

Pathogenic yeast fungi have also been found in cases of chronic catarrh of the uterine cervix (Colfe and Buschke), and in proliferative catarrh of the nasal mucosa (Busse). Saccharomycetes have also been reported as occurring in the secretion from a case of peculiar inflammation of the conjunctiva and cornea; in pharyngitis; in the purulent discharge of otitis media; in the blood, sputum, and urine of a case of typhus (Calmette); in a pseudomembranous angina in a patient suffering from typhoid (Froisier and Achalme). *Saccharomyces ruber* has been regarded as the cause of a house epidemic of intestinal catarrh, the infection occurring through the contamination of milk. This same yeast was isolated by Casagrandi from diabetic urine. When inoculated into animals it produced small nodules containing pus. A variety closely related to, if not identical with *Saccharomyces cerevisiæ*, has been found in the coating of the tongue, in diarrhœal stools, in vomited material, and in diabetic urine.

Inasmuch as the organism of thrush is classed by some writers as a yeast—*Saccharomyces albicans*—the lesions of thrush would be considered under the head of saccharomycosis. (See *Mouth, Diseases of*, in THE APPENDIX.)

Pathogenic saccharomycetes have been found in a number of diseased conditions of the lower animals. *Saccharomyces niger* (Maffuci and Sirleo) has been regarded as the cause of a pulmonary affection which occurs in guinea pigs and resembles tuberculous pneumonia, and of an intestinal condition in the same animal, characterized by ulceration of the mucosa and enlargement of the mesenteric glands. *Saccharomyces guttulatus* has been described by Casagrandi and Buscalioni as occurring in the intestinal tract of mammals. These authors isolated it from the stomach and intestines of rabbits. It causes glucose to ferment with the formation of alcohol and it inverts saccharose. When inoculated into rabbits, guinea-pigs, and rats it produces nodules containing pus, and finally death. Sanfelice obtained from swine a non-liquefying, gas producing yeast—*Saccharomyces granulomatosus*—pathogenic only for swine, and producing granulomatous nodules, containing giant cells, in which the parasites often become calcified. The experimental "pseudo-tumors" produced by the injection of blastomycetes have also been described under the head of saccharomycosis.

The various pathogenic organisms described as saccharomycetes and the lesions ascribed to them can hold but a tentative position in pathology, until more definite light has been thrown upon the subject by additional observation and experimentation.

Aldred Scott Warthin.

SACRO-ILIAC DISEASE.—Tuberculous disease of the sacro-iliac articulation is uncommon and extremely so in childhood. The symptoms are pain, limping, weakness, and change in attitude. The pain is referred to the side of the pelvis or radiates over the buttock or thigh. It is increased by jars, by turning the body suddenly, sometimes by coughing or laughing. A peculiar feeling of insecurity and weakness about the pelvis and hip-joint is a common symptom. The trunk is inclined toward the sound limb, as a result of which the pelvis is lowered on the affected side. The leg seems longer than its fellow, and the patient walks with a peculiar awkward limp. In the early stage of the disease there is no deformity of the limb, but if a pelvic abscess forms the thigh may become flexed. Locally there may be sensitiveness to direct pressure on the articulation and swelling in the neighborhood of the disease, although this is usually a late symptom. Pain is induced by lateral pressure on the pelvis or by any manipulation that disturbs the articulation.

Abscess finally appears in the majority of cases. It may be extra- or intrapelvic. In the latter case it may present itself above the crest of the ilium. It may pass through the sciatic notch or appear in the ischiorectal fossa, or it may break into the rectum.

Sacro-iliac disease may be mistaken for sciatica or for disease of the hip or spine. The freedom of motion and the absence of muscular spasm when the pelvis is fixed, if examination is carefully conducted, should exclude both the one and the other, although the pain on lateral pressure, which is described as the most characteristic symptom, may be simulated closely by primary acetabular disease. The attitude is similar to that of sciatica, but the symptoms of local sensitiveness to jars and to manipulation are much more marked.

TREATMENT.—The local treatment consists in protecting the sensitive parts from injury, and the removal of the disease if it be possible. In the ambulatory treatment a plaster spica bandage or a double Thomas hip brace combined with the use of crutches may be indicated, but in most instances a broad, strong pelvic girdle, which may be drawn tightly about the pelvis, will be most efficient. If motion of the spine causes discomfort, this girdle may be reinforced by some form of spinal brace. Constitutional treatment is of course indicated as in other forms of tuberculous disease.

The PROGNOSIS is unfavorable, probably because the majority of the cases are in adults, a class in which the prognosis of any tuberculous disease is more serious than in childhood. In addition there is usually the complication of an infected and burrowing abscess.

Injury of the Sacro-Iliac Articulation.—All the symptoms described as characteristic of the tuberculous disease of the sacro-iliac articulation may be induced by strain or other injuries of this region, and doubtless by other affections than tuberculosis, such, for example, as rheumatism or infectious arthritis.

Such causes are perhaps more common in early life than is tuberculous disease. The principles of treatment (that is, rest and protection of the sensitive part by the pelvic girdle or other support) are indicated. If this treatment is efficient the cure is usually rapid and complete.

Royal Whitman.

SAEGERSTOWN MINERAL SPRINGS (formerly Eureka Springs).—Crawford County, Pennsylvania.

POST-OFFICE.—Saegerstown. Hotel and sanatorium.

ACCESS.—Viâ main line of the Erie Railroad to Saegerstown, six miles east of Meadville.

Saegerstown is situated on the historic Venango River, now called French Creek, in a beautiful and healthful valley, 1,200 feet above the ocean level. The scenery here is of a charming rural character, and the surroundings offer excellent opportunities for fishing, rowing, hunting, driving, bicycling, etc. The sanatorium is a large and commodious building, having all the modern conveniences of a hotel combined with facilities for the care and treatment of invalids. The grounds are tastefully laid out, and include spaces for croquet, lawn-tennis, and other games. A billiard room and bowling alley have been fitted up for the guests of the house, and during the busy season an orchestra will furnish music in the evening hours. The hotel is open the entire year. There are two mineral springs at Saegerstown, issuing from a bed of rock about three hundred feet deep. An analysis, made in 1896 by W. H. Dean, analytical chemist of Wilkesbarre, showed the following chemical ingredients of one of the springs:

One United States gallon contains (solids): Sodium chloride, gr. 7.46; sodium sulphate, gr. 0.62; potassium sulphate, gr. 0.22; calcium sulphate, gr. 4.33; calcium carbonate, gr. 3.26; magnesium carbonate, gr. 2.85; iron oxide and alumina, gr. 0.15. Total, 18.89 grains.

The water is free from nitrates and nitrites or other organic impurities, and will keep indefinitely without undergoing impairment of mineral properties. The water is bottled and shipped to all points. It will be found useful in the diseases benefited by this class of waters. Elaborate bathing facilities are supplied to visitors at the springs. *James K. Crook.*

SAFFRON.—*Spanish Saffron. Crocus* U. S. P., B. P., P. G. *Stigmata croci. Safran,* Fr. Cod. The dried stigmas of *Crocus sativus* L. (fam. *Iridaceæ*).

The saffron plant is a perennial herb, resembling colchicum, but with an inferior ovary. It grows from a flattened fleshy corm and bears one or two flowers, each possessing a long thread-shaped style, terminating in three long stigmatic branches. These branches, with a very short portion of the style, are collected and dried and constitute the drug. The nativity of the plant is not certainly known. Cultivated plants yield the whole of the product, which is mostly exported from southern Europe, especially Spain. It grows readily in most warm-temperate regions, but the profitable production of saffron is chiefly a labor problem, since nearly four thousand flowers are required to yield an ounce, and its successful production requires exceedingly low-priced labor.

FIG. 4139.—Spanish Saffron.

DESCRIPTION.—Separate stigmas or three attached to a very short portion of their style, each 2 to 3 cm. (about 1 in.) long, flattish-filiform below, dilated and funnelform tubular above, with the margin irregularly notched; orange-brown, the style portion yellow; texture somewhat cartilaginous, unctuous to the touch, strongly and peculiarly aromatic and bitterish. When chewed it tinges the saliva deep orange-yellow.

So costly a drug is of course subject to numerous and cunningly devised methods of adulteration, some of which are provided against as follows by our Pharmacopœia:

When soaked in water, it should not deposit any pulverulent, mineral matter, nor show the presence of organic substances differing in shape from that described.

On agitating 1 part of saffron with 100,000 parts of water, the liquid will acquire a distinct yellow color. No color is imparted to benzin agitated with saffron (absence of *picric acid* and some *other coal-tar colors*).

On drying saffron at 100° C. (212° F.), it should not lose more than fourteen per cent. of its weight (absence of *added water*).

When thus dried, and ignited with free access of air, 100 parts of the dry saffron should not leave more than 7.5 per cent. of ash (absence of *foreign inorganic substances*).

One of the commonest methods of increasing the yield of saffron is that of collecting a large portion of the style with the stigmas, and the possible presence of these styles is referred to in our own and other pharmacopœias. Onion roots have been chopped up and colored to substitute saffron, as have other fibrous or filamentous bodies. The most important substitute, however, and that very generally sold for saffron in this country, is safflower, which will be found described at the close of this article. The detection of adulterants of nearly all kinds is far less easy when the product is pressed into cakes, so that loose or "hay" saffron is always to be preferred. All things considered, the microscope probably offers the most reliable means for detecting adulterants, and a moderately low power suffices for most of them.

CONSTITUENTS.—Saffron owes its odor to about one per cent. of a volatile oil, which differs considerably according to the method of distillation, being sometimes lighter, sometimes heavier than water. Its color is due to the presence of the yellow glucoside *crocin* ($C_{44}H_{70}O_{28}$), which yields reddish *crocetin*. The name *polychroit* was formerly applied to this coloring matter, but the substance so described was subsequently found to be a mixture, consisting largely of crocin. The bitterish taste of crocus is due to a glucoside which has been called picrocrocin. The other constituents of crocus are unimportant. Crocin is very slightly soluble in water, unless rendered alkaline, but is soluble in alcohol. It becomes blue, then violet-brown with concentrated sulphuric acid, and green, afterward yellow and brown, with nitric acid. The yield of volatile oil is greatly increased by previous treatment with sulphuric acid.

ACTION AND USE.—Crocus has had a wonderful history as a drug. It was credited with remarkable powers by the ancients, and is still so, to some extent, by the more ignorant classes. It, however, probably possesses no other medicinal properties than those of a mild aromatic, stimulant, carminative, and antispasmodic, and may be given in doses of 0.3–2 gm. (gr. v.–xxx.). The Pharmacopœia provides a ten-per-cent. tincture. As used at the present day, especially in the United States, it is almost wholly for the purposes of coloring and slight flavoring.

Safflower, Carthamus, African or dyer's saffron, False, American or *Thistle saffron,* consists of the florets of *Carthamus tinctorius* L. (fam. *Compositæ*). Although called American saffron, this plant is of Oriental nativity. It is widely cultivated for ornament and also, to some extent, for the product here described. It produces handsome large flower heads, of an orange-yellow color, at the ends of the branches. From these the florets are plucked out, dried, and constitute the drug. They were formerly largely used for dyeing purposes and are still so used to a considerable extent in India. They constitute a red or deep orange-red mass, of a rather slight characteristic odor and an aromatic and bitterish taste. The individual florets are about 2 cm. ($\frac{4}{5}$ in.) long, though often broken, tubular, and very deeply divided into five linear and nearly equal lobes. The stamens have long exserted coherent anthers and a slender style which is considerably longer than the stamens. The ovary should not be present. The principal coloring matter of safflower is deep yellow and constitutes one-fourth or more of the weight of the drug. It is known as *safflor yellow* ($C_{24}H_{30}O_{15}$) and is soluble in water. There is also a fraction of one per cent. of the red coloring matter *carthamic acid* or *carthamin* ($C_{14}H_{16}O_7$), which is not soluble in water but gives a beautiful purple color in alcohol. The latter coloring matter exists in commerce as a reddish brown, somewhat metallic powder. It is used in rouge-making. The properties and uses of safflower differ but little from those of saffron, and its principal use is in fact the substitution of the latter. *Henry H. Rusby.*

SAGE.—*Garden Sage, Salvia,* U. S. P. The dried leaves of *Salvia officinalis* L. (fam. *Labiatæ*).

This is a half shrubby, gray-hairy perennial, the stems dying down to within a foot or so of the ground in the fall, but branching very freely into herbaceous flowering branches, which are quadrangular and attain a height of two or three feet. The leaves are opposite, the flowers in a mixed spike, with two-lipped, pubescent, bell-shaped calyx, and a conspicuously labiate, blue corolla, with a ring of hairs at the base, inside; upper lip of the corolla concave, notched at the apex, the lower three-lobed; the central one much the largest and longest. Perfect stamens two, with widely divergent anther cells, but one of which in each stamen is perfect. Ovary four lobed. Fruit of four nutlets. Sage, like so many others of our household mints, is a native of Southern Europe. It has, however, been cultivated for centuries, and transplanted to all temperate countries. Leaves rather long and stoutly petioled, the blades 3–7 cm. (about 1–3 in.) long and nearly half as broad, oblong or slightly broader below the middle, rounded or subcordate at the base, mostly blunt at the summit, crenulate, thickish, gray-green, and densely hairy, especially underneath, very strongly veined, the veins finely reticulate, often pinkish or purplish, as is the petiole; aromatic in odor and taste, the latter also bitter and somewhat astringent.

Sage owes its very characteristic odor and its properties as an aromatic drug to a peculiar volatile oil (less than one per cent. in the fresh, up to 2.5 per cent. of the dried leaves). It also contains an unknown bitter substance and apparently tannin, together with resin and a little gum. Oil of sage is a commercial article, and is of a yellowish or greenish yellow color, with a specific gravity of about 0.92. Its chief constituent has been called salviol, but it is now considered identical with thujone, the active constituent of Arbor vitæ, and this occurs also in some other volatile oils. A small amount of cineol is also contained.

Sage resembles the rest of the Mint family in its general action; it is aromatic, a gastric stimulant, and by reason of its bitterness also tonic. It is also, what all are not, mildly astringent. In large quantities of hot water, like many other mints, it is given as a sudorific in the beginning of feverish colds, etc. Sage is useful in mouth washes and as a gargle. It is, however, almost entirely a domestic remedy, and even as such but little used of late, although formerly in high repute. It is one of the ingredients of the formerly official aromatic wine (*Vinum Aromaticum*), an old-fashioned liniment.

W. P. Bolles.

SAINT AUGUSTINE, FLORIDA.—This picturesque and well-known winter resort is situated on the Atlantic coast of Florida, thirty-eight miles southeast from Jacksonville, and about two hundred and fifty miles north of Palm Beach. The city occupies a narrow peninsula opposite Anastasia Island, which forms a breakwater against the open ocean. The surrounding country is flat and sandy and covered with the scrub palmetto.

The town is the oldest in the United States, and has a permanent population of between four and five thousand inhabitants, which number is doubled or more at the height of the season. The city retains many of its antiquities, and is exceedingly quaint and attractive. The narrow streets; the ancient Spanish "coquina," or shell-limestone residences, with their overhanging balconies; the old "City Hall," and Fort Marion, are all exceedingly interesting relics of the Spanish occupancy.

Many new and attractive buildings have of late years sprung up—several extensive hotels of the Spanish style of architecture, with beautiful grounds and courtyards; villas, with grounds ornamented with orange, lemon, and fig trees, palms, and a variety of tropical flowers and shrubs; churches, convents, and the restored Cathedral and Old Market.

The attractions at this resort are many and varied, as can easily be imagined. Besides those already mentioned, there are a United States military post, with daily guard mount, the sea wall affording a delightful promenade along the water front; many excursions by water; visits to the orange groves; drives, hunting, fishing, sailing, golf, and the never ending delight of wandering through the old town. Connected with one of the hotels is a casino, where are Turkish baths, a swimming pool, various entertainment halls, lawn-tennis courts, etc.

The winter climate is a mild, equable, moist one; and in summer the heat is tempered by the sea breezes. Frosts are rare. Although the climate is of a somewhat less tropical nature than that of the resorts on the lower half of the peninsula, such as Palm Beach, Tampa, and Miami, still a very comfortable, mild atmosphere is found here in the winter, and there is a good proportion of sunny days.

The average mean temperature of twenty years for the four seasons, as given by Dr. Wall (*The Climatologist*, October 15th, 1891), is as follows (degrees Fahr.): Spring, 68.5°; summer, 80.3°; autumn, 71.5°; winter, 58.1°, and for the whole year, 69.6°. For the four winter months, according to the same authority, it is, for December, 57.2°; January, 57°; February, 59.9°; March, 63.3°. The average yearly rainfall is about 49 inches, varying quite considerably in different years; for example, it was 67.4 inches in 1880 and 33.9 inches in 1851. The least rainfall appears to be in January. The prevailing winds are from the northeast. The climatic data of Jacksonville, which is only thirty miles to the north of St. Augustine, can be taken as fairly accurately representing those of the latter resort, and the reader is referred to the article upon *Jacksonville* in Vol. V. of the HANDBOOK for more extended meteorological facts.

The water supply is abundant and obtained from artesian wells; and the streets are clean and well lighted. The sanitary conditions of the hotels are carefully looked after.

There is a well-appointed, indeed a luxurious, hydrotherapeutic establishment where hot and cold saline and hydro-electric baths are given by skilled attendants; and cases of rheumatism, gout, and nervous disorders are treated in this way. The Nauheim baths and the Schott system of treatment for heart disease; various methods of electrical applications, gymnastics, douches, and massage are also included in this establishment.

January, February, and March are the months in which St. Augustine is the most frequented. On account of its easy accessibility, mild climate, excellent accommodations and many attractions, this has become a popular and fashionable winter resort, and has been compared to Newport and Saratoga. Excursions to other portions of Florida can easily be made from this point.

Edward O. Otis.

SAINT CATHARINE'S WELL.—POST-OFFICE.—St. Catharine's, Ontario. Hotel, The Welland House.

ACCESS.—Viâ Grand Trunk Railway from Toronto, or Buffalo.

Analysis (Professor Croft).—Ten thousand grains of water contain: Carbonate of iron, gr. 0.5210; carbonate of lime, gr. 0.0820; sulphate of lime, gr. 19.7934; chloride of calcium, gr. 174.4876; chloride of magnesium, gr. 40.6641; chloride of sodium, gr. 378.4196; chloride of potassium, gr. 2.8119; bromide of sodium, a trace; iodide of sodium, gr. 0.0140. Total, 616.7938 grains.

St. Catharine's is situated twelve miles from Niagara Falls in what is termed "the Garden of Canada." There are a number of springs which have long been famous, and at different times sanatoria have been opened. The Welland is under excellent management and has during the past year been enlarged and furnished with all the appliances of a modern sanatorium. A resident physician is in charge with a staff of skilled nurses. Every provision is made to utilize the water after the most approved methods of hydrotherapeutics. The hotel is open throughout the year.

Beaumont Small.

SAINT CLAIR SPRINGS.—St. Clair County, Michigan. POST-OFFICE.—St. Clair Springs. Hotel, The Oakland.

ACCESS.—From Detroit by steamer from the foot of Griswold Street, twice daily; distance fifty miles. Also from Detroit viâ Grand Trunk Railway (foot of Brush Street), twice daily; distance fifty-one miles. Railroad connection for springs can also be made at St. Thomas, Ontario, viâ Canada Southern Railroad. Steamer connection once daily is made at Port Huron, Mich.

St. Clair Springs is one of the strictly first-class health and pleasure resorts of the United States. The Oakland Hotel, situated in a tract of about one hundred and sixty-five acres fronting on the St. Clair River, at the extreme southern portion of the city of St. Clair, affords all the comforts, conveniences, and luxuries to be found at our older Eastern resorts or at the European spas. The hotel is open for the reception of health- or pleasure-seekers all the year round. Two classes of mineral waters of very pronounced yet very different type are found here. The first of these is a powerful muriated saline water. The analysis is by Professor Duffield:

One United States gallon contains (solids): Sodium chloride, gr. 8,120; calcium chloride, gr. 7,382.20; magnesium chloride, gr. 1,012.20; calcium sulphate, gr. 144.20; silica, gr. 416; alumina, gr. 830; and traces of magnesium carbonate, calcium carbonate, magnesium iodide, and magnesium bromide. Total, 17,904.60 grains. Sulphureted hydrogen gas, 25.59 cubic inches.

It will be observed that the water contains an unusually large quantity of chloride of lime. The salt is believed by some observers to possess valuable alterative properties and to be of great assistance in the treatment of the strumous diathesis. The water also possesses all the well-known virtues of the densely charged chloride-of-sodium groups. It is used only for bathing purposes and as a spray or douche. An elegant and elaborate bathhouse, presenting all varieties of baths, sprays, douches, etc., is maintained in connection with the hotel.

The "Salutaris" is a natural gaseous alkaline mineral water, very wholesome and pure. It is said to be entirely free from organic matter, and constitutes an excellent table water. It is bottled and extensively sold in the United States.

The attractions in and about the Oakland Hotel are of a manifold character: expansive shaded lawns, picturesque drives; boating and sailing on the river, and all the indoor pastimes of the day will be found here.

James K. Crook.

SAINT HELENA WHITE SULPHUR SPRINGS.—Napa County, California.

Post-Office.—St. Helena. Hotel and cottages.

Access.—Take ferry from San Francisco foot of Market Street, at 8 A.M. and 4 P.M. Arrive at St. Helena viâ Calistoga train at 11:03 A.M. and 7:08 P.M. Take stage to springs, two miles distant.

One United States Gallon Contains:

Solids.	Spring No. 2. Grains.	Spring No. 6. Grains.	Spring No. 7. Grains.
Carbonate of iron	.62	.56	4.36
Carbonate of magnesium	8.26	11.33	12.84
Sulphate of sodium	21.72	23.41	14.23
Chloride of sodium	1.32	.86	.78
Chloride of calcium	.87	2.22	.65
Sulphides of sodium and calcium	2.65	1.85	1.62
Total solids	35.44	40.23	34.48
Gases.	**Cubic inches.**	**Cubic inches.**	
Sulphureted hydrogen	6.15	4.25	Trace.

This beautiful summer resort is located in one of California's loveliest valleys. The neighboring mountainsides are covered with forests, shrubbery, ferns, and wild flowers of every description. Brooks and cascades are seen on every hand. The grand old California redwoods, which are found here in great abundance, are alone worth a visit to this region. The mineral springs are numerous and valuable, and chiefly of the saline chalybeate type. Mr. Sanford Johnson, the proprietor, furnishes us with the accompanying analysis of three of the springs.

There are six other springs which have not been completely analyzed. The waters vary in temperature from 64.4° to 97.25° F. The analysis shows them to possess valuable tonic properties. They are said to have considerable value in rheumatism and kidney affections.

James K. Crook.

SAINT LOUIS, MO.—This great city of nearly 600,000 inhabitants is situated in the northeastern corner of Missouri upon the Mississippi River, not far from its junction with the Missouri.

A description of the city is hardly necessary or pertinent in this connection, as the climate is the chief consideration, of which certain marked peculiarities deserve mention.

In the first place, as will be observed from the table, the excessive extremes of temperature are striking, the annual range being 123.4° F. Although the winter mean temperature is only a few degrees higher than that of New York, for example, the mean summer temperature is five and one-third degrees higher. In July a maximum temperature of 104° F. is noted, while in January a minimum temperature of − 16° F. occurred in the cold wave of 1889. St. Louis is called a "Southern city," and yet it is seen that the winters are severe and quite like those of a Northern city. The summers are usually very hot, the nights as well as the days, and a continuous high temperature may exist for many days in succession; moreover, this heat may continue through the month of September. In July, 1901, there was hardly a day for three weeks in which the temperature was not 100° F. or over. The daily range of temperature is also seen to be considerable, and, consequently, one might hastily conclude that the summer nights would be comparatively cool; but if the day temperature is very high, a diminution of fifteen or eighteen degrees would still give a high night temperature.

Another striking feature of this climate is the prevalence of south winds throughout the year, except in March, when the blizzards change the direction from south to northwest.

The mean relative humidity indicates a moderate amount of moisture, a little less than that of New York City. The rainfall is not excessive and is pretty evenly distributed throughout the year, rather more falling in the spring and summer. There are a few more clear and fair days in St. Louis than in New York, especially in the summer and autumn. The flatness of the surrounding country and the atmospheric conditions favor the

formation of tornadoes; and on May 27th, 1896, there occurred in St. Louis one of the most terrific ones ever known in the United States, ploughing in a moment a huge furrow through the city and destroying a large number of lives and an immense amount of property. Such calamities, however, are rare, but, nevertheless, the latent conditions are always existent, and what has happened may happen again.

During the summer months all who are able seek a cooler climate at the seashore or in the mountains; but during the rest of the year St. Louis is a comfortable and wholesome place of residence. It has been feared that the Chicago drainage canal, which empties into the Illinois River,—which latter in turn flows into the Mississippi above St. Louis,—might pollute the waters of this river as it flows past St. Louis. No sure evidence, however, to the writer's knowledge, has been adduced to show that this is the fact, or that the drinking-water, which is derived from the river, is injuriously affected.

For a description of the manifold attractions in and about the city, the guide books must be consulted; and for the history of the founding of the city, the reader is referred to Parkman's fascinating works.

From St. Louis interesting excursions can be made either up the river to St. Paul, or in the other direction to New Orleans. The steamers are comfortable and commodious. From St. Louis to New Orleans is a distance of 1,250 miles, and the steamer occupies about a week in traversing it. For one who desires a slow, restful journey amidst oddly picturesque scenery, a journey soothing to tired nerves and yet of strange interest, this voyage down the Mississippi can be unqualifiedly recommended from personal experience. *Edward O. Otis.*

SAINT LOUIS SPRING.—Gratiot County, Michigan. Post-Office.—St. Louis. Hotels and sanatoriums. Analysis by S. P. Duffield:

One United States gallon contains (solids): Sodium bicarbonate, gr. 88.66; calcium bicarbonate, gr. 57.83; magnesium bicarbonate, gr. 14.58; iron bicarbonate, gr. 1; calcium sulphate, gr. 55.41; calcium silicate, gr. 5.60; silica, gr. 2.40; organic matter and loss, gr. 1.66. Total, 227.14 grains. Gases, sulphuretted hydrogen, a trace; carbonic acid, 5.17 cubic inches.

The results of treatment with these waters, according to Dr. Stiles Kennedy, show them to be especially beneficial in dyspepsia, neuralgia, and chronic rheumatism. The water, as shown by the analysis, is strongly alkaline, and also contains sufficient iron to impart to it the properties of the chalybeate class. The waters were once supposed to be strongly magnetic, but it has been proved by the experiments of Walton, and corroborated by a committee of the Michigan State Medical Society, that the so-called magnetic properties were derived from the metallic tubing which encased the well. The resort is still kept up well and is very popular. *James K. Crook.*

SAINT MORITZ, SWITZERLAND. See *Engadine.*

SAINT PAUL, MINN.—This city, and several other points in Minnesota, were formerly popular as winter health resorts for consumptives, on the theory that steady cold weather was peculiarly bracing to the constitution, and thus hardened the patient was put in a more favorable condition to overcome his disease. There is undoubted truth in this, provided the air is pure as well as cold, and provided other favorable climatic factors exist, such as sunshine, absence of high winds, and dryness. There have been developed, however, other and better climates of the bracing winter type, such as the various well-known resorts in the Alps and in Colorado; and, in consequence, the former reputation of Minnesota has declined. Further, large cities are obviously never so favorable as health resorts for pulmonary tuberculosis, and hence St. Paul and its sister city, Minneapolis, now grown so large, could not be recommended for a residence to those suffering from this disease, even if the climate were better than it actually is.

The characteristics of this climate are, first of all, the steady cold winter weather, the mean temperature of the four months, December, January, February, and March, being 19.6° F., while the minimum temperature has been as low as − 39° F. in December and − 31° in January. Secondly, may be mentioned the freedom from the sudden and constant great variations in temperature so common along the Atlantic coast; it is very cold in winter, but it is a steady cold, and there are no thaws. Again, when we consider the low winter temperature, a relative humidity of 72.4 per cent. indicates a dry atmosphere, quite different from that of New York City, for instance, with about the same relative humidity in winter, but with an average mean winter temperature 14.8° F. higher, the absolute humidity at St. Paul being only half as great in the winter as at New York City; so that we have a dry as well as a cold atmosphere. The average precipitation is seen to be small, about two-thirds of that of New York City.

There is no great amount of wind at St. Paul, particularly in the winter; and a very considerable amount of sunshine. In both of these respects St. Paul shows a marked superiority over New York City.

From its inland location, St. Paul is free from all those perturbations of temperature caused by the influence of the sea, which prevail in the large sea-bound cities of the United States, or in the cities lying upon the great lakes.

St. Paul is a beautiful city, and affords many attractive excursions in the vicinity;—one is to Lake Minnetonka, forty miles distant, a popular summer resort with hotels and cottages, where the air is pure and invigorating, and where many opportunities are afforded for out-of-door life. Convalescents and those suffering from nervous affections are said to do well in this climate. From St. Paul the journey down the Mississippi River begins,

and the portion between this city and St. Louis, constituting the first stage, is one of beautiful and grand scenery. The distance is about eight hundred miles.

Edward O. Otis.

SALACETOL — salantol, $C_6H_4.OH.CO.OCH_2.COCH_3$ —is a compound of acetone and salicylic acid containing seventy-one per cent. of the latter. It occurs as fine acicular crystals or scales insoluble in cold water, slightly soluble in cold alcohol, and freely soluble in hot alcohol, ether, and chloroform. In its action it resembles salol, the analogous compound of phenol and salicylic acid, and like it separates into its components in the intestine. The dose is 1-3 gm. (gr. xv.-xlv.).

W. A. Bastedo.

SALACTOL is a solution of the lactate and salicylate of sodium in a one-per-cent. solution of hydrogen dioxide. It is employed in diphtheria as a gargle, or applied to the throat with a brush. *W. A. Bastedo.*

SALICIN.—(*Salicinum*, U. S. P., B. P.), $C_{13}H_{18}O_7 =$ 285.33. This is a neutral principle obtained from several species of *Salix* and *Populus* (Fam. *Salicaceæ*).

Salicin is easily prepared from willow bark by extracting with water, precipitating tannin, etc., with litharge, evaporating and crystallizing out the salicin, and purifying by re-solution and repetition of the process. From populin it is prepared by boiling with lime water or barium hydroxide. It can also be prepared synthetically. The following is the official description:

Colorless, or white, silky, shining crystalline needles, or a crystalline powder, odorless, and having a very bitter taste. Permanent in the air.

Soluble, at 15° C. (59° F.), in 28 parts of water, and in 30 parts of alcohol; in 0.7 part of boiling water, and in 2 parts of boiling alcohol; almost insoluble in ether or chloroform.

When heated to 198° C. (388.4° F.), salicin melts, yielding a colorless liquid which, on cooling, congeals to a crystalline mass. Upon ignition, it is consumed, leaving no residue.

Salicin is neutral to litmus paper.

On heating a small portion of salicin in a test tube until it turns brown, then adding a few cubic centimetres of water, and afterward a drop of ferric chloride T.S., a violet color will be produced.

Cold, concentrated sulphuric acid dissolves salicin with a red color; the solution, after the addition of water, becomes colorless, and deposits a dark-red powder insoluble in water or alcohol.

On heating a small portion of salicin with 1 c.c. of potassium dichromate T.S. and 2 c.c. of sulphuric acid, the odor of salicylic aldehyde (or of oil of meadow-sweet, *Spiræa ulmaria* L., Fam. *Rosaceæ*) will become noticeable.

The aqueous solution of salicin is not precipitated by tannic or picric acid, nor by mercuric potassium iodide T.S. (absence of, and difference from, *alkaloids*).

Salicin is a glucoside, yielding, upon treatment with dilute acids or a powerful galvanic current, glucose and saliretin, or saligenin. It is readily convertible into salicylic and related acids and numerous other compounds. In the system it is partly converted into salicylic acid, so that its effects are very similar to those of that substance; but, since the percentage thus changed appears inconstant, its action is very irregular. Between two and three ounces of it are recorded as having been taken with no marked effect, though far smaller amounts are often very active. Although its chemical reactions outside of the body are thus of great interest, they lend but little assistance in determining its physiological action, and its therapeutics is almost wholly empirical. As indicated above, its action is, weakly and irregularly, that of salicylic acid.

Salicin has undoubted antipyretic power, although less than is possessed by quinine or salicylic acid; its antiperiodic action is much less than that of either of them. As a remedy in rheumatism, salicin has also been obliged to yield to the more useful salicylic acid. As a tonic, in small doses, it is occasionally used, but is far inferior to gentian or quinine. Four or five grams (ʒ i. ad ʒ iss.) may be given as a dose, and repeated every three hours; as a tonic 1 or 2 dcgm. (gr. iss. ad gr. iij.) is sufficient.

Henry H. Rusby.

SALICYLAMIDE.—A compound prepared from salicylic acid by the introduction of the amidogen radical. Its chemical formula is $C_6H_4,OH,CONH_2$. The benefit of the combined action of this stimulating radical had already been demonstrated in chloralamide, and the same advantage was looked for in salicylamide. It may be prepared by the action of concentrated ammonia upon oil of wintergreen. It forms in colorless crystals and in thin transparent plates, melting at 142° C. It is soluble in alcohol, ether, chloroform, readily soluble in hot water, and in two hundred and fifty parts of cold water.

Salicylamide was proposed as a substitute for salicylic acid and its salts, the advantage claimed for it being its greater solubility, its tastelessness, and its freedom from any depressing action on the system. A very careful study of its physiological properties has been made by Dr. W. B. Nesbitt, of Toronto (*Therapeutic Gazette*, October, 1891). He sums up the result as follows: 1. Pharmacologically, it prevents conduction in nerve; paralyzes nerve first, then muscle. 2. On the heart, its chief effect is on the motor apparatus, most probably through its activity on conduction. 3. Diminishes spinal reflex for motor impulses. 4. Diminishes spinal conductivity for painful impressions. 5. Diminishes muscular irritability. 6. In mammals, it exerts no particular effect on respiration. 7. It produces no particular effect on blood pressure. In medicinal doses it reduces temperature and causes ataxic gait and hebetude in fowls.

It is employed for all conditions in which the salicylates are indicated. The dose advised is about fifteen grains daily, in divided doses of three to five grains.

Beaumont Small.

SALICYL-BROMANILID. See *Antinervine*.

SALICYLIC ACID AND SALICYLATES.—Salicylic acid, chemically *ortho-oxybenzoic acid*, $HC_7H_5O_3$, takes its name from the principle *salicin*, found in willow bark, from which substance it is possible to make salicylic acid by fusion with potassium hydrate. Salicylic acid in the condition of the ethereal salt, *methyl salicylate*, constitutes about ninety per cent. of oil of gaultheria (wintergreen), and occurs also in other plants Salicylic acid can be made from oil of gaultheria, but at present almost all the acid used in medicine is made, by the process of Kolbe, from carbolic acid. The principle of this process consists in the forcing of a molecule of carbon dioxide upon the molecule of carbolic acid, an addition which just converts one molecule of the phenol into one of salicylic acid. In this process, carbolic acid and a concentrated solution of soda are first evaporated to dryness, and over the product, heated, a stream of dry carbon dioxide is made to pass As a result, one-half of the phenol used is converted into salicylic acid in the condition of sodium salicylate, which salt, on decomposition by treatment of its aqueous solution with hydrochloric acid, yields salicylic acid under its own form. Kolbe's process, by reason of its cheapness, has practically superseded all others for the procurement of salicylic acid.

It will thus be seen that both the natural and the artificial acids are prone to impurities. Their purification, especially that of the synthetic, is a matter of much importance. Carbolic acid is the commonest and one of the most serious impurities, as are the creosotic acids (see below) frequently occurring in the artificial variety. Salicylic acid is official in the United States Pharmacopœia under the title *Acidum Salicylicum*, Salicylic Acid. It occurs in fine, light, perfectly white needle-shaped crystals, or in a white crystalline powder. A reddish tinge in a sample of the acid signifies impurity, and such a sample should be rejected. Salicylic acid is permanent in the air; is, when pure, free from odor of carbolic acid, but has a sweetish taste, with an acrid after-flavor. It dissolves in 450 parts of cold water and in 14 parts of boiling water; in 2.4 parts of cold alcohol, and very readily in boiling alcohol. Although salicylic acid is but feebly soluble in cold water, it dissolves freely in many saline solutions. Thus the pharmacopœial *solution of ammonium acetate* will dissolve twenty-five per cent. of salicylic acid; a twelve-and-a-half-per-cent. aqueous solution of potassium acetate will dissolve twelve and a half per cent. of the acid; a twelve and-a-half per cent. solution of potassium citrate in equal volumes of glycerin and water will dissolve six per cent. All of these solutions possess the sharp stinging taste of the uncombined acid. A serviceable and permanent solution of the acid, and one that instead of being sharp to the taste has a pure bitter flavor only, can be made as follows: Dissolve two parts of borax in twelve of glycerin by the aid of heat; add one part of salicylic acid, continue the heat, and stir until the acid dissolves. Almost all solutions of salicylic acid, either immediately or after a while, turn of a reddish or of a smoky color, resembling that of solutions of carbolic acid.

Salicylic acid is incompatible with strong oxidizing agents, like potassium permanganate, and with chlorine, bromine, iodine, ferric salts, carbonates, the most of which it decomposes, and spirit of nitrous ether. A soft or semi-liquid mass is formed with exalgin, antipyrin, phenacetin, urethane, and other synthetics, as well as with lead acetate and sodium phosphate. The salicylates give precipitates with strong solutions of most alkaloidal salts, as well as with strong acids. Lime water also yields a precipitate.

Salicylic acid, taken into the mouth, has not much taste, proper, but speedily and quite suddenly after the tasting a sharp stinging seizes the *throat*, often severe enough to bring tears to the eyes. Similarly, a little of the dry acid snuffed up the nostrils will sting quite strongly. The acid brings sharp pain to cuts and abrasions, but, swallowed, is much less irritant to the stomach than its effects on the throat would lead to suppose. Large doses, so taken, may upset digestion and cause a strong sensation of heat, and even actual burning pain, but no serious or lasting results follow. The acid is rapidly absorbed from the stomach into the circulation, presumably in saline combination, and thereupon exerts the peculiar influence characteristic of the salicylates (see *Salicylates*, below).

Salicylic acid was at first used as an internal medicine for the procurement of the therapeutic effects of the salicylates, but now, and very properly, salicylates themselves, because of their freedom from the locally irritant action of the uncombined acid, have superseded the acid for this purpose. The present medicinal application of the acid is for local purposes as a deodorant, detergent, or so-called antiseptic—purposes which salicylic acid fulfils by reason of its having a fairly potent germ-sterilizing faculty. (See Salicylic Acid in article *Germicides*.) For general local use, the solution of the acid in a glycerin solution of borax is convenient, this solution bearing any necessary dilution with either water or alcohol without precipitation. A dilution representing a two per-cent. solution of acid is one very commonly employed. For other salicylic preparations for local use, see Salicylic Acid in article *Antiseptics*.

SALICYLATES.—In saline combination, whether with metallic or ethereal bases, the local pungency of free salicylic acid disappears while yet the faculty for constitutional action remains. As already said, it is probable that the acid, when taken as an internal medicine, enters the circulation only after conversion into a salicylate, so that, as a matter of fact, what is commonly called the constitutional action of salicylic acid is, so far as we know, the action of a salicylate. The constitutional effects in question are as follows: After a full dose a non-pyrexial subject experiences, in about fifteen minutes, a moderate reddening of the face with a sense of fulness of the head, or perhaps even a pronounced headache, and a buzzing or roaring in the ears precisely similar to what occurs in cinchonism. Almost simultaneously free perspiration begins, and, according to dose, there is more or less tendency to a reduction of pulse rate, of respiration rate, and of body temperature. Tests for salicylic acid will reveal the presence of the substance in the urine, the saliva, and the sweat. The urine, furthermore, will be discolored, appearing brown by reflected and green by transmitted light, from the presence of indican or of pyrocatechin. It will also contain a something that will reduce copper salts in copper test solutions (Brunton), and will show an increased amount of urea and uric acid. In overdoses, salicylates readily irritate the kidneys, setting up albuminuria; may derange the cerebral faculties, causing hallucinations and delirium; and may dangerously or even fatally depress the functions of heart and lungs, determining collapse or death by failure of respiration. These several untoward effects occur very irregularly, and, according to Squibb, in "a very large proportion" of instances are determined, not by the salicylic acid, but by a *contaminating acid* very commonly present in market samples of salicylic acid, and hence in salicylates derived therefrom. The constitutional effects of salicylates, which are valuable in medicine, do not appear in experimentation with a subject in health. They consist, in general, in a reduction of fever temperatures, and, in particular, in an abatement of pains in fibrous tissues, notably the pains in acute articular rheumatism. The antipyretic power of salicylates is second to none, in all the three elements of quickness, degree, and duration of reduction of temperature. For a full antipyretic effect, however, considerable dosage is necessary—considerable enough to cause disagreeable sweating, *tinnitus aurium*, depression of pulse and respiration rate, and, every now and then, actual toxic symptoms. Other antipyretics, therefore, which act more kindly, are preferable, except in rheumatism. The antirheumatic faculty of salicylates is unapproached by any other known medicine, so that, as is well known, salicylates constitute a standard set of medicines for the treatment of acute rheumatism. Under salicylate medication the fever lessens, pains abate, and the disease runs a shorter as well as milder course. It is therefore particularly as remedies for rheumatism and, though not so surely, for gout that salicylates are prized in medicine.

The salicylates in *common medical use* for the purpose of salicylate medication are the salicylates, respectively, of *sodium*, *lithium*, and *methyl*. The salicylates, respectively, of *physostigmine*, *quinine*, and other alkaloids, are used for the sake of the medicinal action of the respective bases only.

Sodium Salicylate, $2NaC_7H_5O_3.H_2O$. The salt is official in the United States Pharmacopœia under the title *Sodii Salicylas*, Sodium Salicylate. It occurs as an amorphous powder, white, without odor, and having a sweetish, saline, and slightly alkaline taste. It is permanent in the air, dissolves readily in water, glycerin, and boiling alcohol. In cold alcohol it requires six parts for solution. It should be kept in well-stoppered bottles, protected from heat and light. Sodium salicylate is the most commonly used salicylate, and is a very important medicine. It is easily made *in solution* by mixing salicylic acid and a sodic carbonate in the presence of water, whereupon sodium salicylate results, and remains in solution, and carbon dioxide gas escapes in effervescence. From this solution the salt can be obtained by evaporation to dryness, carefully conducted. Extemporaneous preparation of the medicine *in solution* being easy, Squibb points out an advantage of such extemporaneous making of the salt in all cases in which the prescriber or the dispenser may not be certain of the purity of the market article. The point is that it is not possible to establish the purity of a given sample of *sodium salicylate* except by an elaborate chemical analysis, whereas a good sample of *salicylic acid* is immediately recognizable by the simple fact of its *crystalline condition*. Hence, in making one's own sodium salicylate from a selected well-crystallized sample of salicylic acid, purity is assured. And in the instance of this salt purity is important, since, as above said, there is probably good reason to lay many of the untoward effects of salicylates to the door of the contaminating acid of salicylic acid. Squibb recommends the following formula for the preparation of a solution of sodium salicylate of a strength convenient for use as a medicine: "Take of salicylic acid, well crystallized, 437 grains = 28.32 gm.; bicarbonate of sodium, 270 grains = 17.5 gm.; water, free from iron, a sufficient quantity. Put the acid into a vessel of the capacity of a pint, add 4 fluidounces = 120 c.c. of water, stir well together, and then add the bicarbonate of sodium in portions with stirring, until the whole is added and the effervescence is finished. Filter the solution, and wash the filter through with water until the filtered solution measures 6 fluidounces, or 180 c.c. This solution contains 10 grains (= 0.65 gm.) of the medicinal salicylate of sodium in each fluidrachm (= 3.75 c.c.). If made from good materials, the solution before filtration is of a pale, amber color, but as most ordinary filtering paper contains traces of iron, the filtered solution is often of a deeper tint." The proportions of the ingredients for this solution are estimated so that the solution shall be neutral, but, "owing to the varying proportions of hygrometric moisture in the materials," the neutrality may not always be absolute. According to Squibb, a well-made sample of sodium salicylate, prepared by use of a well-crystallized sample of acid, is always, when evaporated to dryness, *white*, and is free from all *odor of carbolic acid*, unless it has been shut up for a long while in a bottle. Even then, however, the odor should be but very faint—only perceptible on close examination, and should disappear upon exposure of the sample to air. *Solutions* of sodium salicylate of good quality should have none of the carbolic-acid smell.

Sodium salicylate is used almost exclusively as an internal medicine, being commonly held to be lacking in the germ-sterilizing faculty which gives salicylic acid, as such, its applicability as a local antiseptic. For the purposes of internal salicylate medication, as set forth above, the salt is thoroughly effective, and, if made from a well-crystallized and therefore fairly pure sample of salicylic acid, rarely produces untoward effects in reasonable doses. So large a quantity as 5 gm. (about seventy-seven grains) has been given at a single dose in rheumatism without producing serious derangement, but the ordinary dosage for an antipyretic or antirheumatic effect does not exceed 1.3 gm. (20 grains) repeated every two hours, for three or four doses, or until a distinct impression is produced, followed by doses of half the quantity every hour or two thereafter, so long as the influence of the medicine may be required. The medicine is readily enough taken in simple aqueous solution, but if the faint, mawkish taste of the salt be objectionable, the addition of twenty per cent. of glycerin and the flavoring with a drop or two of oil of gaultheria will render the mixture perfectly palatable.

Lithium Salicylate, $2LiC_7H_5O_3.H_2O$. The salt is official in the United States Pharmacopœia under the title *Lithii Salicylas*, Lithium Salicylate. It occurs as a whitish powder which deliquesces on exposure to the air. It dissolves freely in water and alcohol, and resembles the sodium salt in taste. It should be kept in well-stoppered bottles. The effects of this salt are similar to those of sodium salicylate, with the possible superaddition of medicinal virtues, in rheumatic or gouty cases, derived from the basic element. The dose is similar to that of the sodic salt.

Methyl Salicylate, $CH_3C_7H_5O_3$. This salicylate is an ethereal body which constitutes nine-tenths of the substance of oil of wintergreen and practically the whole of the volatile oil of betula, both of which oils are themselves official medicines. Under the title, however, *Methyl Salicylas*, Methyl Salicylate, the United States Pharmacopœia recognizes the salicylate as made in the laboratory by distilling salicylic acid or a salicylate with methylic alcohol and sulphuric acid. Methyl salicylate is a colorless or slightly yellowish liquid, with the characteristic odor and taste of oil of wintergreen. It dissolves freely in alcohol. It should be kept in well-stoppered bottles protected from light. Methyl salicylate acts like the salicylates generally, with the usual pungent qualities of the volatile oils. In large doses—half an ounce or more—it is dangerously and even fatally poisonous, causing intense irritation of the stomach and intestines with constitutional symptoms of the salicylic influence. In doses of from five to fifteen minims it makes a very efficient salicylic medicine for rheumatism, and is, with many, the favorite salicylate. It may be administered in emulsion or in capsules.

Sodium Dithio-salicylate. Dithio-salicylic acid is a product of reaction between salicylic acid and sulphur chloride, under the influence of heat. The sodium salt of this product is a grayish-white, very hygroscopic powder, freely soluble in water. It has been proposed as a substitute for ordinary salicylates, on the score of being equally, if not more, potent as an antirheumatic remedy, while it is less apt to disturb the stomach. About 0.2 gm. (gr. iij.) may be given two or three times a day, or oftener, according to indications. It is not official in the United States Pharmacopœia.

Iodo-salicylic Acid is a modification of salicylic acid that has been used as a substitute for the ordinary acid in acute rheumatism. It occurs as a white powder slightly soluble in water, but freely so in alcohol, ether, and the fixed oils. It may be given in quantities of from 1 to 3 gm. (gr. xv. to gr. xlvi.) a day.

Cresotic Acid, Cresotinic Acid.—This is an homologue of salicylic acid to which it is allied in physical, chemical, and physiological properties. Its formula is C_6H_3-$OHCH_3COOH$. There are three isomeric acids, the ortho-, meta-, and paracresotic acids. They are always present in salicylic acid of commerce. In 1890 (*Phar. Jour. and Trans.*, November 22d) Professors Charteris and Dunstan, of Glasgow, pointed out that the ill effects that often followed the employment of salicylic acid were due to the presence of ortho- and paracresotic acids. These statements were described more in detail in a second paper in the *British Medical Journal*, March 25th, 1901.

The only preparation of this acid that has been employed for therapeutic purposes is the paracresotate of sodium. It possess antipyretic and antirheumatic properties similar to those possessed by salicylate of soda, but in a lesser degree. The dose is from five to twenty grains three or four times a day; it is free from toxic action, and may be administered more freely if necessary. *Edward Curtis.*

SALICYLIC ALDEHYDE, salicylous acid, ortho-oxybenzaldehyde, artificial oil of spiræa, $C_6H_4.OH.COH$, is obtained by heating phenol and sodium hydroxide with chloroform. A colorless fluid with the odor of meadowsweet, it is readily soluble in alcohol and chloroform, but in water is soluble only enough to impart its odor. In dose of 0.1–0.5 gm. (gr. iss.–viiss.), it is employed as a diuretic and intestinal antiseptic. *W. A. Bastedo.*

SALICYLIDEN-PHENETIDIN. See *Malakin*.

SALICYLO-ACETIC ACID. See *Aspirin*.

SALICYL-QUININE. See *Saloquinine*.

SALICYL-QUININE SALICYLATE. See *Rheumatin*.

SALICYL-RESORCIN-KETONE, tri-oxy-benzophenone, is a compound which in the intestine sets free salicylic acid and resorcin. It is used externally in skin diseases, and internally as an intestinal antiseptic. Dose, 3–4 gm. (gr. xlv.–lx.). *W. A. Bastedo.*

SALICYL-SULPHONIC ACID.—$C_6H_3(OH)(SO_3H)$-$COOH$. A white crystalline body, very soluble in water and alcohol. It is formed by the action of sulphuric anhydride on salicylic acid.

This compound was recommended as a test for albumin by G. Roch (*Pharm. Centralblatt*, September, 1889) and by Dr. John A. Macwilliam (*British Medical Journal*, April 18th, 1891), working independently of each other. It acts upon all forms of proteid bodies. When the proteid present is a native albumin, a derived albumin, a globulin, or fibrin, the precipitate is not dissolved upon boiling, but becomes decidedly flocculent. When the proteid is an albumose or peptone, the precipitate dissolves upon heating, to reappear on the cooling of the fluid. The peptone and albumose may be distinguished by saturating the solution with ammonium sulphate; the albumose is at once precipitated, while the peptone remains in solution. The peptone may then be detected by adding the salicyl sulphonic test.

Compared with other tests, the delicacy of the salicyl sulphonic test varies, according as a cloudiness immediately (two or three seconds) appears, or follows after one-half to one minute. In the latter case it is one of the most delicate tests we possess, revealing the presence of 1 part of albumin in 12,500 of water; in the former, it is placed by Dr. Macwilliam between the cold nitric acid test and the acetic acid and heat test.

Dr. Roch recommended that a few crystals of the acid should be shaken with the urine, or that 5 c.c. of a twenty-per-cent. solution should be added to 10 c.c. of the urine to be tested. Dr. Macwilliam is more exact in his manipulations. He recommends that a small amount of urine, about twenty minims, be placed in a small test tube, and that to this a drop or two of a *saturated* aqueous solution of the reagent be added. The urine must not be alkaline, and, if necessary, it should be acidulated. On adding the reagent the tube should be shaken quickly, to mix the contents, and the fluid should be examined at once. The occurrence of an opalescence or cloudiness immediately or within a few seconds indicates the presence of proteids. The development of the reaction after an interval of a minute or two shows the presence of proteids in minute quantities, which are probably insignificant from a clinical point of view. The fluid is then to be heated, when the ordinary albumin is coagulated and formed into a flocculent mass. *Beaumont Small.*

SALIFEBRIN, salicylanilid, is a proprietary combination of acetanilid and salicylic acid. *W. A. Bastedo.*

SALIFORMIN, urotropin salicylate. See *Urotropin.*

SALIGALLOL, the di salicylate of pyrogallic acid, is a resinous substance, soluble in chloroform or acetone. Kromayer finds that it has but a weak pyrogallol action, but is of value for the preparation of an excellent skin varnish which may serve as a vehicle for other medicaments. "Solutio saligalloli" is a sixty-six-per-cent. solution of saligallol in acetone. *W. A. Bastedo.*

SALINE SOLUTION, NORMAL. See *Hypodermoclysis.*

SALINS-MOÛTIERS. See *Brides-les-Bains.*

SALIPYRIN.—A compound containing 57.7 parts of antipyrin and 42.3 parts of salicylic acid. It is prepared by adding to a boiling aqueous solution of antipyrin a proper molecular proportion of the acid. It forms as a white, coarsely crystalline powder, odorless, with a not unpleasant sweetish taste. It is almost insoluble in water, about one part in two hundred, sparingly soluble in ether, but readily soluble in alcohol. It is decomposed by acids and alkalies.

It possesses antipyretic and antirheumatic properties, and was introduced as a substitute for the salicylates in the treatment of rheumatic affections. It is probably as serviceable as salicylic acid or antipyrin, but is equally inefficient in preventing relapses, and does not seem to offer any special advantage over other remedies for rheumatism. The amount to be given is one drachm and a half in divided doses, during the day; the first dose being thirty grains and the subsequent doses about fifteen grains each.

As an antipyretic it is not very satisfactory; it requires to be given in doses of thirty grains, to be repeated every hour if necessary. As an analgesic it has proved of value in sciatica, in the pains of myelitis, in neuralgia, and in nervous disease accompanied by pain.

The results of its employment show it to be a harmless and useful drug, but not very reliable. It has not superseded either of its component parts. Profuse perspiration and gastric disturbances frequently follow its employment. *Beaumont Small.*

SALITANNOL, $C_{14}H_{10}O_7$, is a condensation product of salicylic and gallic acids, forming a white, amorphous powder. It is insoluble in water, ether, chloroform, and benzol, slightly soluble in alcohol, and readily soluble in solutions of the caustic alkalies. It is employed surgically as an antiseptic. *W. A. Bastedo.*

SALITHYMOL, $C_6H_3.CH_3.C_3H_7.O.COC_6H_4OH$, is a combination of thymol and salicylic acid somewhat similar to salol. It is obtained by acting with phosphorus trichloride on equimolecular quantities of the sodium compounds of salicylic acid and thymol, and then crystallizing from alcohol. Salithymol is a white crystalline powder of mild sugary taste, very soluble in alcohol and ether, and nearly insoluble in water. Its uses are those of salol, but it is claimed to be preferable, as it sets free thymol in the intestine, while salol liberates phenol. The dose is 0.3–1 gm. (gr. v.–xv.). *W. A. Bastedo.*

SALIVA.—The saliva is formed by the admixture of the secretions of the three pairs of chief salivary glands, viz., the parotid, submaxillary, and sublingual, and of the small buccal glands.

The mechanical and chemical functions of the saliva in connection with deglutition and digestion have already been considered in the articles upon these subjects, and hence the secretion and chemical composition of the fluid only need be taken up in this article.

Secretion.—The three paired salivary glands form typical examples of racemose, tubulo-saccular secreting glands. Each gland possesses a main duct by which the secretion is carried to the mouth. Within the gland this duct divides and subdivides in a racemose fashion, giving rise finally to a large number of minute ductules lined by a single layer of columnar cells. Each ductule, as it passes toward the secreting cells, divides, and the cells lining the secondary ductules so formed become flattened in shape; then each secondary ductule widens to form a tube of secreting cells, which usually possesses branches also lined with similar secreting cells, which may again branch and be lined with secreting cells in similar fashion. Thus a racemose clump of secreting tubules is formed around the end of each ductule. These secreting tubules are termed *alveoli* or *acini*, and are lined by polyhedral cells which surround in a single layer a minute central cavity or *lumen*, into which the secretion is poured when the gland becomes active. This layer of secreting cells is sheathed externally by a thin basement membrane, and lying upon this is a network of fine capillary blood-vessels for the nutrition of the secreting cells. The lymph exuding from this capillary plexus bathes the secreting cells after it has passed through the fine basement membrane, and the cells taking up the lymph, even during periods of rest, transform its constituents into definite chemical substances which are stored up in the cells in such a manner as to be visible under the microscope as minute granules.

When the gland becomes active as a result of stimulation in the natural fashion, two important changes, which have been shown to be independent of each other in their innervation, occur: in the first place, the vaso-dilator fibres supplying the walls of the blood-vessels of the gland are stimulated, so giving rise to an increased blood supply, and hence to an increased flow of water and salts to the secreting cells to serve as a vehicle for carrying off those cell products which have accumulated in the cell during the period of intermission in secretion; in the second place, the gland cells themselves are directly stimulated by the secreto-motor fibres to a change in activity, as a result of which the granules deposited previously in them undergo a chemical modification which renders them soluble and easily transported through the cell into the lumen of the alveolus. The constituent alveoli are bound loosely into small masses visible to the naked eye, which are termed lobules, and these lobules are divided off from one another, and at the same time united to form the gland mass, by coarser bundles of connective tissue, which unite at the outer surface of the gland to form a capsule, varying in the clearness of its definition in the different glands and in different animals, being usually but ill-defined in the case of the parotid gland.

The secreting cells of the salivary glands when observed under the microscope, either in the fresh state or after the use of hardening and staining reagents, present two distinct types of characteristically different appearance, and each type again shows distinct modifications in appearance according to whether it is observed at a period of fasting (loaded) or during a period immediately following digestive activity (unloaded).

These differences in type correspond to a difference in chemical character of the secretion yielded by the respective cells, for it has been shown that one form of cell secretes the *mucin* of the saliva, while the other secretes the *ptyalin*, which confers upon the saliva of certain mammals, including man, its important chemical action upon the starch of the food. (See *Digestion*.)

The relative extent to which the two cells are developed in the corresponding glands of different animals varies within very wide limits, the same gland being almost completely composed of one type in one animal and of the other type in another. In many cases the same gland contains both types of cells, as is particularly well seen in the human submaxillary gland, and in such a case the different characters of the two types of cell can be studied side by side in the same section. Usually the cells occupying any one alveolus are of the same type, either *mucous* or *serous*; but in the mucous alveoli a third type of cell occurs, lying outside the true mucous cells, between these and the basement membrane. From their position and the pressure applied to them by the concentrically arranged cells of their own alveolus on one hand and the adjacent alveoli on the other, these cells as they develop become crescentic in shape and have hence been termed *demilune* cells.

In a mucous alveolus, the mucin-secreting cells present in hardened sections a perfectly clear, homogeneous, glass-like appearance, except for the nucleus, which is usually shrunken and lies at the broader end of the cell close to the basement membrane. This appearance is, however, an *artifact*, and is due to the action of water, alcohol, or other reagent used in the process of manipulation, upon the cell contents; for these mucous cells when examined in the fresh state, teased out in blood serum, are filled up, provided the gland is in the loaded state, by large granules which are stated to be composed of *mucinogen*, a precursor of the mucin found in the saliva. On the other hand, if the gland has been much stimulated before the mucous cells are taken for examination, it is found, according to the degree of stimulation, that these mucinogen granules may either be few in number and confined to the inner zone of the cell, or may be entirely absent. In the process of secretion, then, the mucinogen granules are dissolved, being converted into soluble mucin, which is carried by the stream of water and salts through the mucous cell toward the lumen of the alveolus, and is thence discharged into the duct. Supporting this view, there is the fact that the viscidity and amount of mucin present in the saliva vary with the amount of these clear cells present in the gland.

Various contentions have been put forward as to the nature and purpose of the demilune cells present alongside the mucous cells in the same alveolus, and present also in glands containing no serous alveoli.

These cells differ strikingly in histological appearance from the mucous cells, especially in hardened and stained sections, being not only different in shape and position, as above described, but also smaller, free from mucin granules, and filled instead in the loaded condition with minute highly refractile granules similar to those present in the serous cells (*vide infra*) and disappearing during secretion.

One view was that they were young mucous cells designed later to be pushed toward the lumen and take the place of mucous cells which had broken down in the process of secretion.

There is, however, no good evidence that the mucous cells are disrupted in the process of discharge; no intermediate stages in the process of conversion of demilunes into mucous cells have ever been demonstrated; and, further, the charged and discharged condition of the demilunes as regards their granules, varying as it does concurrently with the state of the gland, proves that they are functionally active and not immature growing cells.

The view has hence been put forward that these demilunes are really serous cells, occurring in chiefly mucous glands and not differing save in shape from the other serous cells which constitute the chief cells in other alveoli. Their peculiar shape can be explained from their position, while the fact that ptyalin in addition to mucin is also found in the secretion of glands containing otherwise only mucous cells points strongly to the demilunes being serous cells.

The cells of the *serous* or *albuminous* alveoli in the loaded condition are filled with minute highly refractile granules which render the cells opaque, disguise the nuclei, and make it difficult even to discern the cell outlines. When the gland is stimulated to secrete, these granules rapidly decrease in number, the cell outlines become clearly marked, soon the nuclei become visible, and the outer zone of the cell clear of granules, and capable of staining with dyes, while the portion of the cell toward the lumen is still loaded with granules. As secretion is pushed to the extreme limit, this luminal zone, however, becomes smaller and smaller, showing that there is a current of dissolution setting toward the lumen.

The intrinsic ferment of the saliva is yielded by these cells, but it is probable, as in the case of the pancreas (*q. v.*), that the ferment is not deposited in the cells in the form of this ferment in the granular condition, but is instead present in the cells in an inactive form called *ptyalinogen*, from which the free ptyalin is formed as solution of the granules takes place in the act of secretion. In some animals, however, as has been shown in the case of the horse, the active ferment is set free in an unknown manner only in the mouth, and not in the gland itself. For if the parotid saliva of the horse be collected, by means of a fine sterilized glass cannula inserted into Stenson's duct, in sterilized glass vessels, it is quite inactive upon starch solutions, and first becomes active when it is agitated by blowing air through it.

Each salivary gland is innervated along two distinct paths, receiving nerve fibres, on the one hand, from the medulla oblongata by a cranial nerve, and, on the other, fibres from the spinal cord through the cervical sympathetic. These nerve fibres have two distinct functions, some passing to the blood-vessels of the glands and regulating its blood supply, while others are purely secretory in character and pass to the secretory cells of the alveoli. The greater number of the secretory fibres are carried by the cranial nerves and are there accompanied by the vaso-dilators; while a smaller number of secretory fibres, which seem especially to be connected with the secretion of the organic constituents of the saliva, pass to the gland viâ the cervical sympathetic accompanied by the vaso-constrictor fibres to the blood vessels.

The cranial fibres for the submaxillary and sublingual glands are carried by the *chorda tympani*, which leaves the facial nerve in the Fallopian canal, crosses the tympanum, and then joins the lingual branch of the fifth. The lingual nerve gives off a branch at the posterior border of the submaxillary gland, which contains the ma-

[illegible] the fibres which had joined previously by way of [illegible] tympani, and this branch, which consists of a number of strands lying close together, contains most of the secreto- and vaso-motor fibres for the submaxillary and sublingual glands. These strands, often wrongly called the chorda tympani nerve, curve backward along the gland ducts and pass with them into the glands.

The cranial fibres for the parotid gland vary in their course in different animals, but frequently they arise from the ninth cranial nerve and course in the nerve of Jacobson, across the tympanic cavity, over the promontory of the tympanum, and pass viâ the small superficial petrosal and otic ganglion to the auriculo-temporal branch of the fifth, by which they are finally distributed to the parotid gland.

The sympathetic fibres to the salivary glands arise from the spinal cord in the upper dorsal region and run to the superior cervical ganglion, where a relay of nerve cells is interposed, round which the original fibres arising from the spinal cord end in arborizations. From the nerve cells of the superior cervical ganglion other fibres arise, chiefly from the lower and middle portion, and, passing to the external carotid, form plexuses upon it and its branches by which the fibres are ultimately carried to the gland without forming any more nerve-cell connections.

A similar cell station has been demonstrated in the case of the chorda tympani fibres, as lying in the many small ganglia between the point at which the fibres leave the lingual nerve and the various points at which the fibres enter the glands.

These ganglia are as a rule microscopic in size, but two can be seen with the naked eye and have been named, viz., the *sublingual*, lying in the angle between lingual and chorda, which is a cell station for fibres passing to the sublingual; and the *submaxillary*, which lies in the hilus of the submaxillary, and forms a cell station on the path of many of the fibres for that gland.

The position of these various cell stations has been demonstrated by Langley by the injection of small doses of nicotine, which paralyzes the junction between nerve fibre and nerve cell, but does not affect the nerve fibres. Hence the position of a nerve station is shown after injection of this drug into a vein, if no effect is now obtained on stimulating centrally to a ganglion, while an effect is still obtainable peripherally to the ganglion, previous experiment before injection of the drug having given an effect at both places.

Experimenting by this method, Langley has shown that every fibre leaving the spinal cord, whether by cranial nerve or sympathetic, ends somewhere on its course in a peripheral ganglion. Such a fibre is termed a preganglionic fibre. From the peripheral ganglion cell a fibre arises which is termed a postganglionic fibre, and this without further interruption passes to distribution in the gland. There is hence in every case one ganglion cell and no more interposed between spinal cord and gland. The preganglionic fibres are in most cases finely medullated (2 to 4 μ), while the postganglionic fibres are probably all non-medullated.

The effect of stimulation upon the nerves has been most closely studied in the case of the submaxillary nerve, but similar results have been obtained by stimulation of the corresponding nerves in the other glands, so that a description of the occurrences in the case of the submaxillary may be taken to hold for the other two glands. Excitation of the peripheral end of the cranial nerve (chorda tympani) causes, after a very short latent period, a rapid flow of a very dilute saliva, containing a very low percentage of organic constituents. Even weak stimulation produces a copious flow, and secretion can be evoked in this manner for a long period without fatiguing the nerve, so that a quantity amounting to forty or fifty times the weight of the gland can be obtained.

Accompanying this rapid secretion there is a marked vaso-dilatation, so that the gland can be seen to become much pinker to the naked eye, and when placed in a plethysmograph shows a large increase in volume.

That the increased flow of saliva is not, however, solely due to an increased blood supply is demonstrated by the following facts:

1. After administration of atropine, the flow of saliva is no longer obtained, although the vaso-dilatation is as great as before, showing that atropine paralyzes secreto-motor fibres but leaves the vaso-dilators untouched.

2. If the cannula placed in the duct of the salivary gland be connected up to a mercurial manometer, and at the same time the carotid blood pressure be similarly observed by means of a second manometer, it is found that the flow of saliva does not stop until the pressure in the salivary manometer has risen considerably higher than that in the carotid. Now, if the secretion were merely an increased filtration due to increased blood supply, this obviously could not be so, for then the saliva would be filtering from a lower to a higher pressure.

These experiments are sufficient to show that a true secretion is taking place in the alveolar cells, under the stimulating influence of a secreto-motor nervous mechanism distinct from the vaso-dilator mechanism.

The effects of stimulation of the cervical sympathetic upon the gland are very different; there is a vaso-constrictor instead of a vaso-dilator effect, and, after a much longer latent period, there is but a scanty flow of a very viscid saliva much richer in organic constituents.

The amount of flow caused by stimulation of the cervical sympathetic is considerably increased if the cranial nerve has been stimulated a few seconds previously.

Now in the natural stimulation of the gland, as by the sight or thought of food, or by the act of mastication, it is a fairly obvious conclusion that both cranial and sympathetic nerve supplies act upon the gland simultaneously, and hence that there will be conjoined the greater flow of water and inorganic salts caused by the cranial nerve fibres, with the stimulation to increased flow of organic substances effected through the cervical sympathetic fibres.

No saliva flows between periods of stimulation, and it has been observed by inserting a cannula into the duct of Stenson in the horse that a flow of saliva occurs only when it is provoked reflexly, as by mastication.

Cutting the cranial nerve gives rise to the so-called "paralytic secretion," first observed by Claude Bernard; this commences commonly in from two to three days after the section, and lasts for a period of three or four weeks, during which time there is a constant slow secretion accompanied by a great decrease in weight of the gland, which finally becomes functionless. No permanent effect of a like nature follows section of the cervical sympathetic.

It is interesting that a much slighter flow accompanies the paralytic secretion, upon the opposite side where the nerves are quite intact; this peculiar secretion is spoken of as "antilytic secretion."

There is no explanation of either paralytic or antilytic secretion, outside the region of mere hypothesis.

The mouth is probably kept moist in man between the periods of eating by the secretion of the small buccal glands, for it has been shown that the secretion of the large glands completely intermits between the meals in cases of artificial fistulæ of the gland ducts.

In man, the sight or even the thought of appetizing food causes an immediate flow; but secretion cannot be evoked in this fashion in some of the lower animals. Thus presenting meat to a dog in which a parotid fistula has been established does not cause a flow of saliva.

Sapid substances are the most powerful reflex stimulants to secretion when placed either on the tongue or on the mucous membrane of the mouth.

The vapors of chloroform and ether cause a rapid secretion when inhaled by the mouth, as a result of the stimulation of the gustatory nerve endings; when administered by the trachea, they are said not to produce this effect.

Alcohol, or water containing chloroform or ether, applied to the mucous membrane of the mouth, causes a rapid secretion.

The sapid substances produce their effect in the following descending order of strength: (1) acids, (2) neutral and alkaline salts, (3) bitter substances, (4) sweet substances; but the acids (including organic acids) are incomparably more effectual in evoking secretion than the other classes of sapid bodies.

Chemical Composition.—The composition of the mixed saliva is very variable, as can readily be understood when it is considered how many glands contribute to its formation. Sublingual saliva is richest in solids, and may contain as much as three per cent.; submaxillary saliva is stated by most observers to contain a higher percentage of solids than the mixed saliva, while parotid saliva is poorest in solid constituents (0.3 to 0.5 per cent.). The total solids of mixed saliva amount to from 0.5 to 1 per cent., and the specific gravity lies between 1.002 and 1.008.

Mixed human saliva is alkaline to litmus and acid to phenolphthalein, indicating that there is an excess of carbon dioxide present above that necessary to form sodium bicarbonate. This is borne out by the large amount of carbon dioxide obtainable from saliva, which contains more of this gas than either blood serum or venous blood. Thus Külz found in saliva 66.7 volumes of CO_2 per 100, and Pflüger 64.7 to 85.1 volumes per 100. This fact is of interest as showing the large amount of metabolism which occurs in the secreting cells, and lends a further proof, if such were necessary, that the process of secretion is not purely one of filtration and osmosis. The average amount of alkalinity to litmus is equivalent to that of a solution of 0.08 per cent. of Na_2CO_3 (Chittenden and Ely).

The organic matter of the saliva is small in total amount, and is present partially in suspension as formed elements and partially in solution.

The formed elements present include squamous cells from the buccal epithelium, salivary corpuscles, and very pale spherules resembling the granules seen in the mucous salivary cells.

The salivary corpuscles are altered leucocytes derived chiefly from the salivary glands, but possibly the tonsils also contribute to their number. The leucocytes pass from the lymph, between the alveolar cells, into the ductules, and become swollen out by imbibition from the saliva, which has a lower osmotic pressure than the lymph. For the same reason the granules which these corpuscles contain are set in active Brownian movement.

The chief organic substances in solution are mucin, ptyalin, and minute traces of proteid. The mucin can be demonstrated by its precipitation on the addition of acetic acid. The presence and action of ptyalin have been considered in the article on *Digestion*. Coagulable proteid is present only in minute traces. Urea is said to be excreted in the saliva in uræmia, and lactic acid in diabetes.

Saliva normally gives a distinct reaction for sulphocyanides when a very dilute solution of ferric chloride is added to it. The test is best carried out by wetting filter paper with ferric chloride so dilute as scarcely to color it, and then adding the saliva, when a red color is obtained. Sulphocyanates are, however, absent in certain individuals, and in the same individual are present at certain times and absent at others.

The inorganic salts present consist chiefly of chlorides, phosphates, and carbonates of the alkalies and alkaline earths, the chief constituent as usual being sodium chloride. The most interesting of the inorganic constituents is calcium bicarbonate; it is this salt which gives rise to the cloudiness observed when saliva is allowed to stand for some time. The precipitation is due to the escape of the excess of carbon dioxide, which had previously held the calcium carbonate in solution. A certain amount of calcium phosphate is similarly precipitated. Such a precipitation occasionally leads to occlusion of the gland ducts by the formation in these of salivary concretions, which consist of a mixture of calcium carbonate and calcium phosphate. When the precipitation occurs on the teeth it is termed tartar; this also contains silica in addition to the calcium salts mentioned above.

Benjamin Moore.

SALIVARY GLANDS AND THEIR DUCTS, DISEASES OF.—*Increased Secretion of the Salivary Glands* (Ptyalism; Salivation).—The normal amount of salivary secretion is from one to three quarts in twenty-four hours, though under exceptional conditions the quantity may be as much as five quarts. While food is being taken the saliva is normally greatly increased, which may also occur during the menstrual period and during gestation. Salivation, likewise, occurs in connection with quite a number of different diseases, such as acute fevers, diseases of the liver, spleen, genital organs, and pancreas, and in all inflammatory conditions of the oral cavity. It is likewise sometimes seen in bulbar paralysis, in diabetes, and in melancholia. Quite a number of drugs are also capable of giving rise to an increased salivary secretion, among which are muscarin, tobacco, pilocarpine, potassium iodide, the salts of arsenic and copper, and mercury and its various compounds. Of all the causes the last mentioned is the one that most frequently occasions the condition, and it is true that the amount necessary to produce this result varies very greatly in different instances—some individuals tolerating large quantities of the drug, while others are affected by very minute doses.

(For the treatment see article on *Mouth, Diseases of*, in THE APPENDIX.)

Decreased Secretion of the Salivary Glands (Xerostomia; Dry Mouth).—The secretions of the salivary and buccal glands may be greatly diminished, or, in some instances, entirely suppressed. The condition is most commonly observed in nervous women, though it is occasionally seen in men as well; it may follow shock or may occur in connection with diabetes and febrile states. As a natural consequence of the arrest of the secretion the tongue and mucous membranes of the cheeks and palate become dry, and mastication and articulation are exceedingly difficult. Osler speaks of a case observed by him in which, on account of the absence of the normal secretion of the mouth, food collected along the gums and became exceedingly hard, presenting somewhat the appearance of a new growth in the oral cavity of the patient; in this instance the affection was cured in about three weeks by the application of the galvanic current.

Treatment. For dry mouth pilocarpine may be used, and, as in the case above cited, electricity may be employed with advantage. Oils applied to the mucous membrane of the mouth are of service in ameliorating the very disagreeable dry state of the oral mucous membrane. The condition is very obstinate.

INFLAMMATION OF THE SALIVARY GLANDS.—There are several distinct and separate varieties of inflammations of the salivary glands at present recognized, and there can be no question but that, as our knowledge increases, many conditions which are at present regarded as being identical will be found to be the result of causes differing widely from each other. There are specific parotitis (see *Mumps*), symptomatic parotitis, and chronic parotitis.

Symptomatic Parotitis.—Symptomatic parotitis is an affection that occurs in connection with a large number of different diseases, though the relationship between inflammations of the glands and the causes that apparently determine them are exceedingly obscure. The condition occurs most commonly during the course of the infectious fevers, such as typhoid, typhus, scarlet fever, rheumatism, pneumonia, peritonitis, pyæmia, septicæmia, and syphilis, but it is also sometimes seen in connection with consumption and gout. When the affection results from acute fevers, the inflammatory phenomena are quite severe, and, as a rule, suppuration results. If the pus be not evacuated by surgical means, it not uncommonly burrows into the tissues of the face to a considerable distance. Inflammations of these glands likewise very curiously often follow laparotomy, and operations upon the genital organs in both men and women. It has also been found associated with facial paralysis, and may occur during pregnancy or follow menstruation.

Treatment.—Ice-bags should be applied in the beginning to relieve the pain, or leeches may be employed for the same purpose. Belladonna ointments are of some service during the acute inflammatory stages. When it is found that suppuration is likely to supervene, poultices should be applied, and at the first indication of suppuration the glands should be incised and the pus evacuated.

Chronic Parotitis.—Chronic parotitis, for clinical purposes, may be divided into two varieties: (*a*) the chronic inflammation of one or more of the glands, with or without history of previous acute disease, and (*b*) the curious inflammatory condition in all of the salivary and lachrymal glands first described by Mikulicz.

(*a*) *Chronic Parotitis with or without Previous Acute Inflammations of the Glands.*—This affection is occasionally observed as a sequel of mumps, and may follow inflammatory conditions occurring in the throat. It has been observed in secondary and tertiary syphilis, in Bright's disease, and as a complication of chronic tuberculosis of the lungs. Some years ago the writer described a case of this kind that occurred in connection with chronic inflammatory changes in the pancreas, in a man suffering from diabetes. The affection may be the result of lead or mercurial poisoning.

Treatment.—Except the condition be of syphilitic origin—in which case mercury and iodide of potassium should be employed—we know of no drugs that affect the course of this disease.

(*b*) *Chronic Symmetrical Inflammation of the Salivary and Lachrymal Glands.*—Since the publication of the paper of Mikulicz, Kümmel has reported a number of instances of this disease, and in this country Osler has recently recorded a very interesting example of the affection. Nothing is known concerning the causation of this malady, but in Osler's case the patient had probably suffered from tertiary syphilis, and the enlargement of the glands gradually subsided under the use of mercury and iodide of potassium. Kümmel found that the salivary glands are completely replaced by mononuclear leucocytes, and suggests the name of achroöcytosis. Osler's patient died later of tuberculosis, and at the autopsy the lachrymal glands were found to be represented by masses of fibrous tissue. Though all of the glands are usually involved, in some instances this is not the case. The swollen glands are painless and the disease generally persists for a number of years. It is of interest to note that it has in some instances rapidly subsided following acute fevers.

Treatment.—In cases in which the disease is secondary to syphilis the appropriate treatment for the latter affection would, of course, be called for, and even in instances in which there is no history of this disease it would be wise to give the patient the benefit of the doubt and to test thoroughly mercury and iodide of potassium. Should these remedies fail, it is not likely that other means would be efficient.

Tumors of the Salivary Glands.—Carcinoma, sarcoma, adenoma, fibroma, fibro-adenoma, chondroma, myoma, and lymphoma occasionally occur in these glands, though none of them are common. Of these tumors fibro-adenoma is perhaps the most frequent. The malignant neoplasms found in the glands generally belong to the epithelial type. In all instances in which the tumors show evidence of malignancy they should be immediately removed.

Diseases of the Ducts of the Glands.—*Calculi*, consisting of carbonate and phosphate of calcium, are occasionally formed in the ducts of the salivary glands, and either they may be discharged or they may lodge in some part of the ducts; they sometimes occasion a retention of the secretions of the glands. Under these circumstances an operation should of course be resorted to to relieve the condition. Occasionally the ducts become dilated in glass-blowers and in musicians; when this occurs the distended ducts present the appearance of a tumor, and contain air which may be mixed with saliva and pus.

Henry Fauntleroy Harris.

SALIX.—*Willow. Saule blanc*, Fr. Cod.—When it was official, this drug was defined by the United States Pharmacopœia as "the bark of *Salix alba* L. and of other species of *Salix* (fam. *Salicaceæ*)." Salicinum now entirely replaces it in the Pharmacopœia. The species named is the common *European white willow*, now quite extensively naturalized in North America. It is a large tree with, when old, a very thick, irregular trunk, dividing near the ground into several great limbs; branches numerous, ascending, rather densely massed; twigs slender, lightly attached to the branches, possessing a light-yellow or greenish-yellow bark and white soft wood; young shoots,

A. B.

Fig. 4140.—Salix Alba. *A*, Staminate; *B*, pistillate.

buds and the under surface of the leaves silky; leaves numerous, alternate, with small lance-ovate stipules and short petioles; the blades two to four inches long and about half an inch wide, lanceolate, acute, whitish beneath, finely serrate; flowers diœcious, in slender weak spikes, each in the axil of a small bract, appearing in early spring. Only the bark of the younger branches should be collected.

Willow bark is "in fragments or quills, from one-twenty-fifth to one-twelfth of an inch (1 to 2 mm.) thick, smooth; outer surface somewhat glossy, brownish or yellowish, more or less finely warty; under the corky layer green; inner surface brownish-white, smooth, the fibres separating in thin layers; inodorous; bitter, and astringent.

Constituents.—Besides ordinary plant constituents, willow contains the following three glucosides: *tannin*, about ten per cent.; *salicin* (which see), about two per cent.; *helicin* ($C_{13}H_{16}O_7 + \frac{3}{4}H_2O$). The properties and uses of the drug depend almost wholly upon the salicin contained, and our article on the latter substance should be consulted. As an antiperiodic, the bark is employed in doses of an ounce or more, in the form of fluid extract, or, as is more common in domestic practice, a decoction or infusion. It is often used as a tonic in doses of about one fifth or less of this amount, the powdered bark being often used for this purpose; also as an intestinal astringent. Salix has sometimes produced good results as an anthelmintic. The powdered bark was formerly considerably employed as a vulnerary, salicylic acid having now entirely replaced it for this purpose in medical practice.

Allied Drugs.—The genus Salix contains about one hundred and sixty species, many of which have been employed like *S. alba*. The plants fall naturally into two classes, the one characterized by the yellow, the other by the purple color of their young shoots. The latter are said to contain more salicin, sometimes above three per cent., the former more tannin.

Populus L. is the botanical name of the Poplars, Popples, Cottonwoods or Aspens, a number of which, both European and American, are used, in the form of their barks and leaves, as willow bark is used. These drugs contain the same constituent as the willows, besides the closely allied glucoside *populin* or *benzoyl-salicin*.

The buds of *P. balsaminifera* L. and *P. candicans* Ait. are known as balm of Gilead buds. Their scales are thickly coated with a very pleasant balsamic scented oleoresin, which possesses mild aromatic, diuretic, expectorant, and vulnerary properties.

Henry H. Rusby.

SALOL—$C_6H_5C_7H_5O_3$. Salol is the name given to the salicylic ether of phenol (carbolic acid). It is compounded of salicylic acid and phenol and represents sixty per cent. of the former substance and forty per cent. of the latter. It is official in the United States Pharmacopœia under the title *Salol*, Salol. Salol is a white crystalline powder, melting at 43° C. (109.4° F.) into a colorless, oily fluid. It is nearly insoluble in water, but dissolves in alcohol, ether, and fixed oils. From its insolubility in aqueous fluids it is practically tasteless in powder, but it has a faint aromatic smell.

Salol is used as a substitute for the common salicylate salts, on the grounds that it is equally effective as a medicine, while at the same time, in medicinal doses, it is much less deranging to digestion on the one hand, and less productive of constitutional toxic effects on the other. It is insoluble in the fluids present in the stomach—whence the lack of gastric derangement in its employment—but suffers solution by chemical decomposition in the small intestine through the action of the pancreatic juice, resolving into salicylic acid and carbolic acid (phenol). Constitutionally, salol, in ordinary dosage, has produced little disturbance beyond an occasional and trifling ringing in the ears. In experimenting, however, with a dosage exceeding 6 gm. (about a drachm and a half) distributed over the twenty-four hours, toxic symptoms have been observed, as might be expected, considering that the medicine is nearly one-half carbolic acid. Salol, taken internally, imparts to the urine of the subject the peculiar coloration seen after ingestion of carbolic acid, a phenomenon that may persist for several days after discontinuance of the medicine. The average medicinal dose of salol for an antirheumatic or antipyretic effect is from 0.6 to 1 gm. (gr. x. to xv.), given twice, or thrice, daily. A dosage reaching 8 gm. (about two drachms), in the course of a day, was followed, in one instance, by severe vomiting, gastralgia, and tinnitus. Salol may be taken dry upon the tongue, in powder, the dose to be washed down with a little water, or may conveniently be administered in pill form.

Because of the fact that salol only gradually suffers resolution into its constituents, the substance makes a useful intestinal disinfectant in diarrhœa or typhoid fever.

Salol should not be given when there is any disease of the kidneys, because of the carbolic acid of its constitution.

Edward Curtis.

SALOL-CAMPHOR.—These two substances, when mixed in certain proportions, alter their physical state and become an oily, colorless liquid, insoluble in water, freely soluble in ether, chloroform, and oils. It is prepared by adding twenty parts, by weight, of powdered camphor to thirty parts of salol, and warming gently until fusion is complete.

It possesses the properties of its constituents, and is highly recommended as a stimulating antiseptic.

Beaumont Small.

SALOPHEN.—(*Acetyl-para-amido-salol.*) A patented compound which is, chemically, salol in which one atom of hydrogen in the phenyl group is replaced by the monivalent group $N_2H(CH_3O)$. It occurs in minute, white, crystalline plates, insoluble in cold water, very slightly soluble in hot water, soluble in alcohol and ether. Alkalies render it soluble, even in cold water. It is without taste or odor, and is neutral in reaction. Salicylic acid is present to the extent of fifty-one per cent. The acid secretion of the stomach has no effect upon it, but when it comes in contact with the pancreatic ferments it is decomposed into salicylic acid and acetyl-para amido-phenol. The object in view in the production of this compound was to improve upon salol by combining with the salicylic acid a phenol compound which was perfectly harmless.

It is recommended as a remedy for acute articular rheumatism in doses of sixty to seventy-five grains during the day, the usual dose being fifteen grains every three or four hours. It does not disagree with the stomach nor produce any toxic symptoms. Relapses and the ordinary complications are not prevented. Salophen has proved serviceable in neuralgia, sciatica, and other painful affections of the nerves. Reports of its favorable use in severe attacks of pruritus have been published. It has also been used with success in influenza.

Beaumont Small.

SALOQUININE, the quinine ester of salicylic acid, $C_6H_4.OH.CO.O.C_{20}H_{23}N_2O$, is a mild substitute for quinine with added analgesic properties. Its advantages, as stated by Overlach, are that it has no disturbing effect upon the digestive or urinary organs or the nervous system, does not produce cinchonism, and is tasteless. He employed it in sciatica in 2 gm. (gr. xxx.) doses with good effect. Tauszk has used it in supraorbital neuralgia, influenza, the pains of locomotor ataxia, muscular rheumatism, acute articular rheumatism, and typhoid fever. He recommends it as an efficient antineuralgic with mild antipyretic action. In doses of 0.5–3 gm. (gr. viij.–xlv.) daily, no vertigo or tinnitus was complained of, though in some cases mild sweating was observed.

Fitch, Sternberg, and von Kolozsvary speak highly of its use in malaria, large doses 0.3–1.3 gm. (gr. v.–xx.), being administered several times a day. Being free from taste it is easily taken by children.

The salicylate of saloquinine is "rheumatin."

W. A. Bastedo.

SALSOMAGGIORE, ITALY.—This new cure resort is pleasantly situated in Northern Italy, Lat. 44° 48' N., Long. 27° 38' E., two hours' ride by rail south from Milan. It lies in the valley of the Po, surrounded by low hills covered with the vine, maize, and mulberry trees. To the south rises the Apennine range.

The village itself is picturesquely situated at an elevation of about 500 feet, and contains 1,200 inhabitants. It is said to be unusually healthy, and is well supplied with good drinking-water.

The climate is temperate, the heat being never unduly excessive, and the sun is hidden by the hills before five o'clock in the summer.

The country round about is very attractive and affords many interesting excursions either by road or by rail. From here Bologna, Parma, Modena, and other spots of interest are readily reached by rail.

The accommodation is excellent, there having been opened in 1900 "The Grand Hotel des Thermes," with three hundred rooms and fitted with all modern equipments in the way of sanitation and comfort. There are music, billiard, and reading-rooms, elevators and electric lighting, and the baths can be taken in the hotel itself, each floor being provided with special bathrooms for that purpose. The charges are not excessive. The season extends from April 1st to November, although July and August are the least desirable months in which to visit the spa.

Salsomaggiore is one of the two best-known spas in Italy, the other being Bagni di Lucca. The waters are what are known as muriated iodobromine, locally called "salso-iodic," and are furnished by numerous artesian wells. Their natural temperature is 57.2° F. For the "cure" either the "salso-iodic" or the mother water, made by extracting the salt by evaporation, is employed. The analysis of the water is as follows:

IN 1 KGM. OF WATER FROM SALSOMAGGIORE THERE IS:

	Gm.		Gm.
Potassium chloride...	0.000	Aluminum chloride....	0.0590
Sodium chloride......	153.990	Magnesium chloride...	.0057
Lithium chloride.....	.735	Magnesium bromide...	.3037
Ammonium chloride..	.637	Iodide of magnesium..	.0663
Calcium chloride.....	15.848	Borate of magnesium..	.0116
Strontium chloride...	.256	Bicarbonate of iron...	.0778
Magnesium chloride..	5.584	Sulphate of strontium.	.0033
Iron chloride.........	.033	Silicate................	.0230

Hot baths, mud baths, and inhalations are used in the treatment, which occupies from two to three weeks. The temperature of the baths is from 95° to 98.6° F., and the salso-iodic water is generally employed, although salso-iodic water mixed with the mother water can also be used. The duration of the baths is from fifteen to sixty minutes, and after the bath the patient goes to bed and rests. It is recommended that the cure be repeated again during the year, and followed up for two or three years. An after-cure in the mountains is advised.

There is an inhalation hall where this method of treatment is pursued for various affections of the respiratory tract, such as bronchitis, pharyngitis, laryngitis, etc.; for chronic eye affections, such as conjunctivitis, iritis, and keratitis; and for certain skin diseases. The diseases for which the baths are recommended are chronic rheumatism and gout; various gynæcological affections, such as metritis, salpingitis, ovaritis, perimetritis, and sterility; anæmia; convalescence from protracted illness; infantile rachitis; neurasthenia; bone and joint tuberculosis; tertiary syphilis, and some forms of neuralgia and neuritis. Massage and Swedish gymnastics, electricity, and various forms of douches are also employed. The mud baths, which are given in conjunction with and apart from the baths, are used especially for rheumatoid arthritis. The mud obtained from the deposit of the tanks at the well (rich in salt, iodine, bromine, lithium, and petroleum), is applied to the affected parts as hot as can be borne, and is left on for about twenty minutes. It is then removed and generally followed by a bath of medicated water.

Besides the arrangements for baths in the "Grand Hotel," there are bathhouses (*stabilimenti*) where every precaution is taken as regards cleanliness, sanitation, and disinfection. All laundry linen is carefully disinfected and sterilized after being used.

Salsomaggiore can be reached from London in about thirty hours. In going from Milan to Florence one alights at Borgo San Domino, and takes a half-hour's ride in a branch train to Salsomaggiore.

For a charming description of the excursions about this spa, one is referred to "Salsomaggiore and Its Surroundings," by Lady Colin Campbell.

Edward O. Otis.

SALT LAKE CITY, UTAH.—This city and the great region of the Salt Lake basin deserve consideration as a health resort of no mean degree, particularly as a place of residence for the consumptive. This basin of a former great inland sea, a huge remnant of which is the existing Salt Lake, has an average elevation of 4,300 feet, and is bounded on the east by a range of mountains and on the west and south by a desert. It is, then, a plateau of moderate elevation fed by the pure air from the mountains and the desert, and possessing a "maritime" quality from the presence of such a large body of salt water as the great Salt Lake, which covers an area of 2,360 square miles. Such an elevation, moreover, gives the peculiar climatic conditions incident to height above sea-level. The air is pure, cool, and dry; the sensible temperature is not oppressive, on account of the dryness of the atmosphere; the rainfall is small; high winds are absent, and the sunshine is abundant. Further, the softness of the air is a striking feature, very evident to one who first sets foot in this region, and giving a delightful sense of restfulness. The principal place of importance and resort is Salt Lake City, latitude 40° 45′ N., longitude 111° 50′ W., containing 53,531 inhabitants, and located 4,348 feet above sea-level. The city occupies an extensive area, is well built and attractive, with wide and well-shaded streets, and possesses an efficient sanitary system and excellent water works. The accommodations are good, there being several modern hotels. The soil is adobe. Irrigation is used, the water being carried in ditches along the sides of the streets.

"Salt Lake City," says Solly ("Medical Climatology"), "is one of the three Western cities of good size possible for the residence of those to whom a sunny climate is necessary and who desire to settle in an active business centre. The other two large cities are Denver, which shares with Salt Lake City the advantage of altitude, and Los Angeles, which is equally sunny but exposed to ocean influence."

At the Salt Lake Hot Springs Sanatorium sulphur and salt baths can be taken; and on the border of the lake, thirteen miles distant, reached by train, is the Salt Air Bathing Resort, well appointed, with nearly one thousand bathrooms. Here one can enjoy the strange experience of bathing in water containing nineteen per cent. of salt, and so buoyant that one can float in it with a

considerable portion of his body out of water. The lake is very shallow for a long distance from the shore, and it is a laborious task to wade to deep water. The temperature of the water is comparatively high.

Standart ("The Climate of the Great Salt Lake Basin," Transactions of the American Climatological Association, vol. vii., 1890) calls attention to the fact of the longevity of the inhabitants of this region, which he attributes to the influence of the climate; and he narrates the incident of a gathering of old folks representing three per cent. of the adult population of the great Salt Lake basin, where there were a thousand people who had attained the age of seventy years or over.

Good hunting and fishing are to be had in the mountains and streams round about, and there are many short excursions to mountain resorts lying on the banks of attractive lakes. A few miles from the city, reached by an electric road, is Fort Douglas, a military post, from which is an extensive view.

From the climatic table it will be seen that the temperature partakes of the characteristics of that of elevated regions. The diurnal range is large and it does not appear to be very cold in winter or excessively hot in summer. According to Solly, the average number of days above 90° F. is 30, and below 32°, 109. The average annual range as given by Standart is 93.5°. The average relative humidity is very low and the rainfall small, indicating a very dry atmosphere. The prevailing wind is from the northwest, and the average hourly velocity 5.3 miles for the year. The number of clear and fair days is 277, which means a large amount of sunshine.

Edward O. Otis.

SALT LAKE HOT SPRINGS.—Salt Lake County, Utah.

Post-Office.—Salt Lake City. Hotel and sanatorium. The springs are located in the northern outskirts of Salt Lake City. The water is conducted from thence to a sanatorium and bathing establishment in the heart of the city. This fine, commodious structure has a floor space of about fifty thousand square feet. The water, at a temperature of 112° F., is drawn from the springs through an eight-inch pipe, with a flow of about four hundred gallons per minute, and enters the establishment at a temperature of 110° F. Besides large separate swimming pools for men and women, there are twelve private pools and a number of elegant private bathrooms. A hotel and gymnasium are also connected with the enterprise in the same building. According to an analysis by H. Hirsching, analytical chemist, in 1893, the water contains rather more than three hundred grains per United States gallon of solid ingredients. This is largely composed of chloride of sodium (about two hundred grains), but the water also contains appreciable quantities of the chlorides of calcium and magnesium, the sulphates of sodium, calcium, and magnesium, the carbonate of sodium, and small amounts of several other compounds. It is also charged with sulphureted hydrogen in small quantities, as well as a considerable percentage of carbonic acid gas. The water is useful in the various ailments for which hot saline sulphur baths are prescribed.

James K. Crook.

SALTS, DISSOCIATION OR IONIZATION OF.—See The Appendix.

SALT SULPHUR SPRINGS.—Monroe County, West Virginia.

Post-Office.—Salt Sulphur Springs. Hotels.

Access.—Viâ Chesapeake and Ohio Railroad to Fort Spring, where carriages meet visitors for springs.

These well-known springs have been under the present management for many years, and have become justly esteemed as one of the most charming and homelike of the Virginia Mountain resorts. The location is two thousand feet above the sea level, and is surrounded by the usual beautiful scenery and wholesome climate of the Alleghanies. The hotel buildings are chiefly of brick and limestone. The largest, built of stone, contains seventy-two pleasant rooms, and has wide piazzas, two hundred feet long, overlooking the lawn. The parlor and great ball-room are also in this building. There are accommodations for three hundred guests. The springs are three in number, known as the "Old" or "Sweet" Spring, discovered in 1802; the "Salt Sulphur," discovered in 1805; and the "Iodine" Spring, known since 1821. We present analyses of the Old Spring and the Iodine Spring, the former by W. B. Rogers, the latter by D. Stewart.

One United States Gallon Contains:

Solids.	Old Spring. Grains.	Iodine Spring. Grains.
Sodium carbonate	....	10.80
Calcium carbonate	10.26	33.00
Magnesium carbonate	3.31	7.00
Potassium carbonate	....	2.33
Sodium sulphate	22.36	24.00
Calcium sulphate	84.90	68.00
Magnesium sulphate	18.21	20.00
Organic matter	9.24	....
Earthy phosphates, sodium chloride, calcium chloride, magnesium chloride, iron peroxide, alumina, silica, iodine, and bromine	2.00	7.35
Total	150.28	172.48
Gases.	**Cubic inches.**	**Cubic inches.**
Carbonic acid	13.28	34.56
Sulphureted hydrogen	3.44	19.12

These are valuable waters, containing as they do a large proportion of active mineral ingredients. Both contain a sufficient quantity of the purging sulphate to render them cathartic in their effects. The iodine spring contains a fair proportion of iron and appreciable quantities of iodine and bromine, rare ingredients of sulphur waters. This water resembles those of Challes, in Savoy, and possesses alterative properties. It proves especially beneficial in scrofulous and syphilitic diseases. The waters of both of these springs are useful in abdominal engorgement, chronic constipation, chronic metallic poisoning, functional hepatic disorders, rheumatism, gout, and scaly skin diseases. Cases of bronchial troubles and early phthisis also do well at this resort.

James K. Crook.

SALUBROL—tetra-bromo-methylene-di-antipyrin—is prepared by the action of bromine on methyl antipyrin. It is without odor, and is used as an antiseptic dusting-powder in place of iodoform. It is said to be a good hæmostatic like antipyrin.

W. A. Bastedo.

SALUMIN, aluminum salicylate, $Al_2(C_6H_4OHCOO)_6 + 3H_2O$, is a reddish-white powder, insoluble in water and alcohol, and soluble in alkalies. It is employed as an astringent dusting-powder in catarrhal conditions of the upper air passages. It is known as "salumin (insoluble)." With ammonia it forms aluminum ammonio-salicylate, $Al_2(C_6H_4ONH_4COO)_2 + 2H_2O$, which is readily soluble in water and is used in the nose and throat as an astringent spray or gargle. This compound is called "salumin (soluble)."

W. A. Bastedo.

SALVATOR MINERAL SPRINGS.—Brown County, Wisconsin.

Post-Office.—Green Bay.

This spring is the source of the Salvator Mineral Water. It does not appear to be used as a resort. An analysis by Professor Delafontaine, of Chicago, shows the following mineral ingredients: One United States gallon contains (solids): Sodium chloride, gr. 1.60; sodium bicarbonate, gr. 1.30; calcium bicarbonate, gr. 20; magnesium bicarbonate, gr. 17.16; iron bicarbonate, gr. 1.30. Total, 41.80 grains.

This analysis shows an excellent alkaline, diuretic, and mild laxative water, with ferruginous properties. It is valuable in the treatment of acid dyspepsia, sluggishness of the portal circulation, Bright's disease, diabetes, and irritable states of the bladder and urinary passages. The water is entirely free from organic impurities, and is well adapted for table and club purposes. It has a large sale in different sections of the country. *James K. Crook.*

SAMBUCUS.—ELDER. "The flowers of *Sambucus Canadensis* L. (fam., *Caprifoliaceæ*)," U. S. P. (but likely to be dropped from the next edition). This plant is a medium-sized or small shrub, with smooth, upright, rather simple stems, which are soft and herbaceous in the upper part. Their woody ring is very narrow; their pith very large, and much used for holding small objects for microscopical section cutting; leaves opposite, petiolate, pinnate, large; leaflets ovate-acuminate, serrate, rarely pinnate; flowers small, in large, compound, five-branched, flat-topped cymes, regular, pentamerous; calyx minute; corolla cream colored, urn-shaped, with spreading lobes; stigmas three; ovary inferior, ripening to a purple-black, shining, spherical, juicy, berry-like drupe, containing three minute nutlets. The elder is a common plant in moist places over a large portion of this continent, and is represented by nearly related species in many other parts of the world.

The flowers should be gathered in full bloom, and dried without heat. They then form a cream colored or very pale yellow mass, which grows darker with time. They have a peculiar, rather agreeable odor, and a sweetish and slightly bitter taste. Their important constituent is volatile oil, with which occur resin, gum, wax, and sugar.

The use of our elder was unquestionably derived from that of the black elder (*S. nigra* L.) of Europe, which is almost exactly like it in sensible properties. The American has tufts of microscopic hairs in the forks of the branchlets of the inflorescence and in the sinuses of the calyx teeth, while the *S. nigra* has not. Elder is slightly aromatic, and when given in hot infusion is also diaphoretic. Its employment is confined almost entirely to household medication. The twenty-per-cent. infusion may be given *ad libitum*.

The flowers are the least active portion of the plant. The fruits of this and related species, though used in pastry and largely in wine-making, are laxative in the uncooked state, and have been seen to intoxicate fowls. The young buds are powerfully cathartic or even emetic, as is the bark of the root. The leaves have been used for fly poison. The bark of the stem is a useful diuretic and hydragogue cathartic, emetic in over-doses. (See also *Poisonous Plants.*) *Henry H. Rusby.*

SAN ANTONIO, TEXAS.—The southwestern portion of Texas is regarded as the especial health resort region of this State, and San Antonio, occupying a central position in this region, can be taken as illustrating its climatic characteristics. San Antonio (elevation 650 feet) is the chief city of this district, and is situated in Lat. 29° 27' North, about one hundred and thirty miles inland from the Gulf of Mexico. It has a population of over 50,000, composed of Mexicans, Germans, and Americans. The Mexican element presents many attractive and picturesque features, in the architecture, street life, and suggestions of bygone days in the old missions. The historic incidents connected with the life of the city also enhance the charm and fascination of the place; for there is the famous Fort Alamo, the Thermopylæ of Texas.

The country is undulating, with no mountains nearer than thirty or forty miles, and the soil of the city is adobe. There is a pure water supply, and a more or less effective sewerage system. There are a number of hotels, boarding-houses, and restaurants, but the accommodations for invalids are said to be doubtful. Probably the most satisfactory plan would be to keep house in one of the more eligible suburbs of the city. There are many opportunities for outdoor life, in horseback riding, driving, etc. The climate is a mild winter one but uncomfortably hot in summer, although the nights are comparatively cool.

Precipitation—								
Average in inches	2.03	1.42	2.85	.92	2.84	1.30	1.82	25.27
Wind—								
Prevailing direction	N.	S. E.	S. E.	S. E.	E., S. E.	N., S. E.	N.	S. E.
Average hourly velocity in miles	7.5	8.8	7.5	7.5	6.4	7.4	7.8	7.8
Weather—								
Average number of clear days	10.3	9.3	8.1	13.8	11	12.1	14.2	136.2
Average number of fair days	9.0	12.0	13.8	14.8	13	10.3	8.1	138.8
Average number clear and fair days	19.3	21.3	21.9	28.6	24	22.4	22.3	275.0
Average number of cloudy days	11.6	10.8	9.0	2.2	5	6.5	8.3	90.0

From the meteorological table we see that while the winters are mild, nearly as warm as the autumn at New York City, the diurnal variation is large; and also while the summer days are hot—many days above 90° F.—the nights, as has been said, are comparatively cool. The average annual rainfall for the eight years was 25.27 inches; and for twenty-one years, 30.6 inches (Solly, "Medical Climatology"). Occasional "northers" occur at San Antonio, but they do not last long. The average relative humidity is 65.5 per cent. for the year, which, considering the high temperature, means a moist atmosphere. The average number of cloudy days during the year is 90; and the average number of clear and fair days, 275.

Such a climate as this, while it is not an exceptionally excellent one in its various characteristics, yet affords an outdoor life in the winter in a mild and pure atmosphere. For the consumptive in good general condition, and with the disease not far advanced, and who, moreover, is willing and able to "rough it" more or less, this region can be recommended. It does not, however, in the writer's opinion, possess the advantages of Southern California or of many resorts in the southern pine belt, either in the matter of climate or in that of accommodations. Almost every resort has its enthusiasts, and the following quotation from an article upon southwestern Texas by Dr. T. K. Taylor in the Transactions of the American Climatological Association, 1888, may be said to have been written by one such. "For delicate children," Dr. Taylor says, "who require the invigorating influences of moderately cool weather and active outdoor life, that climate is all one could wish during the winter season, while the spring, with its multitude of flowers, its fragrant breezes, its genial sunlight, and its evenings with their soft sweet repose, give one a better idea of an earthly paradise than any place we have ever seen, or hope to see in this broad land."

San Antonio can be reached by three lines of railroad.

Edward O. Otis.

SANATORIA (for treatment of tuberculosis). See *Open-air Treatment, etc.*

SAN BERNABÉ SPRINGS.—Municipality of Dolores, Nuevo Leon, Mexico. These baths, known also as the *Topo Chico*, are situated 8 km. north of the city of Monterey, to which they are connected by a railroad. The water has a temperature of 105.8° F., and, according to an analysis by Gonzalez and Lambert, it contains the chlorides of sodium, calcium, and magnesium, the bicarbonates of calcium and sodium, sulphate of calcium, silicate of alumina, silicate of lime, and sulphuric acid. The gases escaping from the spring are composed of carbonic acid and nitrogen. A bathing establishment of considerable size has been constructed and is considerably resorted to, but as at most of the Mexican mineral spring resorts the accommodations are still very imperfect and in sad need of proper development. In Monterey these baths enjoy a high reputation in the treatment of rheumatism, diseases of the skin, certain nervous affections, and menstrual disorders. *N. J. Ponce de Léon.*

SAN BERNARDINO HOT SPRINGS.—San Bernardino County, California. These springs are fourteen miles from Arrowhead Hot Springs. They are picturesquely located at an elevation of sixteen hundred feet above the sea level. The springs vary in temperature from 100° to 175° F. The waters have acquired considerable reputation in the surrounding district. The following analysis was made by Prof. Oscar Loew: One United States gallon contains (solids): Sodium chloride, gr. 7.46; sodium sulphate, gr. 47.63; potassium sulphate, gr. 1.34; calcium carbonate, gr. 6.23; silica, gr. 11.95; magnesium, carbonate, and ferrous carbonate, traces. Total solids, 74.61 grains.

It will be observed that the waters are saline and calcic.

James K. Crook.

SANDAL WOOD, OIL OF.—(*Oleum Santali*, U. S. P., B. P., P. G.) A volatile oil distilled from the heart-wood of *Santalum album* L. (fam. *Santalaceæ*).

Sandal wood is the product of a small tree of the East Indies. It has been highly valued from the most ancient times for the manufacture of objects which retain the fine fragrance of the wood for a very long time, and for use as incense. The trunk is small and its product is still further limited by the uselessness of the outer or sap wood. This is removed, either by trimming or by leaving it exposed to the action of termites, which find it agreeable and nutritious, while the oleiferous heart wood is highly offensive to them. To discriminate between these two portions, the heart-wood is often known commercially as "pink" or "red" sandal wood. This custom leads, in turn, to some confusion between this and red saunders, which is also often called red sandal wood.

Sandal wood occurs in small billets of a brownish-yellow or reddish-yellow externally and of a more decidedly pinkish tinge internally. It is very hard and heavy, and of a tough and splintery fracture, and emits, especially when heated, the characteristic odor of the oil.

The tree, on account of its very extensive collection and the careless methods employed, was long ago placed under government protection and is now cultivated upon a great scale. The distillation of the oil has also been carried on under government supervision, with the express object of preventing adulteration. In spite, however, of all precautions, such great difficulties have been encountered in securing a pure article of native distillation that many firms prefer to incur the heavy expense of importing the wood and distilling it here or in Europe. The yield of oil from a wood of first quality is said to be about five per cent. The wood itself finds no employment in medicine.

The oil is thus described in the Pharmacopœia:

A pale yellowish or yellow, somewhat thickish liquid, having a peculiar, strongly aromatic odor, and a pungent spicy taste.

Specific gravity: 0.970 to 0.978 at 15° C. (59° F.).

It deviates polarized light to the left (distinction from *Australian Sandal wood oil* [specific gravity 0.953] and *West Indian* [specific gravity 0.965] *sandal wood oil*, which deviate polarized light to the right).

Readily soluble in alcohol, the solution being slightly acid to litmus paper.

If to 1 c.c. of the oil, at 20° C. (68° F.), there be added 10 c.c. of a mixture of three volumes of alcohol and one volume of water, a perfectly clear solution should be obtained (test for *cedarwood oil, castor oil*, and *other fatty oils*, etc.).

Oil of sandal wood belongs to that class of volatile oils commonly denominated "terebinthinate." Like copaiba, which it resembles in many respects, it is often called a balsam, though the term is very incorrect, neither benzoic nor cinnamic acid being contained. It is said to consist almost wholly of the alcohol $C_{15}H_{26}O$ and the aldehyde $C_{15}H_{24}O$.

Action and Use.—The absorption and elimination of this oil are rapid, the latter occurring chiefly through the kidneys and the lungs, so that it might be classed as a stimulating and disinfectant diuretic and expectorant, with some astringent properties also. Its administration is frequently followed by discomfort in the stomach and dryness of the throat, and occasionally by vomiting and colic.

Disagreeable eructations and its taste are complained of by some patients, but on the whole it is less unpleasant than copaiba. Its elimination by the kidneys, which is sometimes accompanied by a feeling of tension there, changes the odor of the urine, and causes it to become cloudy with acid, in the same way as copaiba does: alcohol, by clearing up this cloudiness, which is caused by a resinous precipitate, will distinguish it from albumen. The sandal-wood products in the urine exert upon vesical, and especially gonorrheal, inflammations a beneficial action very similar to that exerted by copaiba or cubebs. Sandal-wood therefore is frequently employed as an elegant substitute for these drugs. Reports differ widely as to the relative value, as antiblennorrhagics, of copaiba and sandal-wood oils, but the preponderance of evidence appears to be in favor of the former. Sandal-wood oil is especially serviceable in recent acute cases, with considerable discharge.

The oil is frequently given dropped upon sugar or shaken up with mucilage, but is far more largely taken enclosed in gelatin capsules, either pure or mixed with copaiba or cubebs. The dose is five to twenty minims four or five times a day, and its administration should be continued for a week or so after the symptoms have disappeared.

Allied Products.—Eight or nine species of *Santalum* are known, all natives of the East Indies. Various attempts have been made to utilize the products of several of these species, as well as somewhat similar products, though not of this genus, from the West Indies and South America; but none of them possesses the fine odor or other characteristics of the genuine, and it is doubtful if they now find their way into commerce.

Henry H. Rusby.

SANDARAC.—*Sandaraca. Resina Sandaraca.* A resin obtained in northern Africa from *Callitris quadrivalvis* Vent. (*Thuja articulata* Shaw.—Fam. *Pinaceæ* or *Coniferæ*), a small evergreen tree not distantly related to the cypress. The resin exudes spontaneously from the trunk and branches, and dries in tears resembling in form short, broad, blunt, simple or compound icicles, and rarely exceeding or even reaching an inch in length. They are dull on the surface and covered by a whitish powder produced by attrition, of a glassy fracture and transparent within. Occasionally insects are found embedded in them. Upon being chewed, the tears crumble to a fine powder which refuses to become plastic, whereas mastiche, which also occurs in small yellowish, though rounded tears, readily softens into a plastic mass. Powdered sandarac, which is non-adhesive and white, with a pleasant resinous odor and a resinous and bitter taste, is called "pounce," and was formerly used to rub over the surface of paper where an erasure had been made, to prevent the ink from running when it was written over again. Either alcohol or ether will dissolve sandarac completely, while turpentine, chloroform, or carbon bisulphide only partly dissolves it.

The volatile oil of sandarac exists in very small amount, as does the unstudied bitter principle. The resin consists almost wholly of sandaracolic and callitrolic acids, about ten per cent. of the latter and between eighty and ninety per cent. of the former. Sandarac is not used at present in medicine. *Henry H. Rusby.*

SAN DIEGO AND LITTORAL CALIFORNIA.—In a consideration of littoral California we select San Diego because there are few places in the United States with a more complete climatic record; it has an uninterrupted temperature and rainfall record extending back for over half a century. This station was also among the first to be equipped with self-recording apparatus, and it has a continuous automatic record of temperature, rainfall, wind velocity, wind direction, and sunshine for each moment of time, thus giving data that are absolutely reliable. It is on account of my familiarity with the excellent records of this station that San Diego and Coronado are selected as the type in this paper, but the statements and deductions apply almost equally to the coast of Southern California.

We must study a wide expanse of country when we are considering the climatic peculiarities of the coast of this region, as the coast has a marked influence on the interior, and it in its turn markedly influences the coast; indeed, further than this, the vast Californian coast line presents three distinct climates, while on the great inland plain there is a fourth type of climate. To quote from my recent paper before the American Climatological Association (*Philadelphia Medical Journal*, October 11th and 18th, 1902), we shall barely mention the northern climatic belt, the centre of which is at the junction of the mountain chains near the northern border of California, and which embraces also the country known as Oregon, Washington, British Columbia, and the coast of Alaska and its islands. The central climatic subdivision extends from a point below this northern junction of the mountains to Point Conception on the coast. It is about here that the mountain chains, by their junction, establish a transverse line of separation, thus warranting us in describing a Northern and a Southern California, each with its distinct topography and its very distinct climatic conditions.

Fig. 1141.—Map in Relief of the Topography of California. A comparison of this map with the temperature and rainfall charts of the State, will show how this topography exerts an influence upon the climate of California. (From California Section, Annual Summary, 1900, of Climate and Crop Service of the Weather Bureau, By Alexander G. McAdie.)

Southern California, then, embraces, so far as a study of its climate is concerned, all that part of the State which lies below the transverse high mountains about Point Conception. It is with this strip of coast that we are alone concerned, from Point Conception to Coronado.

At Point Conception the coast line changes its general direction and runs nearly east, the mountains run eastward for a sufficient distance to protect the country from the north; but afterward they again turn south, thus once more protecting the coast from the desert, which is east of it.

The arrangement of the mountains and the trend of the coast are the keynote of the delightful climate of littoral California. The Alaskan current is separated from the land by the curve in the coast, and the Kurosiwo, or great Japan current, leaves the land at Point Conception and never returns. This separation is materially assisted by the coast islands which are located between San Miguel and the Coronado Islands and by those lying farther south, off the coast of lower California, the Baja California of the Mexicans.

To understand fully the factors that make the coast climate so pleasant we must consider the formation of the country contiguous to the coast. The general topography of California, more marked in the north, is a double mountain range parallel with the long axis of the State, with large fertile plains and valleys, with enormous watersheds included between them. In the south this general plan is somewhat modified. While the eastern range, the Sierras, serve as a wall to protect the country from the great arid desert plains, the coast range is much lower and no longer shuts out the sea; indeed, at some points the whole interior is quite open to the sea, so that the Santa Clara valley, the valley of the San Buenaventura River, the San Fernando Valley, the San Gabriel Valley, the valley of the Santa Ana River, the San Jacinto River, the Los Angeles River and plains, and the San Diego country constitute a great open coast land backed and protected by the high Sierras. A newcomer from the eastern country will be somewhat surprised at the designation of plains as applied to these valleys, and he will also be somewhat disappointed at their size. The first effect will probably be one of smallness and narrowness as compared with the homeland valleys, but their size is greatly increased by the billy uplands into which they insensibly merge. This is most noticeable in the great upland plain of San Jacinto, south toward Coronado and San Diego.

As Lindley and Widney say: "The Sierra, which north of the Mojave Desert makes a great curve westward around the sound end of the San Joaquin plain of the central belt, turns southward again opposite Santa Barbara and Ventura counties, and doubling back upon its course walls in the west end of the desert, then turning directly eastward, separates the desert from the Los Angeles and San Bernardino plains. Turning southward again, it stands as a wall between the Colorado desert and that portion of Southern California lying west of its base."

The range varies in height from five thousand to seven thousand feet.

Unlike the northern and central portions of the chain, the range breaks down in the south at several points into low passes between the coast and the interior. "The pass, by which the Central Pacific crosses the Sierra, is 7,017 feet in elevation. Yet the Soledad Pass, by which the Southern Pacific crosses the Sierra in Southern California, is only 2,822 feet. The Cajon Pass, by which the Santa Fé enters, is of about the same height. There are numerous other comparatively low passes through the Sierras at the west end of the Mojave Desert, leading toward the sea in Ventura and Santa Barbara counties, and also through the range south of San Gorgonio. These passes through the Southern Sierra have a marked influence not only upon the climate of the coast portion of Southern California but also upon that of the deserts lying at the base of the Sierra."

The accompanying map in relief, prepared by Alexander G. McAdie for the California Section of the Climate and Crop Service of the Weather Bureau, 1901, if compared with the statements made above and with the temperature and rainfall charts of the State, will afford a graphic illustration of the influence of the diversified topography of California upon its climate.

*As I have said elsewhere, a great deal that is misleading has been written about the climate of Southern California. Its charms have been exaggerated and its drawbacks have either been passed over in silence or have been painted in glowing and attractive colors. The simple truth is quite good enough. It is a fact that in California of the South is to be found the best yearly climate in the world. Other localities have as good or perhaps a better climate than ours at their best, but certainly none of them has been blessed with this happy condition the year round as we have been on the coast.

A striking peculiarity, and one leading to much confusion, is the great diversity of climate in this country and the different climatic conditions which may be encountered in even a single day's journey.

At the lower stations the various climates have the

* Also 21st, 1883; 7th, 1894.

peculiar charm of California's equability—an equability that is most remarkable. In San Diego, from 1875 to 1901—a total of 9,861 days, there were 9,545 days on which the temperature did not rise above 80° nor fall below 40° F.

Newcomers are often bewildered by the many varieties of climate, and make statements to far-away friends that add chaos to confusion in the minds of Eastern people. One traveller reports California all sunshine and flowers, another all fog and cold. Some complain of the dry desert winds with their exciting electrical conditions, while others dwell upon the excessive humidity; when the probable truth is that the critic has not selected the proper environment and has passed by what he is seeking, which is no doubt within a few short miles of the spot where he may happen to be.

There is little seasonal change in the extreme southern part of the State. I am accustomed to say to inquirers that our winters resemble September and October in the middle Atlantic States and that our summers are like April and May in the same region. The dividing line between summer and winter is more imaginary than real.

The greatest change in the temperature occurs at night, being more marked in the interior than on the coast. I wish to call particular attention to the apparent difference between sunshine and shade and midday and midnight. This change is more a subjective sensation than a reality and is true of all semitropical localities. It is less marked in California than in Italy, but it always appeals strongly to the newcomer, who is surprised at the immediate sense of chill which he experiences when he enters the shade from the direct rays of the sun. As the night advances the temperature decreases, and while this change may not cause the mercury to fall many degrees, still it is very noticeable to the individual. This is less marked on the coast in summer and more so at all seasons of the year in the interior. The days are characterized by a constant sea breeze which blows with astonishing regularity; it is rarely too warm for comfort, as is often the case at Cape May, Atlantic City, Long Branch, or other popular Atlantic coast resorts. Several times during the year the so-called desert spells occur. This is when the land breeze or wind from the desert, many miles in the interior, gain ascendency over the prevailing western or ocean breeze. During this time the thermometer is apt to show a very high registration. Under these conditions I have seen it at San Diego register 98° F., but for only a few hours. These hot winds may last two or three days. The nights at this time are always cool and pleasant. These are the only evenings on the coast upon which one may sit out of doors with comfort and without chill.

Rainfall.—Each rainy season has its own peculiarities. It may be one of constantly recurring rains, or the rains may be light, interspersed with long periods of almost constant sunshine. Hence the records do not help us much to predict for future rain probabilities. It is not altogether unusual to have a very deficient rainfall. Thus, for example, San Diego, with a normal rainfall of about ten inches, has had in the last fifty-two years a minimum of 3.02 and a maximum of 27.59 inches.

Fog.—The coast fog, about which so much has been written, is most frequent during the months of April, May, and June. The fog appears about nightfall and disappears after sunrise; by nine o'clock the coast is usually free from fog. Some days during the months mentioned are foggy until half-past twelve or one o'clock. The records show that Coronado and San Diego have nearly three hundred days a year that are recorded as clear. The East has its cloudy weather in the winter; we have ours in the summer. Again, the maximum sunshine in Southern California is in the winter time, in the East during the summer.

MONTHLY RELATIVE HUMIDITY (PER CENT.) FOR A PERIOD OF THIRTY-ONE YEARS. RECORD BEGAN JANUARY 1ST, 1871.

	January.	February.	March.	April.	May.	June.	July.	August.	September.	October.	November.	December.
A.M.	72.9	77.6	81.2	82.2	82.5	84.3	85.9	85.4	84.7	81.3	72.4	75.0

Humidity.—Carpenter, the weather observer at San Diego, very aptly remarks that the oft-repeated statement, "driest marine climate," as applied to San Diego, is not sufficiently explained. Why is our humidity so much less than that of Seattle or Santa Barbara, for example? We find the explanation in these two circumstances; distance from the average storm track and nearness to the desert. Our humidity is as constant as our temperature, and plays a very important part in the excellence of the climate. So long as the temperature is between 55° and 65° F. (and that is about half the time), the humidity is always seventy per cent. Whenever the temperature increases, the amount of moisture naturally decreases, for the capacity of the air for holding the vapor is correspondingly decreased. Strange as it may seem, this is also true of the other extreme in temperature in this desert-sea climate; the winter cold is a dry cold, just as the summer heat is a dry heat.

A general knowledge of the climate of Southern California is obtained, says Solly, if we remember that the coast is cool and moist and the interior hot and dry; "it should be thoroughly understood by the Eastern visitor, in his search for health, that if he seeks more days of sunshine and opportunities for outdoor life, with a more equable temperature and an average humidity a little greater than that of New York or Boston, he can find what he wants at Santa Barbara or San Diego" (or Coronado). The same writer adds that to those to whom the presence of dry air is not important, California offers many attractions from Monterey to Coronado, and he concludes that it can be said that the coast climate is delightful, equable, and healthful.

Wind.—The wind movement is moderate, the yearly average is about 5.6 miles an hour. During the day the wind blows from nearly every point of the compass. The coast clearly shows the phenomenon of land and sea breezes, for the air, warmed by the earth, rises and creates a draught from the cooler sea, so that by about nine o'clock the breeze commences and increases until about 2 P.M., at which hour it blows at about the average rate of twelve miles an hour. At or about sunset this westerly wind dies down, the land cools, and a current of air starts toward the warmer sea. *William A. Edwards.*

SAN DIEGO DE LOS BAÑOS.—The best-known and most-employed mineral springs of those abounding in Cuba are the springs situated in the town called San Diego de los Baños, in Pinar del Rio. This town is situated about ninety miles from the city of Havana and may be reached by railroad as far as Paso Real and thence by stages or carriages. This part of Cuba is not only one of the most picturesque on the island, but it is also the best known, for San Diego is surrounded by those tobacco estates which have made the name of Cuba so well known wherever the luxury of a good cigar is appreciated.

These springs have been known for over a century, tradition attributing their original discovery to an old negro, a runaway slave, who is said to have been cured of leprosy by bathing in these waters. During the last thirty years these springs have not enjoyed the vogue that they formerly had, but this has been due to the difficulties of transportation and to the disturbed political condition of the country. However, now that the island is at peace, there is no doubt that the springs of San Diego will develop with the rest of the country.

The population of San Diego during the closed season is about 1,500, and this increases to five times that number during the bathing period, which begins in the latter part of January and includes February and March. The temperature the year round fluctuates between 80° and 87° F. The River San Diego during the rainy season becomes a raging torrent, and in 1899 it swept away all the buildings connected with the bathing establishment.

Only three of the springs have thus far been utilized. One of these issues from the river-bed itself, the others are situated on the shore; the waters of the first have been isolated from the general body of the stream by means of dams and retaining walls.

The establishment at San Diego consists of three pools or tanks and twelve tubs with their corresponding buildings, such as dressing and waiting rooms for all the departments.

The Templado Spring.—This bath has, for women, a department measuring 8 metres long by 7 wide; it is lined with vitrified tiles and is furnished with a wooden floor. The tank on the men's side is larger and more comfortable; the pool has a depth of more than three feet and its temperature is constantly at 34° C. This is the largest and most important of the springs; it yields 860,000 litres in the twenty-four hours.

The next most important spring, from the point of view of the volume it yields and the curative properties of its water, is the *Tigre*. This pool is 8 metres in diameter, enclosed on all sides, thus allowing a concentration over the water of vapor and sulphurous acid gas. This has led people to believe that it is the stronger of the two baths, but experiments have proved that the two springs are really one and that the Tigre and the Templado are merely different outlets of the same spring. Years ago this pool was reserved for colored people.

The third spring, called the *Paila*, is certainly the most picturesque. The water issuing from the bed of the river itself reaches it after an admixture of fresh water from the river and the water from about thirty smaller springs. All these waters together collect into a pool about two hundred feet wide and in some places sixteen feet deep, thus allowing the bathers who are so inclined to add the exercise of swimming to the other attractions. From the above it can easily be understood that the temperature and strength of the water of this pool are subject to constant changes. In connection with this pool there is a dressing and waiting room 20 metres long by 6 metres wide, from which steps lead down to the baths.

The *chemical analysis* of these waters was made twenty-eight years ago by the brothers Aenlle. Since that time, however, there have been several earthquakes of more or less severity and the composition of the waters may have varied to a slight extent.

According to the analysis above mentioned one litre of the Templado or Tigre has the following composition: Hydrosulphuric acid, 0.152; sulphate of lime, 0.136; sulphide of calcium, 0.838; chloride of sodium, 0.032; bicarbonate of magnesium, 0.080; alumina, 0.006. Total solids 1.244 gram. Carbonic acid gas is present in slight amount.

Silicic acid, carbonate of iron, nitrogen, oxygen, organic matter, undetermined.

Density, 1.014.

The color of this water is bluish at the spring and in the bath, outside it is colorless and as clear as drinking-water. The odor is characteristic of hydrosulphuric acid. The taste is sulphurous and the temperature is 34° C. (93.2° F.).

The Templado spring yields 860,000 litres of water in the twenty-four hours, while the Tigre yields 240,000 during the same time.

The analysis of the Paila spring gives the following result per litre: Sulphide of calcium, 0.218; sulphate of lime, 0.850; sodium chloride, 0.022; bicarbonate of magnesia, 0.120; alumina, 10 012. Total solids, 1.222 gm. Carbonic acid gas is present in a small amount.

Undetermined quantities: Sulphurous acid, silica, carbonate of iron, nitrogen, and organic matter.

The temperature of this spring varies from 22° to 25° C. According to Dr. Cabarrony, medical director of the establishment, the physiological effects of these waters are as follows: "They stimulate or deaden the appetite according to individual idiosyncrasy, and act as a stimulant on the circulatory and nervous systems. The rapidity of the pulse is increased. They may cause headache, insomnia, and a general stimulating of the capillary circulation. Sometimes tachycardia of a transient nature is observed.

"On the respiratory apparatus the effect of the water is frequently at first to cause coryza, pharyngitis, and bronchitis, which rapidly subside. Upon the kidneys it seems to act as a stimulant, causing increased secretion of urine and a noticeably greater elimination of uric acid. It also stimulates the sexual organs. Like all waters of this nature it also stimulates the functions of the skin."

According to the same authority the use of these waters is beneficial in such diatheses as the herpetic, rheumatic, and scrofulous, especially so in the first two, in which the effect seems to be immediate. It is also of service in syphilitic affections.

By far the largest number of patients who visit San Diego are sufferers from rheumatism, and extraordinary results in the treatment of this disease are said to be obtained by the use of these warm baths. They are of great benefit in all the visceral manifestations of the disease, in endocarditis, pericarditis, cerebral rheumatism, sciatica, neuritis, chorea, etc.

N. J. Ponce de Léon.

SAN FRANCISCO, CALIFORNIA.—The metropolis of the Pacific coast is situated upon the northern end of a peninsula, in latitude 37° 47' N. and longitude 122° 23' W. On the west, north, and east the city is surrounded by water. The Pacific Ocean washes the extreme western side of the city, a fine ocean driveway extending from the Cliff House to the overflow basin of Lake Merced. The Golden Gate (the name was applied by General Fremont while looking westward from what is now Oakland) is a water passage about a mile wide, connecting the Pacific Ocean and the Bay of San Francisco. The harbor is generally conceded to be one of the beautiful harbors of the world. The bay extends twenty-five miles north and forty miles south of the city. There are numerous islands in the bay, and on some of these, as, for example, Belvedere, business men of San Francisco have elaborate summer homes. The coves and lagoons are favorite anchorages for house boats or arks.

The city of San Francisco has many hills, among the more prominent of which are Telegraph Hill, Russian Hill, Nob Hill, and Rincon Hill. In 1850 the city was nothing more than sand dunes and sand hills; and even at the present time in the extreme western end of the city these shifting sand stretches can still be seen. The climate is peculiar; the reasons for which are to follow. The winds are somewhat too rigorous for invalids, but for healthy people they are very stimulating. Overcoats and heavy wraps are worn in midsummer as well as in winter. Indeed heavy underclothing can be comfortably worn every day in the year.

age velocity of twenty miles per hour. From May until September little if any rain falls, and no matter how overcast or threatening the morning may seem, within a few hours, generally before ten o'clock, there is bright sunshine. Great banks of low fog roll in through the Golden Gate on summer afternoons. There is probably no other part of the Pacific coast where such a strange mixture of marine and continental climates can be found. The topography is so remarkable that marked climatic contrasts occur within short distances. Thus at any of the ferries one may see sealskin coats and white duck garments together, because the traveller needs warm garments crossing the bay and in the city; while at Sausalito, San Rafael, San Mateo, or any of the suburbs, summer clothing is necessary. It must be remembered that the great Sacramento-San Joaquin Valley, a basin five hundred miles in a north-and-south direction and fifty miles wide, lies due east of San Francisco, and that on summer afternoons there is often a difference of 55° F. in temperature in a distance of fifty miles.

Owing to the proximity of the Pacific the temperature in San Francisco is very equable. A native of San Francisco cannot say off-hand which is the warmest and which the coldest month of the year; because the range is very small. The mean annual temperature determined from the records of thirty-two years is 56.1° F. May and November have practically the same temperature. The mean temperature for July is 58.7° and for December 51.5° F. The highest temperature ever recorded was 100° and the lowest 29° F. Abnormally warm and cold periods last as a rule about three days. The mean for the three consecutive warmest days at San Francisco has never exceeded 76.3°; and of the three consecutive coldest days the mean temperature was not below 40.7°. The mean daily range of temperature is 12°.

The sunshine is less in San Francisco than at localities a few miles away, which is due to the prevalence of fog. The city is considered a very healthy one because it is washed by water and well ventilated by the strong winds.

CLIMATE OF SAN FRANCISCO, CAL. LATITUDE, 37° 47'; LONGITUDE, 122° 23' W. PERIOD OF OBSERVATION THIRTEEN YEARS, 1891–1902.

* The lowest official temperature recorded in San Francisco was 29° on January 15th, 1888, preceding above record.
+ The rainfall has been recorded with great detail for fifty-three years.

The climate is a moist one, the mean relative humidity exceeding eighty per cent. During the morning hours, especially in summer, the sidewalks look as if a light shower had prevailed, but in reality the dampness is due to condensation of fog. The prevailing direction of the wind is from the northwest, and on summer afternoons the wind blows with great regularity. Between the hours of 1 and 7 P.M. the wind is from the west, with an aver-

It is worth noting that children escape the disorders incident to hot weather in Eastern cities. Women and children have as a rule ruddy complexions, bright eyes, and a good carriage. Natives of San Francisco are in general large and well-formed. The climate is, however, too moist for those affected with renal, rheumatic, and pulmonary troubles. The summer climate is bracing and acts as a tonic in cases requiring such treatment.

The residents of San Francisco go inland during May, June, and July to get warm; while strangely enough country people come to the city to get cool at this time.

The city is supplied with water by the Spring Valley Water Company, and notwithstanding the long period of dry weather each year there has never been any water famine. Nor has there ever been any epidemic traceable to the character of water supplied. The temperature is a little too cool for ocean bathing, but there are large bath-houses at the beach and in the city where salt-water bathing can be had every day in the year. Many of the clubs have large swimming tanks for the use of members.

The average rainfall is about 23 inches, and this falls chiefly from November to March. In the past fifty years there was one January when rain fell on twenty-four days; the average number of rainy days in a midwinter (or so-called rainy season) month is about ten. Physicians sending patients to the Pacific coast should remember that marked differences in temperature, humidity, air movement, and sunshine occur within short distances. Near the Bay of San Francisco this peculiarity of climate is particularly noticeable. Within one hour's ride by boat or rail, from San Francisco, there is often a difference of twenty degrees in temperature at the same moment of time and equally great differences in other climatic features.

San Rafael offers a pleasant shelter from the winds of the coast, while the cities of the Santa Clara valley have just enough of the sea breeze to be delightful summer abodes. Or one can, by going to Mount Tamalpais (elevation 2,500 feet), rise entirely above the fog belt and bask in sunshine with temperatures ranging from 80° to 90° F., while at sea level, under the fog, the temperatures are from 55° to 60° F. *Alexander McAdie.*

SANITARY INSPECTION. See *House Sanitation.*

SANOFORM, di-iodo-methyl salicylate, $C_6H_2.I_2.OH.COOCH_3$, prepared by the action of iodine on oil of wintergreen, forms a colorless, odorless, and tasteless crystalline powder. It is insoluble in water or glycerin, and soluble in ether, chloroform, benzol, carbon disulphide, and petrolatum, and in ten parts of hot alcohol and two hundred parts of cold alcohol. Langaard states that it is non-toxic, has no harmful effect on the skin, and is not decomposed by exposure to air, light, or a heat of 200° C. (392° F.). It contains 62.7 per cent. of iodine, and is a substitute for iodoform. Its stability makes it suitable for antiseptic dressings, as they can be sterilized by heat. It is very absorbent, quickly drying up a wound, but forming with the secretions a pellicle which may retain the subsequent secretions and must therefore be soon removed. It is employed in the form of a dusting-powder, ten-per-cent. ointment, or collodion. Radziejewski and Jacobsohn recommend it in ophthalmic surgery.

W. A. Bastedo.

SAN REMO, ITALY.—This is an Italian town of about 18,000 inhabitants, seven and a half miles east of Bordighera and eighty-four miles west from Genoa. Express trains from Paris run direct to San Remo viâ Marseilles in about twenty-four hours. It is one of the most frequented resorts of the Italian Riviera, and lies upon a small bay formed by Capo Verde and Capo Nero. In the rear are a series of hills and mountain ranges, affording protection from the winds of the north and conducing to the warmth and equability of the climate.

The original town is old and quaint, with narrow, steep streets and picturesque architecture. To the east and west is the new town, where are situated the hotels and villas for the winter residents. The English and Americans frequent the west end, and the Germans the east; it was here that the late Emperor Frederick III. of Germany spent the last winter of his life at the Villa Zirio.

In both the east and the west portions of the town are attractive and extensive promenades along the water, shaded by palms, eucalyptus, and pepper trees, that to the west called the Corso dell' Imperatrice, and that to the east the Corso Federico. These promenades afford

FIG. 4142.—Shore Drive and Promenade at San Remo.

about the only level walks, for, immediately on leaving the sea, the ascent of the hills begins, so that an invalid is restricted to a limited space about the seaside, unless he rides or is strong enough to walk up hill.

The vegetation is varied and luxuriant and of a tropical and semitropical nature—here flourish the olive, lemon, fig, and a great variety of flowers and plants. One is especially impressed with the beauty and abundance of the roses and geraniums. The excursions among the hills and valleys are many and varied and through most attractive scenery, with olive, lemon, and orange groves and a profusion of flowers and plants on every hand. The drinking-water is excellent, and the natural drainage must, from the situation of the town, be good. There are also well-built drains running from the new town into the sea or to the mouth of the mountain torrents which flow through the narrow valleys to the sea. The soil is of clay, which renders it somewhat damp after a severe rain. The accommodations are abundant and good, although, as at most of the other Riviera resorts, they are somewhat expensive. There are competent physicians and all the other requirements of a first class health resort.

The so-called winter season extends from November to April. The chief characteristics of the climate during this winter season are mildness, dryness, and sunshine, with a brilliant blue sky and sea. There is more or less wind, as throughout all the Riviera, and it is sometimes cold. The hills and mountains afford protection from the north wind, but the east and the southeast winds prevail. Occasionally the northeast wind blows in winter, as does also the Mistral. Dr. Hassall ("San Remo, Climatically and Medically Considered," London, 1883) concludes his discussion of the winds by saying that "San Remo, and indeed the whole of the western Riviera, must be regarded as windy. The winds, doubtless on some occasions, interfere with the comfort and movements of some invalids, and they constitute a drawback of what is otherwise an excellent climate; but," he wisely adds, "one must remember that the winds play a very important part, particularly in warm climates, in purifying the air, and exert also for the most part tonic effects on the system."

The accompanying meteorological table, compiled from data given by Hassall, will convey a fairly accurate idea of the various climatic data for the winter season. It will be seen that the average temperature is a high one, and varies but little from month to month, except in April, when it is appreciably higher. The average daily range is moderate, but in the shade and in the early morning and shortly after sunset the air by contrast is cold, and invalids must avoid either suddenly going from the sunshine into the shade or being out after sunset.

The relative humidity is the least—66.7 per cent.—at 3 P.M. The mean number of days on which rain falls is 30, and the mean rainfall 14.05 inches for the whole season. The days on which the sun shines are on an average 164 out of a possible 181, and the mean duration of the sunshine is 7 hours and 56 minutes. To the inhabitant of northern Europe or the northeastern portion of the United States such an amount of sunshine can hardly be appreciated until experienced. There are many winter resorts, however, in America which afford an equal or greater amount of sunshine, accompanied with a mild temperature. Such are found in Southern California, Arizona, New Mexico, Texas, and in various portions of the pine belt of the South.

The general effect of such a climate as that represented by San Remo is thus portrayed by Dr. Hassall (*loc. cit.*): "Owing to the mildness of the climate," he says, "there is less wear and tear and less strain. The several functions are performed in a more moderate and uniform manner. There being less expenditure of power and less waste, a smaller quantity of food is required, and the stomach has less work to do. The circulation, in particular the heart and its vessels, is exempt from the strains entailed by extremes of heat and cold, and which in themselves are often injurious and not unattended with danger." The action of the sun on the human body is very complex; the effects are not confined to the warmth derived from its calorific rays; the luminous and chemical rays all exert powerful effects. The sun acts as a stimulant to most of the bodily functions—to elimination, secretion, and absorption; it determines many chemical changes, and promotes sanguification and the coloration or bronzing of the skin."

With regard to the class of invalids likely to be more or less benefited by this climate, the following may be mentioned: those suffering from pulmonary tuberculosis in its inception or not far advanced, unaccompanied with fever; certain more advanced but very chronic cases, especially in persons past middle life, in regard to whom

FIG. 4163. San Remo as Seen from the Mediterranean.

the only hope is to prolong and make life comfortable; those suffering from chronic bronchitis, chronic laryngitis, emphysema, and asthma; cases of diabetes and Bright's disease; persons suffering from rheumatism and scrofula; the feeble and aged; convalescents from acute diseases or from an operation, and all that great army of persons who find existence in the cold changeable climate of the North a constant struggle. The plethoric and those who have a tendency to cerebral hyperæmia, those with atheromatous arteries, and those suffering from functional nervous disorders, such as neuralgia, insomnia, or hysteria, should not come here.

San Remo can now be easily and comfortably reached from America by steamer direct to Genoa from New York or Boston. Here, as in all health resorts, the selection of a residence and the manner of life to be pursued can be satisfactorily determined only by consulting a local physician, which should always be the first thing to be done by the invalid on arrival at any health resort.

Edward O. Otis.

SANTA BARBARA, CALIFORNIA.—Santa Barbara, a well-known health and pleasure resort of Southern California, a town of about 8,000 inhabitants, founded in 1782 by Franciscan friars from Mexico, under Father Junipera Serra, is situated in north latitude 34° 24′ 30.7″, and west longitude 119° 41′ 22″, on the shores of the Santa Barbara Channel, which body of water is separated from the main Pacific Ocean by the channel islands, Anacapa, Santa Cruz, Santa Rosa, and San Miguel, the average distance of these islands from the mainland being 30 miles. Santa Barbara is 110 miles northwest of Los Angeles and 373 miles southeast of San Francisco, from which points it is reached by the Southern Pacific Railroad and by the Pacific Coast line steamers. The time by rail from Los Angeles is about three and one-half hours, and from San Francisco about eleven hours by express. Santa Barbara lies at the foot of the Santa Ynez Mountains, which rise, on the north of the city, to an altitude of from 3,000 to 4,000 feet, upon an inclined plane having an area of about 3,000 acres and a maximum altitude of 260 feet. The inclined plane slopes in a southerly and westerly direction to the sea, at the rate of about 100 feet to the mile, thus insuring good drainage to the town. This inclined plane is bounded by the foothills of the Santa Ynez Mountains on the north, and on the south and southwest by a so-called "mesa," or tableland, about 400 feet high, which intervenes between the city and the channel, and on the southeast by the channel itself. The soil upon which the city rests is composed chiefly of clayey loam, and is generally very dry, owing to the difficulty with which rains penetrate beneath its surface.

Santa Barbara is noted for the elegance and refinement of its social life, whose leaders have migrated from older social centres, and is annually visited by thousands of travellers from all parts of the world. The facilities for amusement and recreation at Santa Barbara are numerous, embracing horseback riding over broad lowland roads, by the sea, or on mountain trails, pedestrian tours among the mountains, driving, polo, golf and tennis, for the cultivation of which sports special clubs exist. There are two city clubs and a country club, which generously extend many courtesies to visitors. The country clubhouse is delightfully situated by the sea in Montecito, a suburb of Santa Barbara, about three miles from the centre of the city.

There are numerous hotels and boarding-houses in Santa Barbara, offering accommodations commensurate with the means of all comers. The Hotel Potter, of immense proportions and fully equipped with every comfort and luxury, has been recently erected (1902) near the shore; and the Arlington, situated about a mile from the water front, affords suitable accommodations for those who do not wish to live in close proximity to the sea. There are numerous cottages and houses, furnished and unfurnished, which may be rented by those who desire to have private establishments of their own. A new bathhouse, located on the shore, at the Plaza del Mar, affords good facilities for bathing in both hot and cold sea water all the year round, and has dressing rooms for those bathers who prefer a plunge into the sea. During the summer the temperature of the sea water varies from 68° to 74° F., and it is rarely below 60° F. in the winter months. The Cottage Hospital, an institution for the treatment of all classes of medical and surgical cases, is situated at Oak Park, a quiet western suburb of the town. It is supported by voluntary contributions and has a training-school for nurses. The superintendent is a physician, but there is no regularly established corps of attendants, each patient being at liberty to be treated by his own physician. A well-known private sanitarium, Miradero, crowns the heights beyond the western end of the city, and is fully equipped with all modern appointments for the entertainment and the treatment of invalids and convalescents. The city is lighted by gas and electricity, and an electric street railway gives easy access to all parts of the town. Santa Barbara has three daily papers, a free public library, churches of the leading denominations, a chamber of commerce, and a good system of free schools, besides separate private schools for boys and girls and a manual training-school. The water supply of Santa Barbara is derived from the creeks in the mountain cañons and from artesian wells. The climate of Santa Barbara is characterized by remarkable mildness, notable uniformity of temperature, abundant sunshine, low relative humidity, and low average velocity of the wind, advantages which it owes to its low latitude, and its sheltered position, to the topography of the surrounding country and to the proximity of the sea. There is no governmental station at Santa Barbara for the study of climatic conditions, but competent and careful meteorologists have recorded their observations for the last thirty-two years, and the accompanying table embodies their results:

AVERAGES OF TEMPERATURE (DEGREES FAHR.) RAINFALL, RELATIVE HUMIDITY AND WIND MOVEMENT AT SANTA BARBARA, CAL., DURING THE PAST TWENTY-FIVE YEARS (ENDING 1902).

Month.	Average of highest temperature.	Average of lowest temperature.	Mean temperature.	Relative humidity. Per cent.	Average rainfall.	Average hourly movement of wind.
January	74.8	37.1	53.5	67	3.73	3.5
February	78.2	36.1	54.8	69	3.21	4.0

August	87.0	53.5	66.7	75	.00	4.0
September	88.2	50.5	66.0	75	.22	3.6
October	87.9	47.3	62.6	72	.73	3.5
November	84.0	43.2	60.0	66	1.54	3.1
December	77.1	38.6	55.7	65	3.63	3.5
Means	82.7	44.1	60.0	71	17.00	4.0

This table is borrowed from an article by C. M. Gidney, Esq., secretary of the Santa Barbara Chamber of Commerce, in the *Santa Barbara Daily Press*, June 15th, 1902; it was compiled by him chiefly from the published statistics of Dr. C. M. Richter, of San Francisco, and of Hugh D. Vail, Esq., of Santa Barbara. The summer days at Santa Barbara are warm but very rarely uncomfortably hot, and the nights are so cool that blankets are regularly required for the sleeper's protection in the early morning hours. High fogs prevail throughout the summer months, making their appearance at nightfall or sometimes much later, and clearing away between eight and twelve o'clock in the morning. From November to May fogs are very rare. The most disadvantageous feature of the summer climate is the dust, which is abundant, owing to the absence of rain from April to October or November. The dust is combated by sprinkling with fresh or salt water, and recently by sprinkling with crude oil, which is very effective. The winter days at Santa

Barbara are generally clear, calm, sunny, and moderately warm. There is no snow except rarely on the mountain-tops, and no frost severe enough to destroy lemons, roses, violets, or heliotrope. Rain falls, at intervals of days or weeks, from November until April, but the rainy season is really such in name only. In the writer's residence at Santa Barbara, which has extended over a period of seven years, he has not seen a single winter during which an invalid would have been confined to the house more than ten days by rain. If we add to this sum the number of winter or spring days rendered too inclement by high winds and dust, we may safely assert that the health-seeker could advantageously remain out-of-doors during the daylight hours on all but fifteen or twenty days of the entire year. Many people sleep out-of-doors at Santa Barbara all the year round. The average number of absolutely clear and sunny days may be computed at about 250, the fair days at 50, the cloudy ones at 50, and the rainy days at 15. The foothill region of Santa Barbara, north of the town, Mission Cañon, one of the gorges between the Santa Ynez Mountains, and Montecito, an eastern suburb, offer essentially the same favorable climatic conditions presented by Santa Barbara proper, with even purer air, lower humidity, higher temperature, less violent winds and more abundant sunshine.

Renal diseases, cardiac affections, and neurasthenia are all favorably affected by the climate of Santa Barbara, while convalescents after acute diseases, old people, and little children thrive under the influence of its balmy air and genial sun.

Asthmatic patients do not do well at Santa Barbara, in the writer's experience, unless it be in the foothill region or on the heights of Montecito. Patients with bronchitis or with pulmonary tuberculosis do fairly well in the winter, but are unfavorably affected by the dust and fogs of summer. Some cases of tuberculosis have been cured at Santa Barbara under the writer's observation, but the majority do better farther from the coast and at an elevation greater than that of Santa Barbara.

William H. Flint.

SANTA BARBARA HOT SPRINGS.—Santa Barbara County, California.

POST-OFFICE.—Santa Barbara. Hotel and cottages.

These famous hot sulphur and soda springs are situated in the beautiful Santa Ynez Mountains, six and a half miles northeast of Santa Barbara city. The location is 1,450 feet above the sea-level, and unites many advantages of climate and scenery. The resort suffered from unwarranted neglect for a time. The springs are twenty-two in number, and range in temperature from 99° to 122° F. Analyses have been made by Oscar Loew and Winslow Anderson. We present Anderson's analysis as more recent and more complete than that of Loew: One United States gallon contains: Sodium chloride, gr. 1.74; sodium carbonate, gr. 2.17; sodium sulphate, gr. 14.92; magnesium sulphate, gr. 7.75; calcium sulphate, gr. 6.03; aluminum sulphate, gr. 2.90; arsenic, silica, sulphuric acid, and organic matter, very small amounts. Total solids, 36.69 grains. Gases: Free carbonic acid gas, 19.14 cubic inches; sulphureted hydrogen, 9.16 cubic inches.

Loew's analysis shows a slightly greater proportion of solid ingredients. It will be observed that the waters resemble those of the Arkansas Hot Springs. They have been found useful in the treatment of rheumatism, gout, and other joint affections, Bright's disease, and bladder irritation. Excellent results have been observed from the use of the baths in syphilitic and scrofulous contaminations, glandular enlargements, and chronic skin diseases.

James K. Crook.

SANTA CATALINA ISLAND, CAL.—This very attractive insular resort, with a delightful climate both winter and summer, lies off the coast of Southern California about twenty-five miles distant. It is reached in three hours and a half from Los Angeles by railroad to San Pedro Harbor, and from thence by steamer. The island is twenty-three miles long, and with an average width of four miles in the southern part and two miles in the northern. It is mountainous in character, rising to

FIG. 4111.—Avalon in the Island of Santa Catalina, California.

the height of three thousand feet, with deep valleys or gorges, and a great transverse depression running partly through it and forming a bay or anchorage on either side. The shores are bold, high cliffs, broken here and there by tiny bays or coves, with a sandy beach. Upon one of these coves, on the eastern side (called Avalon Bay), is situated the little town of Avalon, the only settlement on the island and the chief place of resort. Here are a number of good hotels, many boarding-houses, and, in the summer, tent villages with macadamized streets and rows of shade trees, where furnished tents can be rented—a popular mode of living at this season. There are also opportunities for camping in the many recesses of the island.

The climate exhibits the essential characteristics of that of the shore opposite, modified somewhat by local conditions; the rains here are said to be less frequent than on the mainland, the sea breeze is not so strong, and there is not so much fog. "They (the channel islands, of which Catalina is the principal one) are bathed in sunshine when the mainland opposite is enveloped in fog." The reader is referred to the article upon *Los Angeles* and the meteorological table therein contained for climatic details applicable in the main to the climate of Santa Catalina. The average July temperature at Santa Catalina is 65° F. In August the highest mean temperature observed at six in the morning was 72°; the highest at noon, 78°; the lowest, 69° F. The water temperature at noon, 76° F. The average relative humidity is 67 per cent. It is never uncomfortably warm in summer or too cool in winter. For both seasons it appears to be an admirable climate.

For a summer resort it is very popular and very much visited, and in the height of the season there are often five or six thousand people on the island; indeed, one of the objections to this resort for an invalid is the crowd of summer excursionists. As a genuine health resort it would appear to be more suitable and in many ways more attractive in the winter, for it is then "that the true beauties of this isle of summer are seen. The rains, which, curiously enough, are less than on the mainland, change the brown hills to a vivid green, and we have an emerald in an azure setting. Myriads of flowers spring up, and the face of the island is changed as if by magic. . . . In February and through the winter months Catalina is still an island of summer" (C. F. Holden, in *California Magazine*, December, 1892, quoted by Solly).

The outdoor attractions are many and varied. There are golf links in the Grand Canyon; various excursions among the mountains and valleys; a stage road across the island winding along the mountainside, affording delightful views of sea and land; boating, fishing, and bathing. The fishing is a feature of the place, and here are caught the large black sea bass, the leaping tuna, the yellowtail, and the barracuda. The water is so transparent that the bottom can be clearly seen at a depth of from fifty to one hundred feet, and for this purpose glass bottom boats are much in use, from which the most varied and fascinating sea vegetation, as well as a variety of fish life, can be seen. There is also wild-goat shooting from horseback in the fastnesses of the mountains.

Altogether, a region affording so many attractions of climate, scenery, water and land sport as that of Santa Catalina can hardly be imagined. Moreover, it has the great advantage of being an all-the-year-around resort. The sanitary regulations are said to be excellent, being under the supervision of a resident physician and health officer. Especial attention is paid to the sanitary condition and cleanliness of the tent villages. The bathing and swimming in the bay of Avalon are very delightful, both on account of the temperature of the water and on account of the absence of wind and surf.

Edward O. Otis.

SANTA ROSA WHITE SULPHUR SPRINGS.—Sonoma County, California. These springs are pleasantly situated about two miles from the town of Santa Rosa. The surrounding country is delightful in character and the climate very genial. There are good accommodations for visitors, and the resort is prosperous and thriving. The springs are mostly sulphureted and cold, having temperatures ranging from 59° to 62° F. The principal spring was found by Anderson to have the following composition: One United States gallon contains (solids): Sodium chloride, gr. 5.72; sodium carbonate, gr. 2.19; sodium sulphate, gr. 6.90; magnesium sulphate, gr. 9.07; and very small amounts of potassium carbonate, magnesium carbonate, calcium carbonate, calcium sulphate, ferrous carbonate, alumina, borates, silica, and organic matter. Total solids, 28.75 grains. Gases: Free carbonic acid gas, 4.16 cubic inches; free sulphureted hydrogen, 6.47 cubic inches. The action of this water is slightly aperient and diuretic. It is useful in congestion of the liver due to malarial poisoning, and in rheumatism, kidney and bladder troubles, and skin diseases. Excellent bathing facilities have recently been provided, the water being artificially heated.

James K. Crook.

SANTA YSABEL SULPHUR SPRINGS.—San Luis Obispo County, California. Hotel and cottages.

These valuable springs are located two and a half miles southeast of Paso Robles, on the line of the Southern Pacific Railroad, by which they may be reached. The location is a very delightful one, being in a small canyon about one mile east of the Salinas River. It is surrounded on all sides by the rolling hills covered with groves of gigantic oaks, towering pines, and clustering manzanitas. The atmosphere is sweet and balmy, and ranges from about 60° to 75° F. all the year round. The elevation is one thousand feet above the sea level, and the distance from the coast is about thirty miles. The soil of the neighboring land is exceedingly fertile, producing almost every known variety of fruit, as ascertained from the United States Experiment Station close by. The main warm sulphur spring flows twenty thousand gallons per hour. The waters are clear and sparkling, lightly sulphureted and freely carbonated. The waters are tonic, antacid, diuretic, aperient, and sedative.

The cold springs, being less densely impregnated with mineral ingredients, possess these qualities in a lighter degree than the warm. The waters have been found highly useful in a wide range of affections, embracing disorders of the liver, stomach, and bowels, catarrhal affections of the kidneys, chronic rheumatism, glandular indurations, obstinate syphilitic infection, and chronic cutaneous diseases. There are other valuable springs on the property, including a warm sulphur mud spring. This hot sulphurous mud is excellently adapted for bathing purposes. Extensive improvements are under way at this resort. Good roads and building sites have been laid out, and a depot landing selected. A small mountain lake is in course of construction; it will be from eight hundred to one thousand feet long by several hundred feet broad. On its waters will be several pleasure boats. About one hundred feet above the lake, on a pleasant plateau commanding magnificent views of the Salinas Valley, a spacious modern hotel and a number of cozy cottages will be reared. Thorough bathing facilities will also be provided. With its natural advantages of climate, soil, and surroundings, Santa Ysabel resort promises to be one of the pleasantest inland watering-places in that section of the country. It will be under the patronage of the Presbyterian denomination.

James K. Crook.

SANTONICA.—See *Wormseed.*

SANTONIN.—(*Santoninum*, U. S. P.; Br.; P. G.—$C_{15}H_{18}O_3$=245.43). A neutral principle obtained from santonica.

The source of this substance is described under *Wormseed, Levant.* It is extracted as a compound of lime by boiling in water or macerating in dilute alcohol to which lime is added. The calcium is then separated from the santonin by the addition of acetic or hydrochloric acid to the solution, and the santonin is purified by appropriate processes. Although now rarely intentionally adulterated, commercial santonin is very apt to be but imperfectly purified, and to contain artemisin. It is thus described by the Pharmacopœia:

Colorless, shining, flattened, prismatic crystals, odorless, and nearly tasteless when first put in the mouth, but afterward developing a bitter taste; not altered by exposure to air, but turning yellow on exposure to light.

Nearly insoluble in cold water; soluble in 40 parts of alcohol at 15° C. (59° F.), in 250 parts of boiling water, and in 3 parts of boiling alcohol; also soluble in 140 parts of ether, in 4 parts of chloroform, and in solutions of caustic alkalies.

When heated to 170° C. (338° F.), santonin melts, and forms, if rapidly cooled, an amorphous mass, which instantly crystallizes on coming in contact with a minute quantity of one of its solvents. At a higher temperature it sublimes, partly unchanged, and, when ignited, it is consumed, leaving no residue.

Santonin is neutral to litmus paper moistened with alcohol.

Santonin yields, with an alcoholic solution of potassium hydrate, a bright pinkish-red liquid which gradually becomes colorless.

From its solution in caustic alkalies, santonin is completely precipitated by supersaturation with an acid.

Its solution in cold, concentrated sulphuric acid is at first colorless (absence of *easily carbonizable, organic substances*), but after some time turns yellow, then red, and finally brown. If water be added, immediately after it is dissolved without color in sulphuric acid, it will be completely precipitated, and the supernatant liquid should not have a bitter taste, nor should it be altered upon the addition of potassium dichromate T.S. (absence of *brucine* or *strychnine*), or of mercuric potassium iodide T.S. (absence of *alkaloids in general*).

Action and Uses.—Although santonin produces very pronounced and in some ways remarkable physiological effects, it is very little used in those directions. It is actively diuretic, the action being dependent chiefly if not wholly upon local irritation, for it is excreted by the kidney. On this account it is occasionally employed as an emmenagogue. The urine is at the same time colored yellowish-brown, or, if decomposed, purplish-red. Upon the centres it acts as a motor excitor, this action being followed by depression, and there are evidences of cerebral congestion. Vision is most strongly and peculiarly affected, all objects appearing yellow or greenish-yellow, sometimes bluish at first.

It is occasionally administered in small doses, one-half to one grain, for correcting dimness of vision, especially that resulting from tobacco poisoning. With this exception, its sole use is that of an anthelmintic, destroying lumbrices and ascarides, especially the former. Advantages possessed by it over most other anthelmintics are its small bulk, freedom from bad taste, and availability for use in the form of confections, which are easily administered to children. Also in its favor is its slight solubility, on account of which it remains in the intestine sufficiently long to act upon the parasites and is then dejected without entrance into the circulation. This property cannot, unfortunately, always be depended upon, since, for reasons but little understood, it sometimes becomes unexpectedly absorbed, with poisonous effects. It must therefore be given with caution, and its effects should be kept under observation by the physician. Its administration should in all cases be followed by a cathartic, chiefly in this case as a precaution against poisoning. Unlike some poisonous substances, its absorption is not favored, but rather inhibited, by fats. Great caution should be observed in administering it to very young children. The dose of santonin for a child of five or six years is 0.03 to 0.06 gm. (gr. ss. to gr. i.). Adults may take from 0.12 to 0.25 gm. (gr. ij. to gr. iv.). The official preparation is the troches (*trochisci santonini*), each containing 0.03 gm. (about gr. ss.) of powdered santonin, with sugar and tragacanth, and flavored with a little stronger orange-flower water. *Henry H. Rusby.*

SANTONIN-OXIM.—A derivative of santonin, obtained by the action of hydrochlorate of hydroxylamine, in alcoholic solution, upon santonin. Its chemical formula is $C_{15}H_{18}O_2NOH$, that of santonin being $C_{15}H_{18}O_3$. It is a white crystalline substance, having a melting-point of 323° F. It is scarcely soluble in water, but soluble in alcohol and ether, and in weak alkaline or weak acid solutions.

Santonin-oxim is recommended as a substitute for santonin, as it is said to be free from any toxic properties. This is explained by the statement that it is not absorbed from the alimentary canal, its anthelmintic action being effected, therefore, without any influence on the general system. The dose for children of two or three years is one grain; for those from four to six, one grain and a half; for those from six to nine, two grains; and for adults, five grains. This quantity is to be given in two portions, an hour intervening between them. The dose should be repeated daily for two or three days, and should be followed by a purgative. *Beaumont Small.*

SANTONIN, POISONING BY.—Santonin is a neutral, crystalline principle obtained from the unexpanded flowers of the *Artemesia pauciflora* Weber. The formula $C_{15}H_{18}O_3$ has been assigned to it. It is but slightly soluble in cold water; more so in alcohol. Its principal use is as a vermifuge, and for this purpose it is given to children in doses of about half a grain; adults may take from two to four grains. Serious symptoms have arisen in children from as little as two grains, and one fatal case is believed to have been due to six grains. It has a marked bitterness, which is, however, not at once perceived owing to the slight solubility of the drug. The symptoms produced by overdose are dizziness, stupor, paleness, and subnormal temperature, followed by vomiting, dilatation of pupil, and unconsciousness. Occasionally convulsions involving the trunk muscles occur. Disturbances of color-vision often occur, objects appearing usually yellow, but sometimes green or blue. The drug is eliminated in part by the urine, which will acquire a distinct red tint on adding an alkali, or spontaneously on standing owing to the formation of ammonium carbonate from the urea.

There is no specific antidote. A few grains of potassium permanganate in a tumblerful of water might be of service. If this is given, no coffee, milk, or other organic matter should be added. Washing out the stomach might be of some use. Hot applications to the extremities are advisable. *Henry Leffmann.*

SAPOCARBOL is an aqueous solution of crude carbolic acid and potash soap, intended as a substitute for lysol. It is said to contain from thirty-seven to forty-four per cent. of phenol. *W. A. Bastedo.*

SAPODERMIN is a soap containing 0.2 per cent. of mercury in the form of caseinate; though the soap is alkaline, the mercury salt retains its solubility. Sack says that it is not only non-irritating, but in prolonged use acts as a preservative of the skin. In aqueous solution (1 to 1,000) it inhibits the growth of streptococci, and is best applied in bacterial and fungous skin diseases by letting the concentrated lather dry upon the skin.

W. A. Bastedo.

SAPOLAN consists of 2.5 parts of crude naphtha, 1.5 parts of lanolin, and three or four per cent. of anhydrous soap. It is a brownish-black salve, preferred by Lesser to the tar preparations because of its non-irritating properties. Mracek has used it with excellent results in eczema of different kinds, in favus, herpes, tinea tonsurans, etc., and he considers it distinctly bactericidal.

W. A. Bastedo.

SAPROL is a dark-brown oily substance, consisting of a forty-per-cent. solution of crude cresols in the lighter petroleum hydrocarbons (benzin, etc.). It is immiscible with water and is very inflammable. It is used as a disinfectant. *W. A. Bastedo.*

SARANAC LAKE. See *Adirondacks.*

SARATOGA SPRINGS.—Saratoga County, New York. Post-Office.—Saratoga. Hotels, boarding-houses, and cottages.

Access.—Saratoga is a station on the Delaware and Hudson Railroad, 38 miles north of Albany and 183 miles north of New York. The trip may be made by steamers on the Hudson River to Albany or by two lines of railroads, the New York Central and the West Shore to Albany, thence viâ Delaware and Hudson Railroad. Through trains run daily from New York during the season. From Buffalo and the West Saratoga is reached by way of the Delaware and Hudson Railroad and its Western connections, and from Boston and the East viâ the Fitchburg Railroad to Albany and thence viâ the Delaware and Hudson Railroad.

This famous resort is perhaps the most celebrated watering-place in the United States, as it is undoubtedly in the Northern States, and, with the exception of Berkeley Springs in Virginia, the oldest in the country. The village is situated toward the eastern border of the State, at the southern termination of the Adirondack range of mountains, and at about the centre of a valley extending from Ballston to Quaker Springs. The altitude of Saratoga is about 300 feet above the sea level, and the population varies from about 11,000 in the winter to 35,000 during the season, which lasts from the middle of June to the middle of September. The accommodation for visitors of all classes is ample and excellent. The name Saratoga is derived from the Iroquois tribe of Indians, and there is ample evidence to show that some of the springs here were known to and used by the aborigines many years prior to the advent of the European settlers. The well-known High Rock Spring on Willow Walk was apparently the first of these springs to be used by the whites. It is said to have been resorted to by Sir William Johnson as early as in 1767. The first real impetus given to the resort, however, was in 1789, when Gideon Putnam, of Sutton, appeared at the springs, leased three hundred acres of land, and thereafter was the leading spirit of improvement. In 1802 he built a portion of Union Hall upon the site of the present magnificent Grand Union Hotel, and this may be regarded as the starting-point of the Saratoga which we know to-day. Since those days many new springs have been added to the list, and the number at the present time will exceed fifty. As late as May 10th, 1897, the New York *Sun* contained an account of a new spring which had been struck at the Geysers on the preceding day by workmen who were drilling for the Carlsbad Company.

Saratoga presents many attractions beside the mineral springs and the grand hotels. The village has numerous elegant private residences, densely shaded streets, attractive walks, and beautiful drives. "The grounds of the different fountains are picturesquely adorned and shaded, and each hotel has its embowered court, where pleasing music is discoursed at intervals through the day and evening. Congress Park, at the southern extremity of Broadway, is a favorite resort where during the morning hours visitors congregate at the spring, drink of the waters, and stroll along the beautiful walks beneath the shade of ancient forest trees" (Walton). Among the numerous attractions in the neighborhood are the Saratoga Lake, nine miles long and four or five miles wide; Prospect or Waring Hill, said to rise two thousand feet above the sea level; Chapman's Hill, Hagerty Hill, etc. Bemis Heights, the scene of the surrender of Burgoyne to General Gates, is in the town of Stillwater, fifteen miles distant. All these points and many others may be easily reached from Saratoga by carriage drives or by bicycles.

The predominant ingredients of the Saratoga waters, as will be seen from the analyses, are the chloride of sodium, the alkaline carbonates, and carbonic acid gas. Some of them are, furthermore, quite heavily impregnated with iron. All contain one or more of the salts of lime. They are properly described as muriated alkaline-calcic carbonated waters. The further designation of chalybeate may be applied in many instances. Owing to lack of space we shall be able to give the analyses of only a few of the better known springs:

1. Congress Spring—(C. F. Chandler).

One United States Gallon Contains:

Solids.	Grains.	Solids.	Grains.
Sodium carbonate	10.77	Sodium chloride	400.44
Calcium bicarbonate	143.40	Potassium chloride	8.05
Magnesium bicarbonate	121.76	Sodium bromide	8.56
Strontium bicarbonate	Trace.	Calcium fluoride	Trace.
Lithium bicarbonate	4.76	Sodium iodide	.11
Iron bicarbonate	.34	Alumina	Trace.
Barium bicarbonate	.93	Silica	.84
Potassium sulphate	.89		
Sodium phosphate	.02	Total	700.90
Sodium biborate	Trace.	Carbonic acid gas	392.30

2. Empire Spring—(C. F. Chandler).

One United States Gallon Contains:

Solids.	Grains.	Solids.	Grains.
Sodium bicarbonate	9.02	Potassium chloride	4.29
Calcium bicarbonate	109.66	Sodium bromide	.27
Magnesium bicarbonate	42.96	Calcium fluoride	Trace.
Strontium bicarbonate	Trace.	Sodium iodide	Trace.
Lithium bicarbonate	2.08	Alumina	.42
Iron bicarbonate	.79	Silica	1.46
Barium bicarbonate	.07	Organic matter	Trace.
Potassium sulphate	2.77		
Sodium phosphate	.02	Total	680.44
Sodium biborate	Trace.		
Sodium chloride	506.63	Carbonic acid gas	344.67

3. Hathorn Spring—(C. F. Chandler).

One United States Gallon Contains:

Solids.	Grains.	Solids.	Grains.
Sodium bicarbonate	4.29	Sodium bromide	1.53
Calcium bicarbonate	170.65	Calcium fluoride	Trace.
Magnesium bicarbonate	176.46	Sodium iodide	.19
Strontium bicarbonate	Trace.	Alumina	.13
Lithium bicarbonate	11.45	Silica	1.26
Iron bicarbonate	1.13	Organic matter	Trace.
Barium bicarbonate	1.74		
Sodium phosphate	Trace.	Total	888.40
Sodium biborate	Trace.		
Sodium chloride	509.97	Carbonic acid gas	375.75
Potassium chloride	9.60		

4. High Rock Spring—(C. F. Chandler).

One United States Gallon Contains:

Solids.	Grains.	Solids.	Grains.
Sodium bicarbonate	34.89	Sodium bromide	0.73
Calcium bicarbonate	131.74	Calcium fluoride	Trace.
Magnesium bicarbonate	54.92	Sodium iodide	.08
Strontium bicarbonate	Trace.	Alumina	1.22
Iron bicarbonate	1.48	Silica	2.26
Barium bicarbonate	Trace.	Organic matter	Trace.
Potassium sulphate	1.61		
Calcium phosphate	Trace.	Total	627.56
Sodium chloride	390.13		
Potassium chloride	8.50	Carbonic acid gas	409.46

Kissingen or Triton, now Arondack Spring—(Professor Sharples).

One United States Gallon Contains:

Solids.	Grains.	Solids.	Grains.
Sodium bicarbonate	67.62	Sodium bromide	1.80
Calcium bicarbonate	140.26	Calcium fluoride	Trace.
Magnesium bicarbonate	70.47	Sodium iodide	.01
Strontium bicarbonate	Trace.	Alumina	Trace.
Lithium bicarbonate	5.13	Silica	1.28
Iron bicarbonate	1.56		
Barium bicarbonate	.99	Total	644.63
Potassium sulphate	Trace.		
Sodium chloride	338.50	Carbonic acid gas	361.50
Potassium chloride	16.98		

It will be observed that all the waters contain large quantities of carbonic acid gas, ranging from about 212 cubic inches per United States gallon in the Saratoga Alum Spring to 465 cubic inches in the Champion Spouting Spring. All contain the chlorides of sodium and potassium, the former salt ranging from 702 grains per United States gallon in the Champion Spring to 108 grains in the Flat Rock Spring. The bicarbonate of sodium is also present in each of the springs, the Vichy Spring leading with 82 grains and the Kissingen follow ing with 67 grains per gallon. All contain magnesium salts, the Champion Spring being first with 193 grains of magnesium bicarbonate per United States gallon. All the springs analyzed according to the more recent methods of examination are found to contain lithium, the Hathorn having 11 grains and the Geyser, Pavilion, and the New Putnam each about nine grains of the bicarbonate to the United States gallon. Most of the other springs contain an appreciable amount of lithium. Iron is always present in all of the waters, from the merest trace in some to 1.62 grains per gallon in the Hamilton, 5.88 grains in the Columbian, and 7 grains in the Putnam springs. All of the springs also contain calcium, while many of them contain the iodide and the bromide of sodium. The Putnam Spring contains the bicarbonate of magnesium. Several well known springs are not included in the above list, but recent analyses show that they possess the same general characteristics as those of which we have given the analyses.

The Saratoga waters have been recommended in a wide range of disorders and diseases, in many of which they have been found useful, while in others their influence has been pernicious. It can be laid down as an axiom that waters of this strength should not be taken at random; the consumer should invariably give himself the benefit of the advice of a physician of skill and experience before entering upon a course of the waters, either in his own home or at the springs. We cannot in this place enter into a detailed discussion as to the indications and contraindications for the Saratoga waters, but it may be said in a general way that their best application has been found in dyspepsia, engorgement of the liver and portal system, and chronic constipation. The chalybeate waters have been found beneficial as a tonic and reconstructive in general debility, in neurasthenia, and in anæmic states. The springs containing lithia may be counted upon to exercise the same influence upon the protean uric acid states as is to be expected from the widely advertised lithia waters. Many of the waters are also capable of producing a very appreciable alterative effect when taken for a considerable period of time.

There are three bathing establishments at Saratoga: the Saratoga Baths, recently opened and luxuriously appointed; the Red Spring bathhouse, and the misnamed Magnetic Baths. There is also a bathhouse at the White Sulphur Spring, south of Saratoga Lake. All are well conducted. *James K. Crook.*

SARCOMA.—The term sarcoma is loosely applied to the individual members of a large group of cellular, rapidly proliferating tumors of mesenchymal origin. It is applied more specifically to the members of that subdivision of these tumors in which the tumor cells secrete intercellular substances. The latter are usually small in amount, but they are similar in character to the intercellular substances found in ordinary connective and myxomatous tissues, cartilage, and bone. The tendency is more and more to restrict the name sarcoma to this single class of tumors.

The sarcomata, like other simple tumors, consist of two parts—of the tumor cells which may or may not secrete an intercellular substance, and of a stroma furnished by the tissue in which the tumor grows, in consequence of a physiological demand for nutrition and support made by the tumor cells. The stroma consists of blood vessels which may or may not be accompanied by a varying number of connective-tissue cells and fibrillæ. The blood vessels are often of the simplest type and may consist of endothelium only.

The sarcomata may be divided into several groups, according to the production or not of intercellular substances, and the form, arrangement, and differentiation of the cells. These groups can be further subdivided according to the kind of intercellular substance produced, and the size, shape, pigmentation, or other peculiarities of the cells.

The several groups adopted here and the subdivisions under them are as follows:

Group A. Sarcomata Characterized by the Production of an Intercellular Substance.—1. Spindle-cell sarcoma. 2. Myxosarcoma. 3. Chondrosarcoma. 4. Osteosarcoma. 5. Giant cell sarcoma. 6. Malignant leiomyoma.

Group B. Sarcomata Possessing a Reticulum.—1. Malignant lymphoma. 2. Chloroma. 3. Myeloma.

Group C. Sarcomata having an Alveolar Structure.—1. Melanoma. 2. Alveolar sarcoma.

Group D. Endotheliomata.—1. Hemangioendothelioma. 2. Lymphangioendothelioma. 3. Endothelioma of dura.

GROUP A. SARCOMATA CHARACTERIZED BY THE PRODUCTION OF AN INTERCELLULAR SUBSTANCE.—The mesenchyma of the embryo gives rise to a series of tissues of which the most closely related are ordinary fibrillar connective tissue, myxomatous tissue, cartilage, and bone. The tumors arising from these tissues, or, in the case of cartilage and bone, from the tissues which produce them, are, in their most actively proliferating types, owing to a lack of differentiation, indistinguishable; but the cells almost always preserve, to some extent at least, the property of differentiating in cell or intercellular substance like the cells of the tissue from which the tumor has arisen. For example, the periosteum gives rise to spindle-cell sarcomata with fibrillar intercellular substance; certain parts of such tumors frequently cease to grow rapidly, the fibrillar intercellular substance increases in amount, and is transformed into a hyaline material (osteoid tissue) in which lime salts may be deposited. In other words, some of the tumor cells have gone far enough in their differentiation to betray the nature and properties of the tissue from which the tumor originated.

It is usually claimed that sarcomata starting from ordinary connective tissue never produce bone, but this may not be a correct assumption. A few sarcomata containing bone have been described as arising in situations where no bone ordinarily exists. They may have arisen from misplaced periosteal tissue, but the simpler explanation is that ordinary connective tissue may give rise to tumors containing bone just as we know it often does under inflammatory conditions, as, for example, in the healing of wounds.

In this group are included those sarcomata which produce intercellular substances, such as the fibrillæ of ordinary connective tissue, the mucus of myxomatous tissue, and the hyaline substances of cartilage and bone. The amount of intercellular substance varies considerably and often is quite small, but even in the most cellular tumors, where mitotic figures are very numerous, proper staining of tissues carefully fixed while perfectly fresh always shows a certain definite and often large amount of intercellular substance.

The tumors of this group are subdivided chiefly according to the character of the intercellular substance produced, to some extent, however, according to the character of the cells. The whole group of tumors is, however, so closely related that the division is largely artificial. Combinations of almost any two or more of the varieties recognized is not at all uncommon. They are really classified in accordance with the amount of differentiation shown by a part or all of the cells. For example, if a spindle-cell sarcoma produces in places a mucoid intercellular substance, it is called a myxosarcoma; if cartilage, a chondrosarcoma; if bone, an osteosarcoma. If, on the other hand, giant cells are present in it, the tumor is called a giant-cell sarcoma.

Sarcomata grow by multiplication of their own cells. They do not infect surrounding tissue cells and cause them to turn into tumor cells. On the other hand, a certain amount of reactive proliferation of normal tissues may take place at the advancing edge of a sarcoma, but the cells preserve their normal characteristics. As a sarcoma enlarges it either simply shoves the neighboring tissue back on all sides by expansive growth, or infiltrates and destroys it. No tissue, not even bone, is able to withstand it.

The various sarcomata have the common characteristics of rapid growth, a tendency to ulceration, to local return after extirpation, and to early and extensive metastases. The metastases may be local by discontinual peripheral growth, or regional by way of the lymphatics, or general by means of the blood-vessels. As a result of local metastases sarcomata often have a lobulated form. As a result of the frequent extension of sarcomata into blood-vessels, general metastases are common; multiple nodules occur in the lungs, liver, spleen, and bone marrow, and occasionally in other organs. Regional metastases are rare except with certain varieties of sarcoma.

Retrograde changes are frequent in sarcomata, especially fatty degeneration, necrosis, and calcification. With some forms hemorrhage is common and may give rise to pigmentation simulating that present in melanotic sarcomata.

The form of the cells in the different sarcomata can be studied best in teased preparations of fresh or macerated tissues, while the intercellular substances are best demonstrated by means of the aniline blue connective-tissue stain.*

1. *Spindle-Cell Sarcoma.*—Of the sarcomata of which the cells produce an intercellular substance, the most common and typical example is the spindle-cell sarcoma (Fig. 4145). The cells are elongated and terminate at each end in a process which may be long or short. In the swollen centre of the cell is an oval or elongated nucleus; occasionally two or more nuclei are present. When the cells are seen in cross section they look like small round cells. The arrangement of the cells is fairly regular: they overlap each other so that the slender ends of one cell come opposite the middle of the cells adjoining it. The cells tend in a general way to run parallel with the blood-vessels; in this way are formed the bundles of cells which in a mounted section are seen to run in different directions. The bundles of cells may be large, or small and closely interwoven.

FIG. 4145.—Spindle-Cell Sarcoma showing the Connective-Tissue Fibrillæ Between the Cells.

The cells vary considerably in size and shape in different tumors; they may be large or small, and short and plump with oval nuclei, or very long and slender with rod-shaped nuclei. The two extremes of size are recognized as the large and the small spindle-cell sarcomata.

Mitotic figures vary considerably in number in different tumors and in different parts of the same tumor, but

FIG. 4146.—Sarcoma Composed of Large Cells, Round to Spindle in Shape, with Connective-Tissue Fibrillæ Between the Cells. Two mitotic figures of which one is compound. One very large cell contains lobulated nuclei and hyaline droplets. This sarcoma started in the uterus and probably originated in smooth muscle fibres.

usually they are comparatively numerous. The number of them in a given area affords the best means of judging of the rapidity of growth of the tumor.

Running between the cells and in the same direction as their long axes are very delicate connective-tissue fibrillæ, which are produced by the tumor cells. In the more slowly growing sarcomata, and often in certain parts of those which are proliferating rapidly, the fibrillæ are more numerous and tend to unite into coarser fibres.

As a rule, the blood-vessels are very delicate and usually are lined with endothelium only.

All spindle-cell sarcomata do not grow at the same rate of speed. Some contain great numbers of mitotic figures and little intercellular substance; others have fewer proliferating cells and more intercellular fibrillæ. It is not always easy to draw the line between them and the more slowly growing connective tissue tumors to which they are intimately related. When the cells and fibrillæ are about equal in quantity and the tumor is growing rather slowly, it is called a fibrosarcoma. When the fibrillæ greatly preponderate and the growth is very slow, the tumor is called a fibroma. Names are assigned to but these three rates of speed, and all tumors of this nature are arbitrarily classed under one or another of them.

The spindle-cell sarcoma has its prototype in young connective tissue which it sometimes very closely resembles. I have recently found that young connective tissue cells of inflammatory origin produce two kinds of fibrillæ—the ordinary delicate wavy fibrillæ which stain blue by the aniline blue connective-tissue stain, and delicate refractile straight fibrillæ which stain intensely red by the same method, provided the staining with acid fuchsin be prolonged for twenty four hours, and which have about the same relation to the cell protoplasm that the neuroglia fibres have. These red-staining fibrillæ do not stain by Weigert's method for elastic fibres, but can be brought out sharply by a method which has not yet been published. These same fibrillæ occur in spindle-cell sarcomata.

Although the spindle cell sarcoma is the typical and most common example of the tumors which produce a fibrillar intercellular substance, certain other sarcomata occur in which some or all of the cells may be oval, polymorphous, or even round (Fig. 4146), but they must be carefully distinguished from those tumors in which the cells lie in a reticulum or have an alveolar arrangement.

2. *Myxosarcoma.*—The tissue (Wharton's jelly) of

* *Aniline Blue Connective-tissue Stain.*—This method, slightly modified from the original, is as follows:

1. Fix thin sections (2 to 4 mm. thick) of perfectly fresh tissue in Zenker's fluid for twenty-four hours. Wash in running water twenty-four hours. Dehydrate in ninety-five-per-cent. alcohol.
2. Stain celloidin or paraffin sections in a one-half-per-cent. aqueous solution of acid fuchsin for five minutes.
3. Wash off quickly in water (not over five seconds).
4. Place in a one-per-cent. aqueous solution of phosphomolybdic acid for ten to twenty minutes.
5. Wash off quickly in water (not over five seconds).
6. Stain in the following aniline blue solution five to ten minutes. Aniline blue soluble in water (Grübler), 0.5; orange G (Grübler), 2.0; oxalic acid, 2.0; water, 100.0.
7. Wash very quickly in running water (not over five seconds).
8. Wash in several changes of ninety-five-per-cent. alcohol.
9. Absolute alcohol, xylol, xylol balsam.

Water extracts the acid fuchsin very quickly. Alcohol has little effect on the acid fuchsin but extracts the aniline blue rather quickly.

which the umbilical cord is composed has always been held up as the type of myxomatous tissue. It is usually said to be composed of delicate irregular cells united by protoplasmic processes between which is a fluid or gelatinous ground substance containing mucin. Such a tissue composed of delicate protoplasm and fluid would tear

FIG. 4147.—Osteochondrosarcoma. An area where the fibrillar intercellular substance shows partial transformation into the hyaline matrix of cartilage and bone.

with the greatest ease; the umbilical cord is unquestionably rather tough. As a matter of fact, proper staining of the umbilical cord, even in the very smallest embryos, shows that innumerable exceedingly delicate connective-tissue fibrillæ run in parallel strands everywhere between the cells. Myxomatous tissue is, therefore, to be defined as connective tissue in which the individual fibrillæ are more or less separated from each other by a fluid containing an excess of mucin. The ordinary staining methods do not bring out these fibrillæ distinctly. Myxomatous tissue differs from œdematous connective tissue chiefly in the amount of mucin present in the fluid.

A myxosarcoma is to be defined as a sarcoma which produces a fibrillar intercellular substance together with a fluid containing an excess of mucin. The amount of fibrillar material varies with the rapidity of growth of the cells, just as it does in a spindle-cell sarcoma. A pure myxosarcoma is rare; its cells are irregular, more or less stellate, with branching processes. As a rule, only parts of a tumor are myxomatous and the stellate cells grade off into others of the spindle type and the intercellular fibrillæ are closer together and more evident.

3. *Chondrosarcoma.*—The chondrosarcoma is a sarcoma, usually of the spindle cell type, in which in places the fibrillar intercellular substance has become homogeneous and transformed into a hyaline material having the appearance and chemical properties of cartilage. The change is perfectly analogous to that which takes place under normal conditions in the repair of injuries to cartilage, where the new cartilage is produced by a proliferation of the perichondrium which forms young connective tissue; this is then transformed into cartilage. At the same time the spindle cells change their form and become more or less round or irregular. A chondrosarcoma is, therefore, a sarcoma of which a part of the cells have differentiated far enough to produce cartilage (Fig. 4147).

4. *Osteosarcoma.*—The osteosarcoma is a sarcoma, usually of the spindle-cell type, in which in places the cells have been transformed into bone corpuscles and the intercellular fibrillæ into a homogeneous substance in which lime salts have been deposited (Fig. 4147). This process is analogous to that which takes place in the repair of bone, the periosteum and endosteum produce young connective tissue which is transformed into bone.

If lime salts are not deposited in the osteoid tissue, the tumor is called an osteoid sarcoma. Osteosarcomata usually arise from the periosteum and endosteum.

5. *Giant-Cell Sarcoma.*—It is a question whether or not sarcomata containing giant cells should be put in a class by themselves. Giant cells occur in spindle-cell sarcomata which have no relation with bone (in one case they were present in a primary sarcoma of the left auricle of the heart), they occur in fibrosarcomata, in tumors which grow so slowly and are so benign that they must be regarded as fibromata, and most frequently of all in osteosarcomata. Many writers seek to restrict the term to those tumors which arise from bone, but this seems hardly justifiable. A tumor should be classed by what it contains and itself shows, not by the tissue from which it is supposed to have arisen.

Large cells containing several nuclei, or a large lobulated nucleus, occur in many rapidly growing tumors. These cells are usually, perhaps always, the result of irregular mitoses; that is, the mitotic figure is compound and the nucleus divides into several or even into many nuclei; the nuclei may remain more or less connected together and form a large lobulated nucleus. It is not customary to speak of these cells as giant cells. The term is reserved for cells which contain usually many more nuclei, often a hundred or more; and so far as known these giant cells are not the result of mitoses but of direct division and possibly also of fusion of cells. They have been regarded by many as foreign-body giant cells, but Ribbert looks upon them as attempts at the formation of osteoclasts; that is, they represent on the part of the tumor a certain form of differentiation of the cells. In favor of the foreign-body irritation view is the fact that the protoplasm of these cells usually contains clumps of minute elongated fissures which may have been filled in the fresh state by fat or other crystals. The nuclei do not have the bipolar or mural arrangement so characteristic of the giant cells in tuberculous lesions, but are generally grouped together, usually centrally, but sometimes toward one end of the cell. They never extend to the periphery of the protoplasm.

Giant cell sarcomata arise most commonly from the endosteum of the long bones and from the periosteum of

FIG. 4148.—Giant-Cell Sarcoma, showing Connective-Tissue Fibrillæ Between the Cells.

the jaw, but they may occur in other organs, as, for instance, the breast, where they are not so exceedingly rare. The naked-eye appearance of them is characteristic. The cut surface is almost always brownish red over a considerable extent, in consequence of previous hemorrhages, as a result of which the tumor cells often contain much pigment.

While the cells associated with the giant cells are usually spindle-shaped in type (Fig. 4148), they may be polymorphous or even round, although the latter form is rare. The formation of bone in these tumors is common, but may be absent even where the growth develops from endosteum.

The term *epulis*, applied by the clinician to all tumors growing on the jaw, is sometimes employed clinically as practically synonymous with giant-cell sarcoma, because most tumors of the jaw are of that nature.

6. *Malignant Leiomyoma.*—It has been a much disputed question among pathologists whether or not a sarcoma ever arises from smooth muscle tissue. A number of writers claim to have demonstrated the transformation of a myoma of the uterus into a sarcoma, but each later writer doubts the work of his predecessors, and it has been the tendency of pathologists in general to doubt the conclusions of all of them. It is probable that many of these tumors were of smooth-muscle origin, but perfectly satisfactory proof was not offered.

I have recently studied a tumor of the uterus which seems without much question to be a malignant leiomyoma. It was of the size of a cocoanut and was situated in the posterior wall of the uterus. From its inner side a nodule as large as an orange projected into the uterine cavity. The nodule on section was grayish, homogeneous, rather soft, and friable; it cut and looked like a sarcoma. The main tumor mass was in general of the same appearance, but there were scattered through it, especially at the periphery, areas of a tough fibrous character resembling a myoma. The diagnosis made at the time was "large mixed-cell sarcoma."

Smooth muscle fibres have two sets of fibrillæ: those in the periphery are known as the coarse or border fibrillæ; the others are situated between these and the nucleus, and are known as the fine or "binnen" fibrillæ. It is possible to stain the coarse fibrillæ differentially by means of the aniline blue connective-tissue stain and by other methods, so that they stand out in sharp contrast to other tissues. Benda has recently studied these fibrillæ by means of a modication of Weigert's neuroglia stain. He finds them comparable in many respects to neuroglia fibres and names them myoglia fibres. They are probably a supportive tissue for the smooth muscle fibres, for they pass without break from cell to cell.

The tumor in question would naturally be classed as a large spindle-cell sarcoma, although in some places where the cells are largest they are round in shape. Multinucleated cells also occur and mitotic figures are exceedingly numerous. Yet, in spite of its rapid growth, there is between and around all of the cells an abundant fibrillar intercellular substance which has the staining reactions of ordinary connective tissue. In addition, however, all of the spindle cells over large areas have another set of fibrillæ (Fig. 4149), which stain differentially like the coarse fibrillæ of smooth muscle fibres. These cells differ considerably from smooth muscle fibres; they are much larger and have abundant protoplasm; the nucleus is large and oval in shape; the fibrillæ are usually finer; but every gradation between them and typical smooth muscle cells can be found; in other words, some of the tumor cells tend to differentiate into perfect muscle cells. Where the cells are largest, and oval to round in shape, no differentiated fibrillæ can be demonstrated, although the ordinary intercellular fibrillæ are numerous. The tumor seems unquestionably to be a very cellular, rapidly growing, malignant leiomyoma, which probably developed in a myoma. Some parts of the tumor show invasion of smooth muscle tissue; the tumor cells either press between strands of muscle fibres, or infiltrate them and cause the muscle cells to degenerate.

So far as I know, there is only one source of error in the above diagnosis. Young connective-tissue cells of inflammatory and tumor origin produce, besides the ordinary intercellular fibrillæ with which we are acquainted, a second kind of fibrillæ which stain differentially in the same way as the border fibrillæ of smooth muscle fibres; but the two kinds of cells look very different, and the fibrillæ of connective-tissue origin are usually much finer. Moreover, as the connective-tissue cells differen-

FIG. 4149.—Malignant Leiomyoma, showing One Cell in Mitosis and many Differentially-Staining Coarse Fibrillæ Characteristic of Smooth Muscle Cells. The ordinary connective-tissue fibrillæ between the cells are not stained by the method employed and hence do not show.

tiate and produce an increased amount of intercellular substance, the red-staining fibrillæ diminish in number. In smooth muscle tissue under the same conditions they increase in number.

I have had the opportunity of studying but three other sarcomata of the uterus; two were typical spindle-cell sarcomata derived without doubt from connective tissue; of the third only a small piece projecting into the vagina was obtained. Histologically it closely resembled the most cellular portions of the malignant leiomyoma just described, but no differentially staining fibrillæ could be found in it.

The large amount of ordinary fibrillar intercellular substance in this tumor, in spite of its rapid growth, makes one wonder if it also, as well as the differentially-staining coarse fibrillæ, may not be the product of the cells. Probably the simpler explanation is that the tumor cells, like ordinary smooth muscle fibres, make a demand on adjoining connective tissue for an abundant supply of connective-tissue fibrillæ to surround and support each cell.

GROUP B. SARCOMATA POSSESSING A RETICULUM.—Lymphoid tissue throughout the body, in lymph nodes, spleen, and elsewhere, is composed, aside from blood-vessels, of three different kinds of elements—of a connective-tissue reticulum with the cells which produce it, of endothelial cells which line the reticulum in places, and of lymphocytes (*i.e.*, the different cells of the lymphocyte series) which fill the spaces in the reticulum.

When a tumor develops from these lymphocytes, new blood-vessels and reticulum are formed and there may be more or less proliferation of the endothelial cells, but these are all secondary or reactive processes. The essential part of the tumor is the cells derived from the lymphocytes. They alone give rise to metastases, and, wherever they lodge and proliferate, blood-vessels and reticulum are provided for them.

The lymphocytes of lymphoid tissue are in part undifferentiated lymphocytes such as fill the germinative centres of Flemming, in part the typical differentiated small lymphoid cells such as are met with in the circulation, and in part the more or less differentiated cells, including the plasma cell, between these two extremes of the lymphocyte series.

The undifferentiated lymphocyte corresponds with and is probably identical with the undifferentiated cell of the bone marrow. Dominici has shown that, in the rabbit at least, the undifferentiated lymphocyte in the spleen under the influence of various toxins can give rise to cells which are identical with the orthobasophilic myelocytes of the bone marrow, and from these cells ordinary polynuclear leucocytes may be produced.

It is evident, therefore, that the tumors arising in lymphoid tissue will not necessarily all show exactly the same type of cell. As a matter of fact, the cells vary considerably. Sometimes they resemble the typical lymphoid cell, sometimes the undifferentiated lymphocyte, sometimes they differ more or less from both.

The normal bone marrow contains undifferentiated cells identical with those in lymphoid tissue. From them develop not only lymphoid and plasma cells, but also the amphophile and other myelocytes. Tumors can evidently arise, therefore, in the bone marrow identical with those originating in lymphoid tissue; but as the cells of the bone marrow under normal conditions undergo much greater differentiation than the cells in ordinary lymphoid tissue, it is not surprising that tumors arise in the bone marrow which are peculiar to that tissue.

This group of tumors arising in lymphoid tissue and in the bone marrow agree in two points: the cells are more or less spherical and are embedded in the meshes of a connective-tissue reticulum. It is difficult to define and classify them exactly, because there is comparatively little that is known positively about them. They unquestionably should be classified according to the differentiation of the chief cell of which they are composed.

The clinical history of this class of cases is always of the greatest importance, and yet even with that, if only material obtained at a surgical operation is available, a final diagnosis may not be justifiable unless the subsequent history also is obtained and in case of death a careful post-mortem examination is made. Various causes can lead to great enlargement of lymph nodes. The difficulty is to know when the enlargement is due to true tumor formation and when to other causes, when the tumor is primary and when secondary.

The inflammatory lesions of the inguinal lymph nodes secondary to gonorrhœa are fairly characteristic and should lead to no trouble in diagnosis, especially with a history of infection. The same is true of many other acute enlargements. The chronic enlargements are more difficult. Some are due to tuberculosis, others to syphilis, and still others to causes not yet fully understood. Hodgkin's disease is a clinical picture which has not a definite pathology. The name is best limited probably to those chronic enlargements of the lymph nodes which at present have no known etiology. Such enlargements are characterized by thickening of the reticulum, the

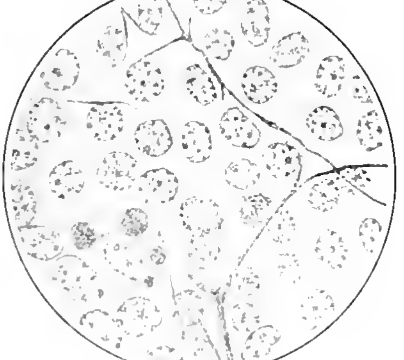

FIG. 4150. Malignant Lymphoma, showing the Characteristic Reticulum, One Cell in Mitosis, and One Large Phagocytic Cell.

presence of many eosinophiles and of numerous large cells with multiple nuclei or with a large lobulated nucleus. These large cells are probably derived from the endothelial cells which normally line the reticulum in places. The enlarged nodes remain discrete; the sinuses and lymph nodules usually do not disappear.

The most difficult question remaining to be settled in connection with these tumors is their relation to the leukæmias. If the latter, as seems not impossible, should prove to be true tumor formations with metastases growing in the circulating blood because the cells are highly enough differentiated to find the best conditions for their growth there, the relation would be a simple one, and they could readily be classified. If, on the other hand, the leukæmias are simply the expression on the part of the bone marrow of a reaction to toxins or other definite causes, they would have no relation at all to the class of tumors under discussion. The term pseudoleukæmia should probably be given up. The cases diagnosed as such should be included under malignant lymphomata or under the chronic inflammatory processes (Hodgkin's disease).

1. *Malignant Lymphoma.*—The term lymphosarcoma is often used for this class of tumors, but malignant lymphoma is probably better. It is applied to a rapidly growing tumor, of which the actively proliferating cells are of the type of the cells in the lymphocyte series and are embedded in the meshes of a delicate reticulum (Fig. 4150). The small round-cell sarcoma and probably some of the large round-cell sarcomata belong under this same heading. It may be possible later to subdivide this group according to the differentiation of the cells, which are not always of the same character. In the majority of the cases they resemble more or less closely the undifferentiated lymphocyte, but apparently cases occur, although I have seen none, in which the cells are of the type of the differentiated lymphoid cell.

The nuclei of these cells are in general round, although irregular and indented forms are common. They are vesicular in type and contain one to several coarse chromatin granules, but no differentiated nucleolus. Mitotic figures are as a rule numerous. The protoplasm is almost always small in amount, non-granular, but sometimes finely reticular. The cells vary more or less in size in different cases. As a rule they are about as large as the undifferentiated lymphocyte, but occasionally cases occur in which the cells are considerably larger, although otherwise agreeing with them in all respects.

Phagocytic cells are always present in these tumors, so far as my experience goes. They vary greatly in different cases both in size and in number. Often each phagocyte will contain half a dozen or more inclusions. They are unquestionably derived from the endothelial cells lining the reticulum.

Eosinophiles, although generally few in number or altogether absent, occasionally occur in great numbers. In one case at the Boston City Hospital, in a man fifty-five years old, the tumor started just over the symphysis pubis and reached the size of "two fists" in the ten months preceding operation. It extended into the scrotum, along the left vas deferens, and infiltrated the skin. It recurred within a few weeks in the skin covering the dorsum of the penis, in the corpora cavernosa, in the left inguinal lymph nodes, and in the left hypogastrium. The cells were of the type of the undifferentiated lymphocyte. Unquestionably the case was one of rapidly growing malignant lymphoma, and yet polynuclear eosinophiles were present in great numbers everywhere in the tumor, and in places formed one-fourth to one-half of the cells present.

The reticulum is fairly abundant and usually quite delicate, but may sometimes in places be dense and even hyaline.

A malignant lymphoma may arise anywhere where there is lymphoid tissue, but originates most commonly in lymph nodes and in the lymphoid tissue of the pharynx and intestine. Although when the tumor starts in lymph nodes several of them almost always appear to be affected together from the start, it is probable that the growth starts in one node and rapidly spreads to others.

Sometimes the invasion of a lymph node is distinctly visible to the naked eye on section. At other times it can readily be made out on microscopic examination. The normal tissue is rapidly invaded and destroyed, so that the sinuses and lymph nodules disappear. The tumor cells also early infiltrate the connective, fat, and other tissues outside of the lymph nodes, and sometimes extend into blood-vessels and occlude their lumina.

Metastases are frequent. In the great majority of cases they occur only in lymphatic tissue, especially in other lymph nodes, or in the lymph nodules of the intestine where large prominent nodules may arise. The tumor cells spread to the rest of the body by direct infiltration, by way of the lymphatics, and through the blood-vessels. It is by the last method chiefly that they get to the organs where they become fixed in the capillaries, and proliferate, compress, and destroy the cells between the capillaries. In the larger lymph nodes the metastases take place mostly in the peripheral parts near the capsule, where at first more or less circumscribed nodules are formed.

The gross appearance of a malignant lymphoma is more homogeneous and uniform than that of a lymph node, because there is no division into lymph nodules, sinuses, and trabeculæ. The cut surface is grayish-white and juicy, and the consistence usually soft, but hard malignant lymphomata occur in which the reticulum is coarse. This difference in consistence may occur in different cases or in the same case; if in the same case, the older nodules are the harder, the younger the softer.

2. *Chloroma.*—In its histological structure the chloroma corresponds in all respects to the type of the malignant lymphoma; it is composed of mononucleated lymphocytes embedded in the meshes of a reticulum. Its distinctive and characteristic feature is its color, which may vary from grass green to dirty green. The nature of the color is not known. Certain nodules in a given case may be green, while others are colorless. Von Recklinghausen thinks the color is due to the cells, while Huber and Chiari claim that the color is contained in very fine fat droplets. Against this latter view is the fact that the color is not extracted by alcohol (Dock), although it readily disappears on exposure to air.

In all but one case the bones of the skull were the primary focus affected, and the metastases were chiefly in bone tissue or in the periosteum. Only about twenty cases of the disease have been reported. In most of the cases double or unilateral exophthalmus was one of the earliest symptoms due to the development, behind the eyeball, of tumors which soon became palpable.

3. *Myeloma.*—The myeloma is also closely related to the malignant lymphoma. It consists of small round cells embedded in a delicate reticulum. The cells closely resemble plasma cells in certain respects. The protoplasm is basophilic, and the nuclei, of which there are often two or three in a cell, are more or less excentrically situated. The chief point of difference is that the cells have a very distinct nucleolus, which can be stained differently from the chromatin of the nucleus and which has a clear space around it. The chromatin granules are not so coarse as in a plasma cell.

The tumor affects chiefly the flat bones of the skull, the sternum, ribs, bodies of the vertebræ, less often the bones of the pelvis. It always starts from bone tissue, and metastases occur in other bones but not in other organs. The individual nodules are not sharply limited. The growth causes destruction of bone tissue, so that fractures, as, for example, of the ribs, take place easily. Albuminosuria is a fairly characteristic but not absolutely diagnostic symptom of the disease, as it has been found rarely in certain other conditions.

GROUP C. SARCOMATA HAVING AN ALVEOLAR STRUCTURE.—The structure of these tumors is more or less like that of a carcinoma; they consist of a connective-tissue stroma in the meshes of which the cells are embedded.

In this group belong the melanotic sarcomata of which the origin is now pretty definitely settled, and certain other tumors about which but little definite is known.

1. *Melanoma, Chromatophoroma, Melanosarcoma, Melanotic Sarcoma.*—The melanoma is a sarcoma which owes its distinctive name to its color: in the most characteristic cases this is a very dark brown, but it may be a clear brown, or only a light-brownish tint. The tumor is frequently irregularly pigmented, in some parts brown, in others light-colored, in still others colorless. Sometimes only small areas are colored, so that the pigmentation might easily be overlooked.

According to Ribbert, melanomata occur primarily only in the skin, in the mucous membranes arising from it, in displaced parts of the skin, and in the eye. They

FIG. 4151.—Melanoma of Skin, showing Alveolar Arrangement of Cells with Deep Pigmentation of a Few of Them.

arise from pigmented cells or chromatophores, certain differentiated cells of mesenchymal origin which produce pigment but probably no intercellular substance. These cells occur normally in the choroid and iris of the eye, and in certain situations in the pia and skin. They are also present more or less abundantly in the congenital soft warts or nævi of the skin. As it is from these nævi that melanomata of the skin almost invariably arise, some account of their structure is important. They consist of groups of medium-sized cells having more or less of an alveolar arrangement. The cells are round or irregular in shape and often have short processes. Within the cell groups the pigmentation is usually slight or even wanting, but at the periphery, especially adjoining the epidermis, the cells are usually larger, much more irregular in shape with branching processes, and deeply pigmented. These cells are typical chromatophores; the other cells are to be regarded as young forms produced in excess.

Two types of melanomata occur. In one the cells are more or less round or irregular in type, and are arranged in fairly distinct alveoli (Fig. 4151). This form is spoken of as the alveolar melanoma and is the common type in melanomata arising from the skin. The other form, the spindle-cell melanoma, is much rarer; it is composed of long spindle cells, and occurs most commonly in the eye. It bears a close resemblance, except for its pigmentation, to the ordinary spindle-cell sarcoma, but the vessels run between the bundles of cells instead of in the centre of them. Unless it be demonstrated that these spindle cells produce an intercellular substance, this form of melanoma is best regarded simply as a modification of the ordinary alveolar melanoma; *i.e.*, its groups or alveoli of spindle cells are large and rather indefinitely separated from each other by delicate blood-vessels accompanied by a very slight amount of connective tissue. Rapidly growing carcinomata sometimes show an equally indefinite alveolar arrangement. This view is favored by the fact that all gradations between the two types of growths are said to occur.

It is very important, in the study of the forms of the cells in melanomata, to examine teased fresh specimens, because they cannot be made out nearly so well in stained sections. The cells may be round, irregular, spindle-shaped, or have short or long, simple or branched processes. The latter forms are more evident in the melanomata of the eye.

The pigmentation is fairly uniform only in the dark-brown tumors. In the others it affects only a part of the cells or a few of them, or may be lacking in whole sections. The cells in the separating strands are usually deeply pigmented. The pigment occurs in the form of brown angular granules and is an essential product of the cells. It is termed melanin, contains no iron, and is probably derived from albumin because it contains sulphur. Melanomata may contain pigment which gives the iron reactions, but this is secondary to hemorrhage which is not infrequent in this class of tumors.

The melanoma is prone to recur after extirpation and to give rise to metastases. This is probably to be explained in part by its tendency to extend along the lymphatics. It usually affects first the neighboring lymph nodes, but soon spreads throughout the body by means of the blood. It develops in the form of nodules of all sizes in all organs, but usually most abundantly in the liver. The color of the metastases may be like the original growth, or darker or lighter. Black and white nodules may occur side by side.

As the melanoma is derived from the chromatophores, Ribbert suggests the term chromatophoroma for them. The only objection to the term is its length, which renders it somewhat undesirable. Melanoma is simpler and calls attention to the important characteristic of the tumor. The terms melanosarcoma and melanotic sarcoma are in good usage, but might be considered to apply also to tumors colored by iron containing pigments.

2. *Alveolar Sarcoma.*—Under this heading have unquestionably been grouped in the past a variety of tumors of which some at least do not belong here. Many have unquestionably been carcinomata, others endotheliomata. Ribbert has called attention to the fact that melanotic sarcomata are sometimes so slightly pigmented that their real nature might easily be overlooked. Under such conditions they might readily be put into this class. It has been suggested but not proved that alveolar sarcomata may arise from striated muscle cells. For the present this group of tumors must be regarded with suspicion. Many, perhaps all, belong under other titles.

GROUP D. ENDOTHELIOMATA.—The endotheliomata form a group of tumors which are very difficult to characterize so that they can be recognized with ease and certainty. In recent years it has been the custom to call almost every tumor which did not fit in readily with the well recognized tumors an endothelioma. This has been particularly true of certain tumors called cylindromata, which although of various origin (epithelial, mesothelial, and mesenchymal) have the one common characteristic of producing, in some by cell secretion, in others by hyaline transformation of vessel walls, round and cylindrical hyaline masses which are especially noticeable in fresh-teased preparations. At present there is a strong reaction against this tendency.

Endothelial cells normally line blood-vessels and lymph vessels. The cells lining the pericardial, pleural, and peritoneal cavities, and the sac of the tunica vaginalis are now generally recognized as mesothelial in origin and the tumors derived from them are classed with the carcinomata. The space between the dura and the pia is formed by a split in connective tissue, and is lined by connective-tissue cells which become flat and endothelial-like. The tumors arising from these cells are at present classed with the endotheliomata, but further researches may decide that they should be put in a class by themselves.

Endothelial cells possess few characteristics by which they can be recognized with surety; in other words, they do not possess a high degree of morphological differentiation. They are relatively large, thin, flat or curved cells with lightly staining oval nuclei, in which occur usually one or more somewhat coarse chromatin granules but no differentiated acidophilous nucleolus. They line vessels or spaces and are not supposed to secrete an intercellular substance. They are joined to each other at the edges by cement substance along an irregular line, which can be demonstrated in the fresh condition by staining with nitrate of silver. Under certain conditions endothelial cells may become very phagocytic for other cells.

None of these properties is sufficiently marked by itself to characterize with certainty tumors derived from endothelial cells, and yet it is on these more or less characteristic properties that the diagnosis of endothelioma must be based.

The diagnosis in the past has been made largely in two ways: by the process of exclusion and by the demonstration of actual connections between the tumor and blood- or lymph vessels. If a tumor resembled an epithelial growth but originated in a place where epithelium did not normally occur, it was diagnosed as an endothelioma. For example, the cholesteatoma was at one time regarded as a typical example of an endothelioma. The second line of argument used, that a tumor must be an endothelioma because actual connection between vessels or cell masses of the tumor and the blood or lymph vessels of the surrounding tissue can be demonstrated, has been shown by Ribbert to be absolutely untenable. Tumors grow by proliferation of their own cells, not by causing the cells in the tissues around them to multiply and join the tumor mass. Tumors may and often do form connections with surrounding blood- and lymph vessels and with epithelium, but that does not prove that they arose from them. The demonstration of the origin of a tumor from a given cell or tissue is possible only when it is just starting, at a stage when it is rarely or never possible to see it. As a result we are compelled to base our diagnosis on the properties or differentiation of the cells of which the tumor is composed.

Three types of endotheliomata are recognized: one arises from the endothelium of blood-vessels, a second from that of lymph vessels, and the third from the cells lining the dura. The attempt has recently been made to add a fourth, the perithelioma, as a variety of the endothelioma arising from lymph vessels.

1. *Hemangioendothelioma.*—This tumor is derived from the endothelium of blood-vessels and is rare. It grows in the form of narrow or broad anastomosing vessels of a capillary type, which may become filled up with endothelial cells so that solid anastomosing columns of cells are formed. Connective-tissue fibrillæ gradually grow in between the cells, so that the older parts of the tumor resemble more or less closely a spindle-cell sarcoma.

I have recently studied one of these tumors in which all stages of its development could be followed. The primary growth occurred on the back of a boy, sixteen years old, and was followed by three recurrences in the course of the following twenty-one months. Each time the tumor appeared in the form of a group of discrete nodules, from the size of a millet seed to masses 3 or 4 cm. in diameter. The original growth seemed to be attached to the head of a rib, which was resected, but it was not adherent to the skin, and in the recurrences the nodules could always be easily dissected out. The nodules varied from a soft, elastic, almost diffluent to a cartilaginous consistence. On section they varied from reddish to gray; the cut surface was smooth and homogeneous, like a sarcoma.

The earliest appearance of the lesions and the evident source of the recurrences were to be found in the fat and connective tissue outside of the nodules. Here occurred irregular, often long convoluted masses of capillary vessels containing red blood corpuscles and leucocytes, and lined with prominent endothelium. The capillaries ran in the connective tissue often along large blood-vessels and in places invaded fat tissue, gradually causing it to disappear and giving rise to miliary tumor nodules. In all of these small areas and nodules the capillaries were pervious, contained blood, and mitotic figures in endothelial cells were numerous.

In the large, more distinct tumor nodules the appearances were not so simple. Capillaries and larger blood-vessels were very numerous, but there were in addition solid anastomosing columns of cells and a cellular tissue resembling to some extent young connective tissue or a spindle-cell sarcoma. Both of these were found to arise from the capillary vessels in the following way: Mitoses were very numerous in the larger nodules, not only in the capillary endothelium, but also in the cell columns and in the sarcoma-like tissue. Proliferation of the capillary endothelium often led to occlusion of the lumen and the formation of a mass of cells which often assumed a more or less concentric arrangement. Proliferation of cells beyond the point of occlusion produced anastomosing columns of cells. Hemorrhages and other causes which interfered with the circulation in the young vessels probably also led to the same result.

The second stage in the development of these tumors was, therefore, due to the occlusion of a certain number of capillaries. Continued proliferation of the endothelial cells led necessarily to the formation of clumps and anastomosing columns of cells. At this stage the tumor to some extent resembled a carcinoma, but both the cell masses and the stroma showed differences.

The third stage was due to a still further change. The aniline blue connective-tissue stain showed that the very youngest of the newly formed tumor capillaries quickly become backed by connective-tissue fibrillæ. As the vessels get older the fibrillæ increase in number. In the same way the fibrillæ surround and invade the cell masses formed after the capillaries become occluded. They gradually separate the cell masses so that each individual cell is separated from its neighbor by fibrillæ. But even here small concentrically arranged clumps of cells are often found where rapid proliferation has taken place and separation of the cells has not yet been effected.

Whether or not these endothelial cells produce the fibrillæ, I am not prepared to say. The process probably is analogous to that seen in acute desquamative glomerulo-nephritis where connective-tissue fibrillæ soon extend in between all the desquamated epithelial cells, probably in consequence of a physiological demand for them.

2. *Lymphangioendothelioma.*—This form of endothelioma is derived from the endothelial cells lining lymph vessels and lymph spaces. It usually grows in the form of tube-like or slit-like anastomosing canals, but may form solid anastomosing rows and frequently also concentric masses of cells.

In a case which I have had, the tumor was situated in the lumbar region behind the kidney. It measured over 7 cm. in diameter and was made up entirely of freely anastomosing round, irregular, and slit-like cavities of various size, lined with low, endothelial-like cells (Fig. 4152). In a few areas the lumina of the vessels and the cells to some extent approached a cuboidal form. An occasional endothelial cell in mitosis was found. All of the vessels were backed by a small amount of connective tissue which in places was very œdematous and contained numerous plasma cells.

The term *perithelioma* is applied to a tumor which grows in such a way as to form a sheath around blood-vessels. It is supposed to originate from the endothelial cells (the so-called perithelium) lining the perivascular lymph space. The most typical example is found surrounding the vessels of the brain. If this supposition is true, then a perithelioma is a special form of lymphangio-endothelioma.

Sarcomata frequently grow around blood-vessels in such a way as to form a sheath to them, but this manner of growth is rarely or never entirely perithelial. Parts of the tumor or even the greater portion of it may show the picture of an ordinary melanotic, alveolar, or even spindle-cell sarcoma.

The perithelial form of growth is probably largely accidental, and dependent more or less on nutrition. The cells nearest the vessels are best nourished; those farthest away, least so. If necrosis takes place the cells around the vessels are often preserved. The necrotic portions are in time more or less completely absorbed, with the result that the cell sheathed vessels are but lightly bound together, and in the fresh condition can often be pulled out like the tubules of a normal testicle. It is often possible in a single tumor to trace the entire development of a perithelial growth from a sarcoma of an ordinary type.

It is probable that hemorrhage may act like necrosis in giving rise to the perithelial type of growth.

3. *Endothelioma of the Dura.*—This is the best known of the endotheliomata. It occurs usually as a circumscribed, flat, or more or less hemispherical, occasionally pedunculated tumor. The size varies greatly, but is rarely greater than that of a walnut. The tumor is very lightly attached to the dura by blood-vessels and a slight amount of connective tissue.

The structure of the tumor varies greatly; it may be cellular like a sarcoma or more or less fibrous like a cellular fibroma. The cells may have an alveolar arrangement with the cells often grouped in whorls or the cells may be more or less uniformly distributed in the stroma.

Two cases at the Boston City Hospital illustrate well the two extremes of type. The first measured 5 x 4.5 x 4 cm., and was situated in the right cerebral hemisphere 3 mm. from the longitudinal fissure and 3 mm. posterior

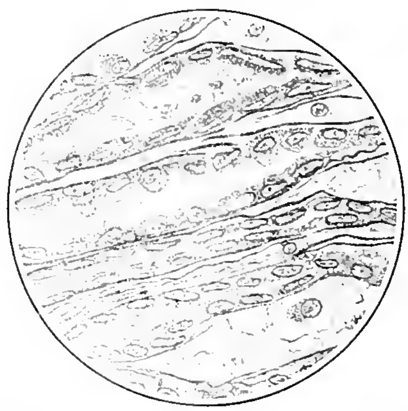

FIG. 4152.—Lymphangioendothelioma, showing Spaces Lined with Flattened Cells and Œdema of the Connective-Tissue Stroma.

to the fissure of Rolando. It was sharply circumscribed, everywhere separated from brain tissue by pia, and presented a cauliflower-like surface. Microscopically it showed dense masses of cells arranged for the most part in whorls, between which ran a stroma consisting of blood-vessels surrounded by a small amount of connective tissue, which showed little tendency to extend out between the cells. The nuclei were oval, vesicular, finely granular, with one or more coarse chromatin granules but no differentiated nucleolus. Numerous mitotic figures showed that the tumor was growing rapidly. In places were many hyaline concentrically-layered bodies often containing the faint remains of nuclei.

The second case occurred in the right occipital lobe and measured 8.5 x 6 x 6 cm. It was slightly lobulated and was separated from the brain tissue by the pia. On section it was almost homogeneous in appearance; the surface was grayish, only moderately translucent, and slightly granular. The tissue could be very easily teased apart.

Microscopically the tumor might readily on casual inspection be mistaken for an odd form of spindle-cell sarcoma. Apparently it consisted of numerous spindle and oval nuclei embedded in a fairly abundant connective-tissue stroma. Careful study, especially of sections stained by the aniline blue method, showed that the connective-tissue fibrillæ and the cells were disposed in layers. The layers of fibrillæ ran in parallel planes, which bent and twisted in various directions and often surrounded the blood-vessels. Both surfaces of each layer of fibrillæ were lined by large flat cells, which sometimes piled up two or three cells in thickness. The nuclei were oval and flat, stained lightly, and contained one, sometimes two or more, coarse chromatin granules. No mi-

... ...ats could be found. A few concentrically lay ...ed bodies were present.

Apparently just as the endothelial cells lining blood- and lymph-vessels attempt in tumor formation to form vessels, and, failing in this, give rise to solid columns of cells, so the endothelium lining the dura tends, sometimes at least, in the new growths to which it gives rise to form spaces lined with endothelium. The connective-tissue fibrillæ may be produced, as Ribbert claims, by the endothelial cells, but I prefer to regard them as produced by true connective-tissue cells which grow in with the blood vessels and extend in between the endothelial cells because there is a physiological demand for them.

F. B. Mallory.

SARSAPARILLA, U. S.—The root of *Smilax medica* Chamisso et Schlechtendal (Mexican, Vera Cruz, or Tampico sarsaparilla), *Smilax ornata* Hooker f. (Jamaica, Central American, Costa Rica, or Lima sarsaparilla), *Smilax papyracea* Duhamel (Brazilian, Para, or Rio Negro sarsaparilla), or a species known commercially as *Honduras* sarsaparilla (fam. *Liliaceæ*). Fruiting specimens just received by the writer from Honduras indicate that the last mentioned is from *S. grandifolia* Regel. Various other species than those here named have been recorded as yielding sarsaparilla, but it is doubtful if any appreciable amount of the present article of commerce so originates. The genus *Smilax* L. is large, being credited with some two hundred species. Its habits and characters are well illustrated by our ordinary cat briars, greenbriars, or bread-and-butter vines, the green, tough, spiny, tendril-bearing stems of which constitute the principal element in dense thickets of the Eastern United States. Apparently, the Northern species do not possess the medicinal properties of those of the tropics. The aerial stems of the latter grow from excessively long slender rhizomes, which run just underneath the loose forest mould, and send down from each joint a fascicle of from few to many tough, elongated roots, which, dried, constitute the drug sarsaparilla. They are collected at

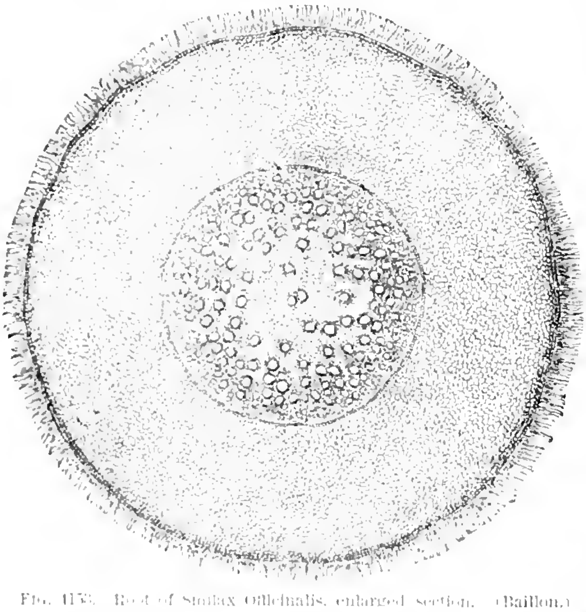

FIG. 4153.—Root of Smilax Officinalis, enlarged section. (Baillon.)

about the close of the rainy season, probably chiefly with the idea of saving labor, since the ground is then soft and the roots are more easily torn out. After being collected and dried, they are packed in various ways, as explained below, these different forms of packing being characteristic and aiding in identification, although the practice of packing a cheaper article to imitate a more expensive one is not unknown. Other forms of sophistication are not common, though other roots, sticks, and even stones are occasionally found in the interior of the packages.

DESCRIPTION.—Mostly more than a metre (more than a yard) in length, and 4–6 mm. ($\frac{1}{6}$–$\frac{1}{4}$ in.) thick, with few or many fine roots adhering; externally varying from light-gray-brown and smooth, with few deep and sharp wrinkles, to dark- or orange-brown and less smooth, and with more and smaller wrinkles; internally whitish, with a thick, mealy, or sometimes horny cortex, a circular wood-zone and a thick pith; fracture tough; nearly inodorous; taste mucilaginous, somewhat sweetish and bitter, slightly acrid.

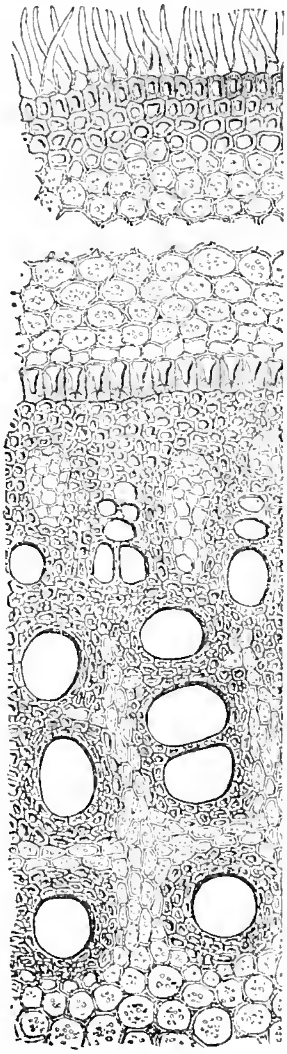

FIG. 4154.—Magnified Section of One-Half Diameter of Root of Smilax Officinalis. (Baillon.)

The thick, woody, knotty rhizome, if present, should be rejected.

As a rule, Honduras and Brazilian sarsaparillas have the cells of the parenchyma more densely crowded with starch grains, so that they are termed "mealy sarsaparillas," the other two being denominated "non-mealy." It is probably due to this excess of starchy contents that the mealy sarsaparilla wrinkle less deeply in their drying, their wrinkles, however, being usually much more numerous than those of the non-mealy varieties.

Honduras Sarsaparilla consists of the roots separated from the rhizomes, folded back and forth to a length of about two feet, and very closely and tightly wound from end to end with one or more of its own roots, the folded ends not cut off, but projecting slightly beyond the winding at either end. These rolls have usually a diameter of about two and a half or three inches. This variety is generally of a rather light brown color. It varies greatly in its tendency to bear rootlets, though as a rule these are not numerous. A transverse section made near to the rhizome shows the diameter almost equally divided between the cortex, wood, and pith. The cells of the endodermis are rather thin-walled, the thickness of the outer and inner walls nearly equal, and the form of the cells nearly square.

Brazilian Sarsaparilla also consists of roots freed from the rhizomes, but it is differently packed. The rolls are very large, a yard or more in length and a foot in diameter. They are rolled with extreme tightness, and closely wrapped with a thin tough vine. The folded ends are cut squarely off and the trimmings enclosed in the centre of the roll next packed, the rolls thus possessing a swollen middle portion. This root is of a very dark-brown color and bears a large number of branching rootlets. It is finely wrinkled. The transverse section shows the woody zone much narrower than the cortical and the pith large. The cells of the endoderm are radially elongated, with an oblong aperture, and the inner portion of the wall is thicker.

Mexican Sarsaparilla has the roots of each node still attached to a short portion of the hard woody rhizome. They are loosely folded into somewhat flattened bundles, much thicker at one end and loosely tied with a root which passes several times around in an irregularly spiral manner. The root is of a pale drab-brown, often a little shining, almost free from rootlets and bearing but a few wrinkles, which are exceedingly deep and sharp. The transverse section shows very small pith and wood zones, with a very broad cortical layer. The endodermal cells quite closely resemble those of the Brazilian.

Jamaica Sarsaparilla presents two distinct forms. The plant named above is native of Central America, whence the most of our supplies are received. This root is of a dark gray-brown color, rather thin, sharply wrinkled, and very abundantly supplied with branching rootlets. It is always separated from the rhizome and may come either pressed into square bales or tied into rolls with folded ends, like those of the Honduras, but usually thicker, looser, and with a much scantier and looser winding. The other form is known as "native Jamaica" (species of Smilax undetermined), and is the product of plants which have been introduced into the island named. This root is usually much thicker and cleaner looking, and is almost invariably of a bright orange-yellow or orange-red color. It is packed either in bales or in short, thick, lightly tied bundles. The endodermal cells are radially elongated and their walls heavily thickened.

The widest differences of opinion exist as to the relative values of the different varieties of sarsaparilla, and the predominant opinion is not constant, one variety maintaining its position as a favorite for a time, and being then displaced by another. On the whole, Honduras sarsaparilla probably enjoys a wider preference than any other, though the native Jamaican is mostly preferred in Great Britain.

Constituents.—Most earnest attempts have been made to find a tangible and useful active principle in sarsaparilla, but with only partial success. From three to fifteen per cent. of starch, according to the variety, a trace of volatile oil, a small amount of resin, pectin, etc., are unimportant. The activity appears to reside in a mixture of three saponin-like bodies, amounting in the specimens examined by Otten to nearly three per cent. Some confusion of ideas has arisen regarding the relations of these substances to one another, on account of the variety of names assigned them by different investigators. Both *parillin* ($C_{26}H_{44}O_{10}$) and *smilasaponin* ($C_{20}H_{32}O_{10}$) have been called "smilacin," and on account of this indefiniteness the last name has been dropped from scientific literature. The third body, *sarsasaponin* ($C_{22}H_{36}O_{10}$), is about three or four times as active as either of the preceding. Like parillin, it is crystallizable, while smilasaponin is not. These constituents are all more or less soluble in water or alcohol, more so upon the application of heat. Either the decoction or a preparation with a warm mixture of alcohol and water well represents the drug. The constituents are fatal to animals, with the general symptoms of poisoning by the sapotoxins.

Action and Use.—Sarsaparilla was first carried to Europe about 1536–45, and first or early employed as a cure for the same disease with which it has been since most generally associated, and for which another smilax, "China" had previously been used. The use in numerous other slow diseases, especially in eruptions and as a "blood purifier" in general, followed, and has continued extensive until the present time. Although now it has been nearly discarded as a serious medicine by physicians, it is still a much-prized popular remedy, and is extensively used, the world over, for syphilitic and scrofulous diseases. Its reputation is doubtless greatly and unduly enhanced by the enormous popular advertising of numerous proprietary articles bearing its name, but in reality quite different substances. On the other hand, there can be no doubt that the judicious use of sarsaparilla by physicians should be extended. The valuable depurative effects of the saponins, not only by promoting excretion by the intestines, but through most other channels, requires no argument, and the timely use of a laxative dose of sarsaparilla, perhaps at the soda fountain—if only a genuine article could be there expected,—may well prevent the necessity for more violent treatment later on. The dose of any preparation should represent from 4 to 8 gm. (ʒ i. to ij.). The Pharmacopœia provides a fluid extract; a compound decoction of ten-per-cent. strength, with two per cent. each of sassafras, guaiac wood, and liquorice root, and one per cent. of mezereum; a compound fluid extract of seventy-five-per-cent. strength, with twelve per cent. of liquorice root, ten per cent. each of sassafras and glycerin, and three per cent. of mezereum.

Allied Product.—China root, from *Smilax China* L., in large, hard, jalap-like tubers, is used in the East for the same purposes as sarsaparilla.

Henry H. Rusby.

SARSAPARILLA, FALSE. (*Aralia nudicaulis* L.) See *Araliaceæ*.

SASSAFRAS, U. S. P.—*Sassafras bark.* The dried bark of the root of *Sassafras Sassafras* (L.) Karsten. (*S. variifolius* [Salisb.] Kuntze—fam *Lauraceæ*). Although all parts of the sassafras tree are aromatic, the bark of the root is selected for official purposes because its aromatic properties differ in kind from those of the leaves and branches, and are far stronger than the similar properties of the bark of the trunk and the wood of the root and trunk. The British Pharmacopœia makes the root,

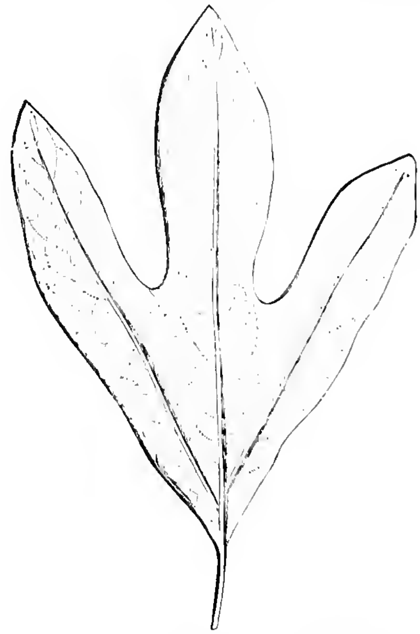

Fig. 4155.—One of the Three-Lobed Leaves of Sassafras. (Baillon.)

the German Pharmacopœia the wood of the root, official, while certain others include, or even specify, the wood of the trunk or at least of its lower portion. There can be no question that the official article of the United States Pharmacopœia is very superior to any other part of the plant. The sassafras tree grows very abundantly in light soil and exposed or partly exposed situations from eastern Canada southward, being collected chiefly in the coast region. It occasionally reaches a height of seventy feet or more and a trunk diameter of upward of three feet, though usually its height is from twenty-five to forty feet and its trunk diameter little more than a foot. The root is much and irregularly branched. When it is freshly dug, its outer color is whitish and its wood yellowish or brownish-white, but the former soon turns gray and the latter of a rusty red or brown after collection. Annual rings are apparent in cross-section, though less conspicuous than in most trees of the same region. The bark of the trunk is ashy gray and deeply fissured externally, whitish within, soon turning rusty brown, though not so deeply as does that of the root. The wood of the trunk is similar to that of the root, though less deeply colored. The young twigs are at first deep green and smooth, gradually becoming brownish warty, then brown and fissured with age. The large pith of the branches is described below. The form of the leaf is displayed in the accompanying cut, though often not lobed or with a lobe on only one side. The leaves are thin and downy when very young, soon becoming thickish and smooth. The diœcious, small, yellowish flowers are borne in umbels or corymbs, and appear somewhat before the leaves. All parts of the tree are aromatic, bitter, and strongly mucilaginous.

The drug is thus described:

In irregular, warped, chip-like fragments, 5 mm. (⅕ in.) or less in thickness, the thicker pieces deprived of most of the gray corky layer; light rust-brown, or with more or less of the gray-brown cork adhering and exhibiting its outer surface softly and rather finely scaly, from numerous short, intersecting, shallow fissures; inner surface obscurely short-striate; light, soft, and fragile, with a short, weak fracture which exhibits a broad, irregular, whitish layer between two rust-brown ones; strongly and peculiarly fragrant; taste sweetish and bitterish, aromatic, mucilaginous, and slightly astringent.

The stem-bark is in strips or elongated pieces, with a lighter-gray, more deeply and longer fissured outer surface, and is less aromatic, more mucilaginous and bitter.

The most important constituent of sassafras is its volatile oil, of which there is sometimes nearly ten per cent. When fresh, the bark contains a large amount of a peculiar tannin, which, after collecting, gradually becomes converted into the peculiar granular yellowish brown substance, *sassafrid*, which is readily dissolved in alcohol. A large amount of starch, much gum, and an unstudied bitter principle also exist. The properties of sassafras are almost wholly referable to its volatile oil. No preparation of it is official, but it is largely used in the household, and to some extent by physicians, as a stimulating diaphoretic and as a deobstruent or alterative ("blood purifier"), stimulating the excretions of the kidney and skin. For these purposes, the infusion is commonly employed. It should have a strength of five per cent., and may be taken in wineglassful doses.

Oil of Sassafras (*Oleum Sassafras*, U. S. P.) is defined as a volatile oil distilled from sassafras, and it is directed to be kept in well stoppered bottles, protected from light. Although thus defined as obtained from official sassafras, it is really obtained from the entire root, the wood of which yields from one and one-half to two per cent. It is thus described by the Pharmacopœia:

A yellowish or reddish yellow liquid, having the characteristic odor of sassafras without the odor of camphor, and a warm, aromatic taste. It becomes darker and thicker by age and exposure to the air.

Specific gravity: 1.070 to 1.090 at 15° C. (59° F.).

Soluble, in all proportions, in alcohol, the solution being neutral to litmus paper; also soluble, in all proportions, in glacial acetic acid, and in carbon disulphide.

If to five drops of the oil five drops of nitric acid be added, a violent reaction will take place, producing at first a red color, and finally converting the oil into a red resin.

If to a few drops of the oil a drop of sulphuric acid be added, a deep red color will be produced at first, which soon becomes blackish.

The oil consists chiefly of *safrol* ($C_{10}H_{10}O_2$), with a small percentage of *safrene* ($C_{10}H_{16}$) and a very small amount of eugenol. Safrol fully represents the properties of the oil.

Oil of sassafras differs but little in its action and uses from ordinary stimulating volatile oils, for example, oil of peppermint. Although an active carminative, it is scarcely so efficient as oil of peppermint or oil of anise in that direction. On the other hand, it appears to be rather more freely excreted through the skin and a more efficient diaphoretic. It is also distinctly laxative and its reputation for stimulating the excretory functions appears to be justified. The dose of this oil is one to five minims. There is no official preparation.

Sassafras pith (*Sassafras medulla*, U. S. P.) is defined as the dried pith of the sassafras and is thus described:

In cylindrical, straight, curved, or coiled pieces, one to several inches in length and 3 to 8 mm. (⅛ to ⅓ in.) in diameter, or in split portions of the same; white, very light, and spongy; inodorous or with a slight odor, as well as taste, of sassafras; very mucilaginous.

Macerated in water, it forms a mucilaginous liquid, which is not precipitated on the addition of alcohol.

Its aromatic content is entirely insignificant and it is valued wholly for its gum, which readily forms a mucilage upon maceration with water. This mucilage possesses the important property of mixing with alcohol without precipitation, and it becomes a useful vehicle for the administration or application, especially to the eye, of active substances. Its properties in general are merely those of mucilages. Its mucilage is official and is directed to be made freshly, when wanted, by macerating 2 gm. of the pith in 100 c.c. of water for three hours and straining.

Several other vegetable products are called sassafras in other countries, but none of them is of interest in our Materia Medica. *Henry H. Rusby.*

SASSY BARK.—*Mancona Bark.* The bark of *Erythrophlœum Guineense* Don. (Fam. *Leguminosæ*), a good-sized, acacia-like tree, growing in tropical Africa, and employed by the tribes of the west side like Calabar beans, as an ordeal. It was made known in Europe and America about forty years ago, and was revived as a medicine about ten years since. It is a ponderous bark, heavier than water, of a dull red color, a fissured external surface, and a short fracture. Odor slight, taste astringent. The active principle of sassy bark is *erythrophlœine*, a crystalline alkaloid, first obtained by Gallois and Hardy. It is an active heart-poison of the digitalis kind, producing slowing of the pulse, increase of blood pressure, and in experiments upon animals death, with the heart in systolic contraction. The powdered drug is a powerful sternutatory. But little use has been found for this potent medicine. It is sometimes used like digitalis, in doses of one to three grains, of the bark, in the form of a tincture, but is far less certain and regular and even more inclined to upset the stomach. It is said to be employed at home in dysentery, etc., with benefit, as well as in intermittent and other fevers. In full doses it is nauseating and emetic, as well as somewhat narcotic.

ALLIED PLANTS, ETC.—See *Senna*. *W. P. Bolles.*

SAUNDERS, RED.—*Santalum Rubrum*, U. S. The heart-wood of *Pterocarpus santalinus* L. f. (fam. *Leguminosæ*).

This article, often called ruby wood or red santal, is the product of a small tree of India, collected chiefly in the Madras Presidency, and now mostly from cultivated plants. The wood is imported in billets three or four feet long and from two to eight or nine inches in diameter, the bark and sapwood having been removed. It is of a bright blood-red color within, but darker upon the surface, becoming at length nearly black with age and exposure. For pharmaceutical use, it is usually cut into chips or rasped into powder. It is almost odorless and has only a slight astringent taste. Its coloring matter is santalin or santalic acid, crystallizing in minute red prisms, soluble in alcohol, ether, alkalies, and a few essential oils, but not in water, which is scarcely colored by red saunders. The article is essentially a dye-stuff, being without physiological or medicinal power and used purely for coloring purposes, as in the compound tincture of lavender, which contains about one per cent. of it.

W. P. Bolles.

SAVILL'S DISEASE. See *Dermatitis Epidemica.*

SAVINE.—*Sabina,* U. S. P. The leaves and young twigs of *Juniperus Sabina* L. (fam. *Pinaceæ* or *Coniferæ*). This is a compact, horizontally spreading, evergreen shrub or small tree, resembling our common red cedar on a small scale, and bearing similar berries. It is widely distributed through the north temperate zone of the Old World, and is also met with in the Northern United States (in the Great Lake region) and in Canada. The medical supply comes from Europe, chiefly from Switzerland, in "short, thin, subquadrangular branchlets, the leaves in four rows, opposite, scale-like, ovate, lanceolate, sessile, more or less acute, appressed, imbricated, bearing on the back a shallow groove containing an oblong or roundish gland; odor peculiar, terebinthinate; taste nauseous and bitter."

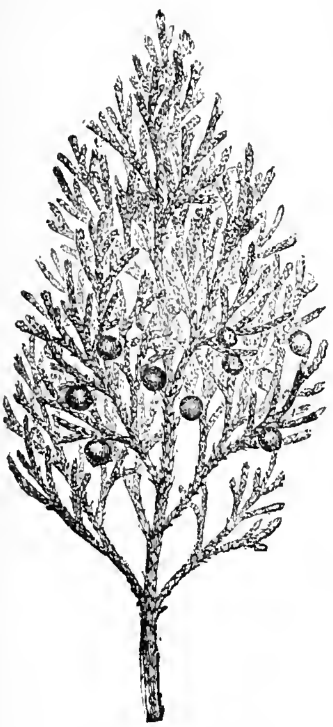

FIG. 4156.—Savine, Fertile Branch. (Baillon.)

The odor and taste of savine are mostly due to from two to four per cent. of essential oil (*Oleum Sabinæ,* U. S. P.), a pale-yellow, terebinthinous liquid, becoming thicker and darker by age, colorless if redistilled, of a specific gravity of about 0.910. It has the odor of savine, a sharp, bitter, camphoraceous taste, and is more rubefacient and irritating to the skin than others of its class. Tannin and resin are less important constituents of savine.

ACTION AND USE.—Savine and its oil are essentially like, but more intense than, oil of turpentine in physiological and therapeutical properties; irritating to the skin and mucous membranes, to the urinary apparatus by which they are eliminated, and to the uterus, which they may cause to abort. Besides these effects, convulsions and coma may follow. Vomiting, diarrhœa, gastro-intestinal inflammation, strangury, with or without convulsions or unconsciousness, these are the usual symptoms of savine poisoning; abortion may or may not take place. This potent drug is not much employed. It has been given as an emmenagogue, also as a hæmostatic, for leucorrhœa and other purposes mostly connected with the uterus. It is not infrequently used with criminal intent to produce abortion, usually without success, unless it nearly or quite kills the mother also; externally it is the basis of some moderately useful stimulating ointments, liniments, and "hair-restorers."

In this country, the oil of juniper, which is milder, is perhaps generally substituted for oil of savine. Oil of turpentine is also often substituted for or mixed with it. Oil of savine can be distinguished by the fact that it does not form a solid mass with hydrochloric acid; also by the fact that very little of it distills under 200° C.

The dose of savine (leaves) is about 0.5 gm. (gr. viij.); of the oil, from one to four or five drops. A fluid extract of the former (*Ex. Sabinæ Fluidum,* U. S. P.) is an eligible preparation and the basis of the cerate (*Ceratum Sabinæ,* U. S. P.), strength about 25 to 100 savine.

SAVORY, SUMMER. See *Labiatæ.*

SAW PALMETTO.—This palm, *Serenoa serrulata* forms the common palmetto scrub of South Carolina, Georgia, and Florida. The whole plant has marked demulcent and nutritive properties, and is extensively used as a local remedial agent in all forms of disease of the mucous membranes, especially when associated with debility and wasting. Its use is followed by an improved digestion, increased strength and flesh, and a soothing influence on any irritable state of the membranes. It is used in catarrh, ozæna, and bronchitis, and has a special value in diseases of the bladder and reproductive organs. Reginald Harrison[1] has found it very beneficial in irritable states of the bladder, and compares its action to pareira. It is also reported to be of benefit in affections of the prostate gland. Another property that is claimed for it is its vitalizing and strengthening action upon weakened and wasted glands of the generative organs. It is said to cause a rapid development of the mammæ, ovaries, and testes, when these organs are debilitated as the result of masturbation and sexual excesses of all kinds.

The berries and seeds contain a large percentage of a fixed oil, upon which the medicinal properties are said to depend.[2] The fluid extract of the seeds is the most convenient form for administering the drug; it is given in half-drachm to one-drachm doses, repeated three or four times a day.

SCABIES (Latin, *scabies,* an itching eruption, from *scabo,* I scratch).—Synonyms: The Itch; German, *Krätze*; French, *Gale.* Scabies is a contagious disease of the skin, wholly local in character, due to the presence of an animal parasite—the *acarus* or *sarcoptes scabiei* (see Arachnida, in Vol. I.) in, and upon, the skin. The eruption present may vary from the smallest amount imaginable, a few papules, up to the most severe development of inflammatory lesions, even such as to render the patient helpless; the subjective sensations may vary from a slight pruritus, which is described as not unpleasant when relieved by scratching, up to an itching which is almost unendurable, causing restless nights and distressing days.

The most common sites for the lesions of scabies are the hands, especially about the wrists, in the soft skin between the fingers, and on the sides of the hands. But in many cases the eruption is entirely absent from this locality and is well marked elsewhere. In males the penis seldom escapes, and in females the region of the nipples is very apt to be affected; the anterior fold of the axilla is a very common seat of the lesions, and the elbows and extensor surface of the forearms are sometimes most severely affected. In those who sit a great deal the buttocks often present an abundant eruption. In infants and children the softer parts of the feet and ankles generally exhibit lesions. It may be said that the head is never affected by scabies.

The eruption of scabies exhibits the greatest variety of lesions, from the smallest papules and vesicles to large pustules, often ecthymatous in character, and in weakly children pustular bullæ may form on the hands. The bulk of the lesions is papular, although small vesicles can generally be seen on tender portions of the skin during some period of the disease. Mingled with these primary lesions there are generally found the results of scratching, viz., abraded surfaces and those covered with crusts.

The only single pathognomonic sign of scabies is the *cuniculus*, furrow, or burrow (German, *Milbengang*; French, *sillon*), which is caused by the penetration of the female beneath the epidermal layer of the skin in the search of a place where she may lay her eggs; the male seldom, if ever, goes beneath the skin. This cuniculus consists of a minute, dark-colored line, generally somewhat beaded in appearance and curved, appearing much as if a bit of dark sewing-silk had been run beneath the surface; rarely, it is as long as a fourth of an inch, more often half that length; and generally it may be seen to terminate at one end in an inflamed papule or vesicle, or sometimes to run over a pustule. The female insect will be found at that end of the furrow, and the dark line is her track, which is found to be filled with eggs in various stages of development, and, among them, black particles of fæces. If the skin is washed these dark lines, instead of being removed, become more apparent; but in recent cases, or in individuals who are very cleanly or have undergone treatment, it is often impossible to discover any of these cuniculi, although the disease may still exist, and, if left alone, it will increase and may be communicated to others.

Scabies is not a very frequent disease in this country, forming only about 1.5 per cent. of a large number of skin cases analyzed. In other countries it is more common, and in Glasgow it formed twenty-five per cent. of ten thousand cases analyzed by McCall Anderson.

DIAGNOSIS.—Considerable care is often required to diagnose a mild or unusual case of scabies, and cases sometimes go unrecognized for a long time. The disease most commonly confounded with it is eczema, which may present almost identical appearances, except that there are no cuniculi; when these latter are positively found the diagnosis is certain. The location and distribution of the eruption, the history of contagion, and the multiform character of the lesions are generally sufficient to establish the diagnosis. Scabies may also be confounded with lichen, pityriasis, prurigo, pruritus, and urticaria papulosa.

ETIOLOGY.—There is but one cause of scabies, the presence of the parasite (acarus or sarcoptes scabiei), whose removal or destruction is followed by the cessation of the disease. It often occurs, however, that the treatment employed may occasion an amount of artificial eruption or dermatitis which may mask the true affection, and may even remain after the real cause of the disease has been destroyed; this second eruption may require a very different treatment, of a soothing character.

PATHOLOGY.—The only pathologial lesions, aside from the presence of the cuniculus, are those connected with inflammation of the skin. The lesions are simply inflammatory areas of greater or less size, caused either by the direct irritation of the burrowing insect, or by the scratching or other measures employed for the relief of the itching, or by both. When the local irritation is removed the eruption ceases; if the acari could all be removed mechanically, picked out, there would be no eruption. In patients who are paralyzed on one side, or who have been unable to scratch, there is very little eruption on the portions of the skin which are out of reach.

TREATMENT.—The treatment of scabies is purely local and consists in such measures as destroy the life of the parasitic insects and their eggs. The patient first takes a warm bath, using plenty of strong soap rather alkaline in character, such as the sapo viridis or the common laundry soap, and rubbing the affected parts so as to break the burrows as much as possible. After drying, the affected parts, or even much of the body, should be well rubbed with an ointment of which sulphur is a chief ingredient. The ordinary sulphur ointment diluted once, with the addition of a drachm of liquid storax to the ounce, answers as well as anything. After thorough friction with this for at least half an hour, the patient puts on underclothes which are to remain on night and day until the end of treatment. The ointment should be freshly rubbed in twice daily for several days, and a bath is to be taken on the third day, the ointment being again rubbed in and a fresh suit of underclothes put on. After three days more of treatment another bath may be taken, and it is then to be expected that the cure is complete. But frequently some of the cuniculi will be found to have escaped being broken, or new infection may come from the clothing or elsewhere, and in such case the treatment must be repeated. Sometimes an artificial eruption is excited by the treatment, when soothing remedies are required. The clothing should always be treated; the underclothes should be boiled a long time and very thoroughly ironed; the outer garments may be baked or very thoroughly ironed on the wrong side. Patients should be more or less isolated, although when they are under treatment the chances of communicating the disease are very small.

PROGNOSIS.—The prognosis is, of course, favorable; there can never be the slightest harm in curing even the most inveterate or severe cases of scabies. In the hospitals abroad it is claimed that a cure is effected in a few hours, but it is questionable if, in the large majority of cases, the relief is more than temporary, a portion only of the parasites being killed. Practically, cases require treatment for a number of days, or even weeks, to make the cure certain; when the skin is delicate the active parasitic treatment may have to be interrupted, owing to the dermatitis excited, and occasionally it will be found difficult to use remedies strong enough to effect a cure.

L. Duncan Bulkley.

SCAMMONY.—(*Scammonium*, U. S. P., B. P.) A resinous exudation from the living root of *Convolvulus Scammonia* L. (fam. *Convolvulaceæ*). This is a perennial herb of the Levant, having a long, thick, cylindrical, several-headed, but otherwise usually simple, milky-juiced root, and numerous twining stems, resembling those of an ordinary morning-glory vine. The root, which is official in the British Pharmacopœia, is up to a metre in length, and a decimetre in diameter, at the crown, light brownish-yellow without, white within, fleshy, and resinous. The scammony is collected by cutting off the living root at the crown and either scraping off the exudation as it appears or placing some receptacle, commonly a mussel shell, at the lower side to receive it as it runs down. It may dry at once, a very high grade of the drug thus resulting; or, as is more usual, the separate collections are laid aside until enough is accumulated to make a "cake," when it is all moistened and kneaded together. In this way the bubbles and sour odor of what is known as "Virgin scammony," are produced.

Scammony is in irregular, angular pieces, or circular cakes, greenish-gray or blackish, internally porous and of a resinous lustre, breaking with an angular fracture; odor peculiar, somewhat cheeselike; taste slightly acrid; powder gray or greenish-gray. The porous, bubbly texture and the sour, cheesy smell are results of fermentation during the process of drying. It is soluble to the extent of three-fourths in ether. The costliness and opaque color of scammony render it especially liable to adulteration. Lime, flour, ashes, gum, etc., are among the common admixtures. The proportion of resin is the best test of purity. This resin (*Resina Scammonii*, U. S. P.) is obtained by digesting the drug with alcohol and evaporating the tincture so obtained, or by treating the root in the same way. It is a brown, translucent brittle resin, with a sweet fragrant odor if obtained from the root; but, as is usually seen, from crude scammony, it is more greenish and dirty in color, and has the odor of scammony itself. In action and value the two products are about the same.

COMPOSITION.—The peculiar resin of scammony, unfortunately called *jalapin*, and now known as *scammonin*, first obtained in a state of purity by Johnston, in 1840, differs from the *convolvulin* of jalap by its solubility in ether.

When purified, it is a colorless, translucent, brittle non-crystalline resin, tasteless and odorless, of nearly neutral reaction, and freely soluble in ether. It is a glucoside, and resolvable into *scammonic acid*, a crystalline substance, and sugar. Good scammony contains eighty or ninety per cent. of this resin.

Action and Use.—Scammony and its resin are to be counted among the very active drastics, excelled only by croton oil and elaterium. Their action is similar to that of jalap, but considerably more intense. They are used as derivatives and hydragogue cathartics in cases of cardiac and renal troubles associated with dropsy. The action of scammony resembles that of jalap, but is more intense. Aromatics and carminatives are appropriate adjuvants. Dose, of good scammony, half a gram or so; of the resin, 3 or 4 dgm. The compound extract of colocynth contains fourteen per cent. of resin of scammony

W. P. Bolles.

SCAPULA, SURGICAL AFFECTIONS OF THE.—Diseases of the Scapula.—Acute periostitis and osteomyelitis of the scapula are rare. When present they are usually the result of traumatism followed by infection, and affect most commonly prominent portions of the bone, such as the spine.

Tuberculous osteomyelitis of the scapula is much more common and may give rise to extensive caries and necrosis. Cold abscesses may form and reach the surface at some distance from the focus in the bone. In rare cases the shoulder-joint may become involved.

The treatment of tuberculous disease will depend upon the extent of the local process. Small foci may be scraped out with the Volkmann spoon and treated later by iodoform injections. Larger foci may require resection of a part of the bone, such as a portion of the body or the spine. Complete excision of the scapula is seldom indicated.

Tumors of the Scapula may be either benign or malignant, the latter being the most common. A recent collection of 64 cases made by Langenhagen showed the following relative frequency: Exostosis, 8; chondroma, 14; fibroma, 5; carcinoma, 23; sarcoma, 12; uncertain tumors, 2.

The tumor may reach an enormous size, and in case of the malignant varieties the surrounding parts may become invaded. Some tumors grow into the axilla, others spread to the adjacent muscles, and may eventually ulcerate through the skin. Metastases may occur in the pleura, lungs, vertebræ, or some other internal organ.

The treatment of malignant neoplasms consists in excision of the scapula provided that the tumor has not involved the arm. In the latter case removal of this as well may be indicated (interscapulo-thoracic amputation).

Benign tumors, when circumscribed, may be removed by partial resection of the portion of bone involved. The usual incision for excision of the scapula begins over the acromion, runs along the spine to its inner border and there descends to the angle. Through this incision the muscular attachments are divided close to the bone, and the whole bone is removed. If possible that part of the acromion should be preserved which receives the insertions of the trapezius and deltoid muscles. Otherwise the function of these muscles will be lost.

Fractures of the Scapula.—These are comparatively rare injuries (according to various authors from one to four per cent. of all fractures), and occur chiefly in adult males.

The following varieties of fractures occur:

1. Fracture of the body of the scapula (including one of the angles).
2. Fracture of the glenoid cavity.
3. Fracture of the neck.
4. Fracture of the acromion and spine.
5. Fracture of the coracoid process.

1. *Fractures of the Body* are the most common. They occur usually in the infraspinous fossa, and the line of fracture is most commonly transverse. The cause is blunt violence, such as a blow or fall, and there may be considerable contusion of the overlying soft parts. In case of multiple fractures, there may be several fissures radiating from a central point. Fractures of the lower angle form a comparatively common group of fractures of the body, and may be accompanied by considerable displacement of the small lower fragment. Fractures of the upper angle are far less frequent.

The objective symptoms of fractures of the body are, as in other fractures: crepitus, false motion, and localized tenderness. These signs are not always easy to make out, especially in muscular subjects or in case of marked swelling. The scapula can be brought into prominence and thus be easier to palpate if the elbow is drawn inward in front of the chest or the arm carried backward and inward. Dislocation of the fragments is most marked in fractures of the lower angle, and is then due to the combined action of the teres major and serratus magnus muscles upon the lower fragment.

The prognosis of these fractures is good. Bony union usually takes place promptly under proper immobilization, and the function of the arm is not impaired. In the rare cases of compound fracture suppuration may occur, and the pus may burrow downward between the scapula and the muscles of the back.

The treatment consists in immobilization of the shoulder and scapula in that position which overcomes the deformity. The arm can be kept in this position by means of a Velpeau bandage to which may be added some turns of a plaster-of-Paris bandage. In about four weeks the fracture should be solid and movements of the arm may be begun. König recommends in some cases suture of the fragments.

2. *Fractures of the Glenoid Cavity.*—These are rare fractures which may involve chipping off of some portion or of the whole of the articular surface (fractures of the anatomical neck). They are sometimes associated with dislocation of the humerus. The symptoms are very obscure, and it is doubtful if a diagnosis can be made. As a dislocation of the humerus is often present, the treatment would be that of the dislocation.

3. *Fractures of the Neck of the Scapula* are of considerable practical importance. The line of fracture runs downward from the incisura scapulæ. The causes are usually some form of direct violence applied to the shoulder region, such as a blow or fall.

The symptoms resemble somewhat those of dislocation of the head of the humerus. There are a flattening of the shoulder and abduction of the arm; the acromion is prominent, and the axis of the arm is not directed toward the shoulder-joint. The chief point of difference is that the fractured piece can be felt in the axilla as an irregular object not resembling the smooth head of the humerus. By grasping the coracoid process with the middle finger and the posterior aspect of the shoulder with the thumb, crepitus can be felt on rotation of the arm. Crepitus can also be felt by palpation in the axilla. The deformity of the shoulder can be readily overcome by upward pressure on the fragments within the axilla, but recurs again as soon as pressure is stopped. In dislocation of the shoulder, on the other hand, the deformity is made to disappear only by special movements for reposition of the head of the bone.

The treatment consists in replacing the fragment by upward pressure and maintaining it in place by a pad in the axilla. The arm is secured to the body by means of a Velpeau bandage. Plaster bandages may be applied as an outside dressing. The fracture sometimes requires as long as from ten to twelve weeks for consolidation.

4. *Fractures of the Acromion and Spine* are produced by direct violence upon these prominent portions of the bone. The line of fracture is usually transverse. The most important symptoms are the irregularity in the outline of the bone, localized tenderness, and occasionally crepitus. In case of the acromion, the fracture lies either in front of the acromio-clavicular joint or near the base of the acromion. The outer fragment may be displaced downward from the weight of the arm. The treatment of fractures of the spine consists in immobilization of the arm in a flexed position. In fractures of the acromion the outer fragment is elevated by pressing the humerus upward. It is retained in position by means of a bandage

bound around the shoulder and body or by an adhesive plaster strip supporting the elbow and crossing itself over the point of fracture.

5. *Fractures of the Coracoid Process.*—These are very rare and are usually combined with some other fracture or dislocation in the vicinity. The fracture is usually near the base of the process, and results most commonly from direct violence, although muscular contraction has been known to produce it.

The chief symptoms are local swelling, ecchymosis, abnormal mobility, and crepitus. Pain can be elicited by flexion of the forearm in a supinated position, as this brings the short head of the biceps muscle into action.

The treatment consists in immobilization of the arm in a flexed position by means of a Velpeau bandage.

Benjamin T. Tilton.

SCARLET FEVER.—Synonyms: *Scarlatina* (English and Italian); *Scharlach* (German); *Scarlatine* (French); *Escarlatina* (Spanish).

Definition.—Scarlet fever is an eruptive contagious fever. Its incubative period is brief, rarely less than twenty-four hours, usually lasting for from four to six days, and not often exceeding this duration. This period is succeeded by a period of invasion, which is ushered in by fever, usually of considerable intensity, and by sore throat. A scarlet eruption begins to appear before the end of the second day, and marks the end of the prodromal, and the beginning of the eruptive, period. The eruption rapidly becomes general, and the tongue becomes stripped of its coating and assumes a raspberry-red color. The eruption slowly fades after the first few days. The fever persists until the sixth, seventh, or eighth day, or longer. As the eruption fades, desquamation begins and continues for from eight to fourteen days or more. It is peculiar in being lamellar, sometimes occurring in very large shreds and exfoliations. During the attack, and for weeks subsequently, there is an especial predisposition to renal inflammation. Scarlet fever attacks children more especially. It usually affects an individual but once.

History.—Scarlet fever is probably a disease of very ancient origin, though until three centuries ago medical writers had not recognized it; indeed, definite knowledge of it as a specific, independent affection dates back hardly two hundred years, although as early as 1589 an epidemic, which we now presume to have been scarlet fever, was described as having occurred in Sicily in 1543 (Paulus Restivas).[1] It was not until 1676 that Sydenham definitely separated this malady, as "*febris scarlatina*," from measles, and gave it an established position. The observations of writers had already been leading them toward similar views, and within a few years scarlatina became recognized all over Europe. Although its place of origin can never be known, it is probably of European birth; for it is a remarkable fact that scarlet fever has never succeeded in gaining a firm foothold in Asia or Africa. According to Hirsch, in whose most valuable work these facts have been recorded, the coast of Asia Minor is the only Asiatic district which is frequently visited with scarlatina in its severe forms. In nearly all other parts of Asia it occurs not at all, or only sporadically. Wernich, in 1871, declared the disease to be quite unknown there. In Africa, Hirsch states that it is only in Algiers and in the Azores that it is at all common. Following the carefully recorded data of Hirsch, scarlet fever appeared first in America, in New England, in 1735. It extended as far south as Philadelphia in 1746, and penetrated to Ohio in 1791. Not until 1851 was it seen in California. In 1830 it began to be generally observed in South America. In the West Indies it was first observed in 1802, in Martinique, as a mild epidemic. Greenland has heretofore escaped with but a solitary case. Australia and Polynesia appear to have escaped until 1848. In the Polynesian islands, except Tahiti, scarlatina has not been known. It is unquestionable that scarlet fever has never occurred in some localities only because the inhabitants have not been exposed to its influence; but there can be no doubt that in other countries influences prevail that oppose the development of the disease. Whether these are climatic or racial, or due to other causes, is at present unknown. The American Indian is not exempt from its ravages, nor can any different degree of susceptibility be observed in the negro race in the United States. Frick,[2] however, noted a somewhat more pronounced tendency in the negro to scarlet fever.

In the epidemic in Baltimore, between the years 1850 and 1854, of every ten thousand inhabitants 13.8 whites and 10.8 negroes died. This would indicate a relatively greater predisposition in the negro, as in the total population the whites were largely in the majority. Frick's observations were too limited to secure an unhesitating acceptance of his conclusions. It must be noted, however, that in this country the negro is rarely of unmixed African descent. He may have inherited from white progenitors some of their especial liabilities to disease. Drake and others have shown that scarlet fever prevails less in the Southern than in the Northern States. It is also probably true that the disease is more frequent in cold than in hot countries. Yet it cannot be determined that the differences depend upon temperature; Greenland has remained without an epidemic, while Algiers has experienced them frequently. In 1873–75 a severe epidemic of scarlet fever appeared in the Faroë Islands, among people who for at least fifty-seven years, and possibly never before, had not been exposed to scarlet fever.[79] The study of this epidemic, to which reference will frequently be made, gives one interesting data as to the natural course of the disease in a community in which each individual may reasonably be presumed to have been exposed, and in which immunity, due to previous attacks, can be excluded.

Frequency of Epidemics.—Scarlet fever at once shows differences from smallpox and measles in not sweeping over localities in great periodic waves. It may, it is true, sometimes invade very wide areas of territory with astonishing rapidity, but the intervals between epidemics are often very great. Without obeying any well-defined periodic law, measles is often known to prevail with noticeable violence every third or fourth year, frequently disappearing completely in the interim; so, too, smallpox usually exhibits unwonted activity at intervals of from five to ten years, or as soon as popular neglect of vaccination renders a large portion of a community susceptible to it. It is not thus with scarlatina. Hirsch has collected very valuable information upon this point. At Münster fifty years elapsed without the disease appearing. At Ulm there was only one small epidemic in seventeen years. At Tuttlingen scarlet fever had not been seen for thirty-five years previous to the epidemic of 1862–63. A number of writers, however, *have* observed an epidemic cycle in scarlet fever. Thus Fleischmann,[3] at St. Joseph's Hospital, in Vienna, observed one of four years. In Dresden, according to Gerhart, there is an epidemic cycle of from four to five years; in Munich, according to Ranke, one of three years. On the other hand, scarlet fever often prevails sporadically for a long time in a locality, finally to disappear or to spread suddenly far and wide. Mayr[4] states that in Vienna the register shows that scarlatina has never absolutely died out in fifty years. Scarlet fever is remarkable in the varying intensity of cases occurring during a given epidemic, and in the differing severity of epidemics. At one time it was regarded as an insignificant disorder, almost never proving perilous to life. Even now epidemics of an exceedingly mild type are frequent. Graves has told how, between 1800 and 1834, whenever scarlet fever prevailed in Dublin, it was so uniformly mild that medical men attributed the bad results of their predecessors to improper methods of treatment, and flattered themselves upon their superior skill, until a change in type brought their death rate quite up to that of former times.

Etiology.—There is presumptive evidence that scarlatina is due to a specific micro-organism, but the direct and positive proof is so far lacking. Authorities admit the constant presence of the streptococcus, which may be the direct cause of the inflammatory lesions of the mouth and pharynx, cervical lymph nodes, and probably of the secondary complications, as the heart, kidneys, and other tissues. It is possible that a streptococcus is the specific organism. With the streptococcus, the staphylococcus pyogenes aureus and the pneumococcus are frequently associated. In the light of our present knowledge it is impossible to state whether the toxins which undoubtedly are present are due to the activity of these secondary organisms or to some specific cause.

Class,[79] in a recent paper on the subject, has described a diplococcus, discovered by him, which he believes to be the primary infectious cause of scarlatina. He finds it invariably present in the throat secretions, blood, and scales. He differentiates it from the other micro-organisms because it produces in the pig a disease closely resembling scarlatina, because the blood of patients convalescent from scarlet fever inhibits the growth of the organism, and because it produces nephritis in guinea-pigs. He also shows that a guinea-pig injected with the blood of a patient convalescent from scarlatina may be protected from the pathogenic action of his diplococcus. The coccus in question closely resembles the staphylococcus albus. It is very sensitive to environment and at times is so modified in form as to appear as a diplococcus, a streptococcus, or a streptobacillus, the three forms sometimes being present in the same culture. Its size varies from that of a small point just to be distinguished by a one-twelfth oil-immersion lens to a coccus one-third of the diameter of a red blood corpuscle, as seen in old cultures. For routine work cultures are made in the same way as in diphtheria. It is impossible at present to state the importance of this organism in the diagnosis of scarlatina. The results of animal experimentation are not, however, conclusive.

Recent bacteriological investigations by Pearce[80] and others have not added materially to our knowledge of the specific primary cause of the disease. While we may assume the exciting cause of the disease to be an as yet undetermined germ, in the presence of which alone scarlatina is possible, the question of the predisposing causes is a much wider one and demands careful consideration.

Predisposing Conditions.—There is a widespread impression that scarlet fever prevails more especially during the fall and winter months. There is, indeed, some difference in favor of these seasons, but by no means to the extent that is generally supposed. Hirsch has tabulated the records of 435 epidemics. These prevailed 178 times in the winter, 157 times in spring, 173 times in summer, and 213 times in autumn. The same relative prevalence is shown in his tables of deaths from scarlatina. Of more than 55,000 deaths from scarlet fever in London, from 1838 to 1853, 32.1 per cent. occurred in autumn, 25.2 per cent. in summer, 24.6 per cent. in winter, 22.1 per cent. in spring. These figures, however, cannot be accepted with perfect confidence, as they must have been influenced by the mildness or severity of the several epidemics. Hirsch's data show also the season of prevalence and the severity of type for two hundred and sixty-five epidemics.

Of 77 winter epidemics	42.2 per cent. were mild. 55.8 per cent. were severe.
Of 50 spring epidemics	54.0 per cent. were mild. 46.0 per cent. were severe.
Of 66 summer epidemics	45.5 per cent. were mild. 54.0 per cent. were severe.
Of 72 autumn epidemics	48.6 per cent. were mild. 51.4 per cent. were severe.

The maxima of malignancy fall in winter and summer; but, as Hirsch remarks, the difference is unimportant. It may be concluded, however, that in the spring epidemics are usually less frequent and milder.

Scarlet fever is chiefly observed in young persons, because older people are generally protected by a former attack. Nevertheless, adults who have never had scarlet fever are less liable to take it than children similarly circumstanced. This is not attributable to differences of age, but to feeble individual susceptibility, which probably held as well during the childhood of these persons. The greatest susceptibility appears to exist between the ages of three and six years. Nearly four-fifths of all cases occur in the first ten years of life. In McCollom's table of 1,000 cases of scarlet fever treated in the contagious wards of the Boston City Hospital,[77] 50 per cent. of all cases occurred between two and six years, 78 per cent. in the first ten years, and 90 per cent. before the age of twenty years. It is certain that a not very small percentage of persons successfully resist exposure to the scarlet-fever contagion throughout life. In the epidemic at Thorshavn, Faroë Islands, in 1873–75, from a total population of 930 inhabitants, comprising all ages and not protected by a previous attack against scarlatina, only 38.3 per cent. was infected by scarlet fever. Holt is authority for the statement that not more than one-half of the children exposed take the disease. While, then, it is not difficult to understand why adults seldom take scarlet fever, it is more difficult to account for feeble predisposition observed during the early months of life. Infants less than a year old are rarely attacked, and often escape even when exposed directly and frequently. They do not, however, possess absolute immunity; indeed, scarlatina during fœtal life has been reported. Leale observed such a case, as did also Tourtual. Thomas records several cases occurring in the practice of others. Veit noted scarlet fever in a child fourteen days of age. Numerous similar observations, more or less trustworthy, have been recorded. On the other hand, Murchison saw two new-born infants remain healthy while their mothers suffered from scarlet fever. New-born children are so subject to cutaneous and other disorders that may readily be mistaken for scarlatina, that we may well demand the most definite testimony. Scientific exactness should require that a new-born child must be proven either to have served as the medium of contagion for others, or to have developed characteristic symptoms in the midst of predisposing surroundings. Both sexes are equally susceptible to infection.

The predisposition to scarlet fever is much less universal than that to measles and smallpox. While the two latter diseases will almost certainly attack all unprotected persons exposed to their contagion, scarlet fever often leaves unscathed persons who have been brought into the most intimate personal relations with it. In the epidemic at Thorshavn referred to above, only 38.3 per cent. of the total population proved to be susceptible to scarlatina, whereas in the same population in an epidemic of measles in 1875, 99 per cent. of those not protected by a previous attack was shown to be susceptible to measles. It is consequently much easier to practise isolation with the hope of success. However, the immunity possessed by an individual, as shown by repeated exposures, may not prove perpetual, and well-marked, even fatal, scarlatina may follow a final exposure. A degree of immunity from scarlatina is sometimes exhibited in families, the members of which escape altogether, or have only light attacks. Unfortunately, on the other hand, a decided family predisposition to the disease is occasionally encountered, one member after another falling a victim to its virulence.

Careful observation has failed to show that predisposition to scarlet fever is especially favored by the nature of the soil or the state of the weather; neither can it be proven that the type of the disease is especially influenced by any ordinary surroundings, further than that conditions of life prejudicial to the maintenance of good health diminish the powers of resistance to the onset of the disease. It is important to remember that in the absence of the contagious principle no degree of filth, deprivation, dampness, bad ventilation or drainage, or exposure, no matter how injurious to general healthfulness, can serve as the starting-point for scarlet fever. Indeed, it is remarkable, considering the bad hygienic environment of the poorer classes, that between them and the rich there should be so small a difference in the degree of predisposition to, and in the relative mortality from, scarlatina.

Mode of Infection.—To develop scarlatina an individual must, of necessity, receive into his body the *materies morbi* derived from one who has, or who has had, the disease. In all cases the contagion must be communicated by the air, or in solids or fluids received into the body. It is probable that physical contact occurs but rarely between infected and unprotected persons, and that when it does occur, the danger of infection is due rather to the increased liability of intercepting emanations from the body. Scarlet fever appears to be not contagious at the very beginning. In this respect it differs markedly from smallpox and measles. In the prodromal stage the contagion is probably not set free as readily as at a later period. Girard, however, has asserted that it is contagious only on the first day. This hardly needs a refutation. Longhurst also claims that it is most contagious during the pre-eruptive stage, and not at all during desquamation. These and similar opinions of individuals are negatived by the almost universal experience of observers. Scarlet fever develops its highest properties of contagion during its period of eruption, and, still unlike measles, retains its contagiousness until desquamation is far advanced. Two children, at the Netherfields Institution at Liverpool, were believed to have been centres of contagion six and a half weeks after the beginning of their illness.[6] Cameron[7] reports a case in which, nearly nine weeks after the beginning of her own attack, a child communicated the disease to her sister by contact. It seems probable that the power of communicating scarlet fever is retained, gradually diminishing in intensity, until the end of desquamation, which may not be completed for six, eight, even ten weeks. Thomas mentions cases in which children, even after the completion of desquamation, while suffering from scarlatinal dropsy, probably served as centres of contagion. The agency of the atmosphere as a contagion-bearer does not seem to extend beyond a few yards. Thus, it often happens that the disease does not spread beyond the sick-room, provided mediate contact can be avoided. Possibly the contagion is of too great gravity to be wafted for any distance. Yet it is certainly, under certain conditions, very tenacious of life, and may be conveyed long distances and preserve its properties for prolonged periods. It has often been carried by a healthy person, who has been exposed to the malady, to persons at a distance. There are authentic accounts of physicians, nurses, attendants, and visitors serving thus to carry infection. Such unfortunate occurrences are not very common, and probably happen only when the carrier of contagion passes directly from the sick-bed to the unprotected person, without due regard to the proper disinfection of the person and clothing. A pernicious custom is the habit of putting on over clothing and wraps over the dress in which the patient has been visited without proper exposure to the free circulation of fresh air. The tenacity with which the contagion clings to inanimate substances is most remarkable. Articles of clothing, bed-linen, furniture, wall-paper, hangings, and the like, frequently serve to communicate the disease, and often after almost incredibly long intervals. Richardson gives an example of this. Four children lived with their parents in a thatched cottage. One child was taken with scarlet fever, and the others were sent away. After three weeks one of these was permitted to return. It took the disease on the first day and died. The walls of the cottage were now cleaned and whitewashed; everything was thoroughly scrubbed, and all wearing apparel was washed or destroyed. After four months another child returned. The next day he was seized with the disease and died. Here the thatch was thought to have retained the contagion. The germs of the disease may be shut up in a letter and conveyed a long distance. Woollen clothing, put away and brought out after many months, pillows, cushions, toys, books, have all been known to preserve the contagion in full vigor. The dissemination of the virus in the atmosphere has been stated to be very limited, but the same cannot be said so confidently concerning the agency of fluids. The spread of scarlet fever has never been directly traced to the water-supply, but there is abundant reason to attribute its occasional extension to the medium of milk. Thomas quotes two examples of this. One, reported by Bell, leaves it an open question whether the milk, its receptacle, or the boy who carried it, was the medium. The other came under the observation of Taylor, who noticed "that one of the first severe cases which initiated an epidemic occurred in the house of a milkman whose wife milked the cows, the milk being supplied to about twelve families in the city. In six of these scarlatina occurred in rapid succession, at a time when the disease was not epidemic, and without any communication having taken place between those who were affected and the person who brought the milk. It is very probable that in this instance the milk was the carrier of the contagion, as, previous to its distribution, it had stood in a kitchen which had been used as a hospital for scarlatina patients." More recently, Airy, in eighteen families, consisting of thirty-five persons, reported twenty-four of these sick with scarlatina within thirty-six hours. Every one of these patients received milk from the same source. Neighbors who had milk from other sources were not attacked. It was found that a person who milked the cows lived with a child in full desquamation from scarlatina. Several observations of this kind make it hardly doubtful that milk may serve as the vehicle for the scarlatina virus, and that it, indeed, may be considered a favorable culture-fluid for it. But until recently it has not appeared that the virus-bearing milk received its contamination otherwise than through human sources. Later investigations seem to throw much light upon the possible origin of scarlatina in man, and upon one of the paths for its dissemination previously unrecognized. An outbreak of scarlatina among persons who received their milk supply from a dairy in Hendon, in England, in 1885, seemed to be traceable directly to a disease of the cow. The cows of this farm were affected with a peculiar affection, among the symptoms of which were a shedding of the hair and the formation of vesicles and ulcers upon the teats and udders. The nature of the disease in this case is, however, doubtful. Crookshank held that it was cowpox and had nothing to do with scarlet fever. In 1900, Kober[31] collected records of 99 epidemics of scarlet fever, and of these there was scarlet fever at the farm or dairy in 68; in 17, employees themselves were infected, and in 10 they acted as nurses; in 6, persons connected with the dairy either lodged in or had visited infected houses; in 2, infection was brought by cans or bottles from the houses of patients suffering from scarlet fever; in 3, the milk was stored near or in the sick-room; in 1 case milk utensils were wiped with an infected cloth. The existence of scarlet fever in animals has been claimed by such authorities as Salmon and Peters; other writers maintain that the disease is not identical with scarlatina as seen in man. In this connection it is an important fact that inoculation of cows, especially when in milk, with the virus of scarlatina, results in the production of definite symptoms.

The scarlatinal virus gains access to the blood through the respiratory tract, and is also conveyed in solid and liquid food to the stomach, whence it is absorbed. Though it is unlikely that absorption can occur through the sound skin, the disease is said to have been inoculated by artificial deposition of contagion-bearing material upon the abraded cutis. Miguel d'Amobise claimed to have inoculated children successfully with blood taken from scarlatinous patches. Stoel and Harwood have been reported as having conducted successful inoculations. On the other hand, Petit-Radel failed in his experiments. New observations upon this point are required. The contagion probably resides in the epidermis, and becomes diffused as this is exfoliated; also in the buccal and faucial mucous membranes, and probably in the secretions, in the lymph, and in the blood. In the absence of reliable inoculation experiments we have no fixed knowledge upon these points.

Incubation.—Scarlet fever has a shorter and much less definite period of incubation than the other eruptive

Scarlet Fever.

fevers. In determining the interval between infection and the outbreak of symptoms, it is much easier to reach correct conclusions when the fever has followed a single exposure than when the exposures have been repeated or prolonged. There is abundant evidence to show that the period of incubation may be less than twenty-four hours. On the other hand, it has been claimed that four or five weeks may elapse before the disease manifests itself. Most cases of scarlatina have an incubation period of from four to seven days. Even this wide limit, differing markedly from that of the other eruptive fevers, is subject to very many exceptions, and the literature teems with examples of scarlet fever developing a few hours after exposure, or only after many days, even weeks. Murchison believed the incubation period to be more often less than forty-eight hours in duration. The shortest authentic stage of incubation was in the case of Richardson, who after auscultating a scarlet-fever patient immediately became nauseated and chilly. He was conveyed home in the carriage of a friend, and dated an attack of scarlatina from that hour. Incubative periods of not more than twenty-four hours have been reported by many writers.[8] In 20 cases Dukes found the duration to vary from one to nine days, in 10 cases it was less than five days. Murchison reported, in the Transactions of the Clinical Society,[9] the incubative periods of 75 cases, none of which exceeded ten days. He considered a person safe from contagion who is not attacked within a week after exposure. Thomas[10] thinks that from four to seven days is the most frequent interval; Kaposi considers it to be about eight days; Gee thinks that seven days are rarely exceeded; Lewis Smith, that it is ordinarily less than six days. Longer intervals, however, are not infrequently noted. In one case, Hagenbach[11] determined it to be eleven days; in another, fourteen days. Intervals of twelve days or more have been recorded by Veit, Paasch, Böning, Lewis Smith, and others. From the rather untrustworthy results of inoculation, seven days would seem to have been the incubative period. Barthez and Rilliet, Gee, and others thought they had observed cases in which the incubative period covered several weeks, and, indeed, in delicate children, especially those with rachitis or with one of the neuroses, it may be much prolonged (Mayr). Holt[75] has collected 113 cases scattered through medical literature, occurring under circumstances which made it possible to determine the exact length of the incubation. The periods of incubation in these cases were as follows:

	Cases.		Cases.
Twenty-four hours or less...	6	Eight days	2
Two days	15	Nine days..................	5
Three days..................	28	Eleven days................	1
Four days...................	25	Fourteen days..............	1
Five days	6	Twenty-one days...........	1
Six days	15		
Seven days..................	8	Total	113

There is a growing belief that the incubation of scarlet fever lasts less than six days, and, without attempting to be more accurate, we accept that as the common duration. It is very often less than this, and but very seldom more. In this, as in most other features, scarlet fever shows great variability, and, if the term be allowable, a capriciousness contrasting strongly with the behavior of other specific fevers.

Symptoms: Period of Invasion.—For convenience of description it will be proper to describe scarlatina as following an *ordinary* or *mild*, and a *graver, course*. The course is very often irregular, from the absence of characteristic symptoms, or from the undue prominence of one or several of them, or from the presence of complications. In fact, scarlet fever may vary from an insignificant, even an unappreciable, disturbance of health, to a malady pursuing its fatal course with lightning-like rapidity; and although the type of the prevailing epidemic may be mild, severe, or malignant, individual cases can only in a measure conform to the standard, from which they will invariably differ to a greater or less extent.

Milder Forms.—At the end of incubation the active symptoms of scarlet fever usually develop suddenly; rarely they appear more gradually. In most cases fever is the first symptom observed. In larger children and adults an initiatory chill is often noted. Convulsions may occur at the outset; usually, however, they usher in graver forms of the affection. The fever develops during the night, or during the day the child loses its playfulness and in a few hours is found to have a high temperature, in most cases not exceeding 103° F. (39.5° C.), but occasionally reaching 104° to 105° F. (40° to 40.5° C.). At the same time the pulse will be full and frequent, beating from 120 to 140 times in the minute very commonly. The rapidly rising temperature and great acceleration of pulse are characteristic, and under favoring conditions should excite suspicions of scarlatina. The face becomes flushed, the eyes bright and injected. There is much thirst, but almost complete anorexia. Nausea and vomiting are so frequent that J. Lewis Smith attaches some diagnostic importance to the symptom. Of 214 patients it was present in 162. Jenner thought that severe vomiting is apt to precede severe throat symptoms. Diarrhœa sometimes occurs, especially in graver cases. The tongue may be only slightly coated; frequently it is covered with a white, creamy fur, but remains red at the edges. Already the little patient complains of sore throat (indeed this may be the first symptom to attract attention), and upon inspection the mucous membrane of the pharynx will be found to be swollen and dry, and of a bright or dusky-red hue, and often spotted with small areas of duskier redness. At this stage no curdy nor diphtheritic deposit will be observed. The nasal mucous membrane sometimes participates in the hyperæmia, and a nasal catarrh is induced. There will now be difficulty in deglutition, and already there may be some enlargement of the submaxillary and cervical lymph nodes. There are often headache and also delirium, sometimes of an active kind. As the fever increases in severity the patient becomes dull, listless, and drowsy, and various symptoms of cerebral disorder are common in graver cases. In very many cases, however, all the symptoms will be mild. There may be little fever, no noticeable disturbance of the various functions, not even sore throat. Beyond slight peevishness and irritability the child may not seem to be unwell. In not a few cases there may be no prodromal period at all, the eruption first attracting notice. During the prodromal stage the urine is rather scanty, acid, and high-colored. According to Gee, the urine is diminished in quantity; urea is not necessarily increased; chloride of sodium is diminished, sometimes decidedly, the diminution generally ceasing suddenly on the fourth, fifth, or sixth day; phosphoric acid, at first normal, is notably diminished on the fourth or fifth day, remaining for four days from one-third to one-half the normal quantity, and then returning to the healthy standard; uric acid is greatly diminished on the second and third days, becoming excessive on the fifth day, and then normal. Even at the earliest observation albuminuria may be noted. Böning, who denies a prodromal stage, and always encounters the eruption on the first day simultaneously with the chill, has found blood corpuscles, renal epithelium, and albumin in the urine from the very start. The respiratory movements quicken in proportion to the rapidity of the pulse. Nearly all cases will begin to show the eruption within twenty-four hours, many within twelve hours, a few during the second day. When the eruption appears later, an abnormal or unusually severe form of the disease often follows.

Stage of Eruption.—The eruption first appears upon the sides of the face, upon the neck and submaxillary region, and on the front of the chest, in the clavicular region, as small, pale-red points, closely aggregated, although at first discrete, and very slightly elevated. It rapidly extends over the chest (where it becomes most intense), and over the upper and lower extremities, and attains its full distribution by the end of the second day, acquiring a bright red or scarlet color. It occasionally happens that the eruption begins on other parts than those mentioned, or may never become general. Rarely it spreads more slowly, even fading in some localities before the lower extremities are invaded. It is especially apt to affect the flexures of the joints. In mild cases the spots remain discrete over most of the body, and may resemble a fine "prickly heat," densely arranged and of minute size. At times the eruption consists of dark-red points, surrounding hair follicles, separated from each other by less intensely red areas (Henoch). In cases of greater intensity it is coalescent almost universally, and presents a continuous brilliant scarlet surface, like the shell of a boiled crab or lobster. The intensity of coloration varies somewhat, even in the same patient, depending much upon the degree of heat; becoming paler when the surface is cooled, more scarlet when this is protected by heavy covering, etc. It is, however, not perfectly smooth, but shows the tiny papules upon the reddened base, and communicates to the hand passed over it a sensation of roughness and of dry and pungent heat. Upon the legs and arms the eruption very often becomes more scattered, assuming the form of separate tiny points; rarely it is distributed over distinct areas of the trunk and extremities, with intervals of faintly erythematous redness (scarlatina variegata). This form, however, is apt to appear in severe complicated cases. At the same time it must be remembered that, unlike measles, scarlet fever affects the face less than other parts. Never very intensely developed over the forehead, temples, or chin, the eruption entirely spares an area around the mouth, including the upper and lower lips and some distance beyond the angles of the mouth, and often extending upward to include the nose. This area contrasts with the surrounding parts by its remarkable pallor. It has been asserted that the cheeks are also spared by the eruption. This is not true. The cheeks do not show the pointed redness of the early eruption elsewhere, but at once assume a scarlet or crimson redness that is deeper than the color induced by fever. The lips are often dry and cracked, and may bleed. The face becomes considerably swollen, especially in the loose tissue about the orbits. The ears are also swollen and of a bright red color. The eruption does not spare the scalp. Upon the backs of the hands and feet the eruption is discrete, and is arranged in groups the size of a lentil, while upon the palmar surfaces of the hands and fingers, and upon the soles of the feet, a bright, diffused redness, with swelling, is seen. At times the eruption will be partial, developing upon the trunk alone, or on the extremities, or in isolated patches about the body. These cases may not be abnormal in other respects. The skin over the joints is especially prone to be affected. The lesions may be more or less disseminated spots, varying from the size of a pin head to that of the finger nail, or a half dollar, or even larger. It has been asserted that the eruption constantly consists of a papulated rash upon a reddened base, even when universally diffused. This is not invariably so, and one may encounter a smooth, uniform redness inappreciable to the touch. Where the eruption is very intense, small hemorrhagic spots or petechiæ may appear. When thus occurring, their occasional presence is not of serious importance. In warm weather especially, and in children too warmly covered with bedclothes, the surface, particularly of the neck, chest, and belly, is sometimes plentifully sprinkled with an eruption of sudamina. In some epidemics these are more often observed than in others. It is not impossible that the "miliary fevers" that formerly occasionally prevailed in Europe were in reality forms of scarlatina. Mayr has said that the eruption of scarlet fever often spares the skin of paralyzed limbs; but Kaposi asserts that it may be unusually intense upon these parts. In dark skinned races the eruption undergoes some modifications, which are greatest in those of full negro blood. In mulattoes and negroes it becomes often exceedingly difficult to distinguish the eruption. Of course the scarlet color is absent, a tinge of red will often struggle through the darkly pigmented skin, especially of the cheeks and abdomen. The true character of the eruption may often be revealed by a finely papular condition, the tiny papules of the size of a pin-point being made apparent by their acuminated summits, which give, against the dark background, a resemblance to a sprinkling of the surface with a fine dust. The hand passed over them can perceive the little asperities. These are closely aggregated. In many cases it is impossible to recognize the eruption, and the diagnosis must rest upon the concomitant symptoms, which will not be peculiarly modified.

While the eruption—which attains its height by the end of forty-eight hours in mild cases, later in severe ones—is developing, the other symptoms become pronounced. The faucial mucous membrane is uniformly redder, or occasionally shows numerous red macules; the uvula, tonsils, and buccal mucous membrane are reddened and swollen, and pain in deglutition increases. As the eruption reaches its height, the tongue parts with its coating in patches, exposing areas of intense redness. By the third day it acquires a uniformly brilliant red color, with enlarged papillæ scattered numerously over its general surface, and presents the characteristic "strawberry" or "raspberry" appearance. Exceptionally this exfoliation of the lingual epithelium does not occur, and the creamy deposit persists. In many mild cases there is slight nasal catarrh, with a thin discharge from the nostrils. A muco-purulent discharge from the nostrils is associated with the throat complications of the graver forms.

During this period the fever continues to increase until the completion of the eruption, or the prodromal temperature remains unchanged. In the type of cases we are considering 105° F. (40.5° C.) is not often exceeded. Should the fever continue to increase after the third day, grave solicitude as to the result will be justifiable. The other symptoms continue with undiminished vigor—digestive disorder, nausea, vomiting, complete anorexia, rarely diarrhœa, persist. The skin burns or itches more or less intensely. Nervous symptoms, restlessness, stupor, headache, delirium, usually diminish, but may continue unabated; or active delirium may occur. Convulsions at this time are very ominous. The sore throat becomes distressing, and the cervical and submaxillary glands enlarge and become painful. Bronchial and pulmonary inflammations occur only as complications. After the fourth or fifth day nearly all of these symptoms cease to increase, and it becomes evident, *cæteris paribus*, that the course of the disease is to be favorable. The eruption, after persisting in full development for a day or two, becomes duller and slowly fades, first in the parts earliest affected, latest from the back of the hands. The color, which at first completely faded, now leaves a yellowish stain when the finger compresses the skin. It is not, however, until after four, five, or six days, that the skin loses its scarlet color. This may last longer. Jenner[12] has known it to persist for from fourteen to sixteen days. The fever slowly declines, until it ceases about the sixth, seventh, or eighth day, or later, and not before the eruption has entirely disappeared. Sometimes, from unknown reasons, it persists for days after all local symptoms have ceased to be active. On the other hand, fever, in some very mild cases, will hardly be noticed, or will endure but a few hours. The throat manifestations, or the supervention of complications, may protract the fever for many days. The sore throat, unlike the other symptoms, often fails to show signs of amelioration after the height of the eruption. The swelling and redness may increase, and white or yellowish curdy deposits form upon the tonsils and uvula, or the posterior wall of the pharynx may be bathed in a thick muco-purulent discharge from the posterior nares. True diphtheritic membrane is not apt to form in these cases, but the neighboring lymph nodes may become highly inflamed and suppurate. It is probable that renal catarrh and nephritis occur more frequently during this period than is commonly supposed. The character of the urine is subject to considerable variation. At the beginning of the disease it has the appearance of the ordinary febrile urine or of a severe active hyperæmia. It is not usual for an acute nephritis to develop in the early stages of scarlet fever, but is most common in the second or third week. It may develop after the mildest forms of infection, and the greatest care should be (even when convalescence is well advanced) to guard against this serious complication. Frerichs, Reinhardt, Eisenschitz, Böning, Begbie, Newbigging, Holder, and others, consider the renal symptoms to be essential in scarlatina. This is, however, not true. Thomas[13] practised microscopic examinations of the urine in twenty-five of eighty patients, and in twenty of these daily. In the prodromal and eruptive stages he found slight albuminuria only rarely and transitorily. Decided alterations in the renal tract were most uncommon. Mild catarrh was more often seen. Only the more severe forms he considered to depend upon a specific scarlatinal influence. Fleischmann,[14] in 472 cases of scarlatina, reported dropsy during the first week in 9 cases. Not enough, certainly, to bear out the sweeping assertions just quoted, but sufficient to direct attention constantly to the condition of the kidneys in scarlatina.

Many cases of mild scarlatina fail to exhibit all the symptoms enumerated. The prodromal stage may be absent, sore throat may be insignificant or absent throughout. The tongue may never assume the "strawberry" appearance. The fever may be of feeble intensity. Finally, the rash may be faint and not widely distributed. It may be limited to a few reddish or pinkish punctate spots upon the neck or chest; or it may affect only the flanks or the flexures of the joints; or it may be so transitory as to escape observation or to be noted only during a few hours; or, finally, it may fail altogether to appear. On the other hand, sore throat may be the only active evidence of the disease. Cases that have been exposed to the contagion sometimes develop sore throat only. These may subsequently become dropsical from nephritis, or they may desquamate more or less abundantly, or even communicate scarlet fever to others. An interesting feature is a tendency, often shown by those exposed to contagion, to suffer from a mild attack of pharyngitis after every exposure. Many physicians, nurses, etc., experience this. Finally, the eruption may fail to appear, knowledge that scarlatina was present being acquired through the occurrence of desquamation or dropsy. Cases of this kind have been designated "*scarlatina sine exanthemate.*" They are not so very rare. At other times the eruption is so indeterminate in appearance that, in the absence of accompanying symptoms, it is impossible to speak positively of its character.

Stage of Desquamation.—After the fading of the eruption the patient passes into the stage of desquamation. This is an immediate result of the eruption. Desquamation begins usually upon the neck, and continues for from eight to fourteen days, but not infrequently for four, six, or even eight weeks or more. Usually not earlier than the sixth day of the disease it is noticed upon the neck and face, and quickly extends over the whole surface, and may even occur upon parts not visited by the eruption. Upon the face and neck the scales are mostly fine, but coarser than those following measles. From other parts the epidermis peels in great shreds. On the hands and feet the lamellæ are always large, and sometimes from these members the cuticle is removed in masses resembling a glove or slipper. Desquamation endures longest where the epidermis is thickest, often for weeks; that newly formed exfoliating repeatedly. The hair and nails are sometimes shed after scarlet fever. Desquamation is at times observed in those who have had no eruption, or at least one of very circumscribed extent. With the completion of desquamation the disease may be said to have run its course. Great care, however, must be exercised for some weeks to protect the patient from the effects of complications and from the sequelæ to which the disease has made him liable. With the fading of the eruption, the cessation of fever, and the beginning of desquamation, general improvement takes place. The tongue gradually resumes its normal appearance or for a time becomes again coated; the sore throat diminishes; the various functions are properly performed; appetite and strength return. Desquamation may, however, be sometimes delayed. The local use of oils and ointments during the eruption tends to make the desquamation less free. The occurrence of dropsy, dependent upon the development of an acute nephritis, sometimes defers the beginning of desquamation, and this may not become abundant until after the dropsy has subsided. Contagion has spread from desquamation beginning in this manner, after isolation has been abandoned as no longer necessary. In rare cases desquamation can hardly be said to occur at all. Even in mild cases, in winter, the patient should not be permitted to leave his bed until the end of the third week, or to leave his chamber until the completion of desquamation. In midsummer it is usually not advisable to insist upon confinement to bed for so long a period. Cases which run the apparently mild course just described are by no means free from danger, as they are often accompanied or followed by local pathological processes which, while they may not be essential symptoms of scarlet fever, are especially prone to affect those suffering from it. Such lesions will be considered among the complications and sequelæ of scarlatina.

Graver Forms.—Every case of scarlatina is dangerous. In those following the type just described the peril arises from processes that are not essential to the disease. Such forms pass, by insensible gradations, into those where life is imperilled by the greater or less intensity of characteristic phenomena. The graver forms of scarlatina may not differ in their initiatory symptoms from those already described. In most cases the severity of the disease is in great measure dependent upon lesions in the throat, while, as a rule, the eruption shows a more general distribution and a more intense coloration. The prodromal symptoms do not differ in kind from those of milder types, but are more severe. Vomiting is more apt to occur, and nervous symptoms to become prominent. Headache, jactitation, and delirium become more marked, or the patient grows petulant, drowsy, and stupid. Convulsions also may occur. Fever attains great intensity at the very outset, reaching 40 to 42 C. (104 to 106° F.), the latter temperature always denoting extreme danger. There is already sore throat, with difficult deglutition and with swelling and deep redness of the faucial mucous membrane, which by the third day, in the less severe cases, shows curdy deposits scattered over the tonsils. These deposits do not involve the mucous membrane, and may generally be detached by a mop or a brush. They are quite like the exudation of ordinary catarrhal pharyngitis. After the third or fourth day, under conditions of constantly increasing fever and general distress, in some cases, diphtheritic exudation begins to show itself over the tonsils and soft palate and posterior wall of the pharynx. It is an interesting point of difference between primary and scarlatinal diphtheria that the latter never begins to appear before the third or fourth day, after which date it is sufficiently common. Fleischmann reported diphtheria 168 times in 472 observations. The diphtheritic deposit is first developed on the lateral portion of the tonsils, except in those rapidly fatal cases in which the whole pharynx seems to be simultaneously involved. The patches are of a whitish or grayish-white color, and involve the mucous membrane sometimes to a considerable depth and superficial extent. At times the diphtheritic membrane rapidly spreads in a continuous sheet over the fauces, extending forward into the buccal cavity and into the posterior nares. In the latter case, a fatal termination is almost inevitable. Heubner[14] asserts that those cases in which the entire mucous membrane, from the root of the tongue to the œsophageal and tracheal orifices, is covered with the membrane, prove fatal within twenty-four or forty-eight hours, without exception. Here the membrane is sharply margined against the dusky-red mucous membrane, and within a few hours the slough shows signs of separation and develops a gangrenous odor. In these cases the membrane hardly ever travels down into the trachea. Bretonneau has made a positive assertion that this does not occur. It does so occasionally, however. Lewis Smith reports cases, with necroscopic examination, in which diphtheritic membranes extended along the trachea into the bronchial tubes. In the most severe cases, however, the deposit does invade the posterior nares, and the ordinary slight catarrhal discharge is supplanted by an offensive sanio-serous or sanio-purulent discharge from the nostrils, which causes excoriation of the upper lip. At the same time the nares become obstructed, and the little patient is driven to breathe almost entirely through the mouth. In many cases of extreme throat involvement the strength rapidly fails, pallor replaces the prematurely receding eruption, except at certain spots where this may persist as circumscribed patches of dusky redness; the temperature remains stationary or falls, the pulse becomes more and more feeble and rapid, and death ensues within a few hours, as if from blood-poisoning. Death either follows a slow spread of gangrene to the soft palate and tongue behind the sinus pyriformis, and to the walls of the throat, or occurs through diphtheritic inflammation of the lymph nodes and connective tissue of the neck, or through œdema of the glottis. At other times the clinical appearances during the first week may not be alarming, danger becoming imminent about the beginning of the second week. The fever may remain elevated, the eruption brilliant and intense, until a short while before death. In the rapidly fatal cases the throat and neck may not appear very much swollen. At other times the neck and submaxillary region are greatly swollen, principally from the inflammation of the glands and periglandular tissue. These parts become hard and brawny, and from the pressure upon the great veins acquire a livid appearance, which may also be communicated to the face and head. The tonsils and soft palate may be swollen until the throat will appear quite closed. The mucous membrane will be deeply congested, and covered here and there with diphtheritic exudation and with ulcers caused by the separation of sloughs. The posterior wall of the pharynx may be bathed in muco-pus. Retropharyngeal abscess is sometimes formed, and may precede the fatal termination. Dyspnœa may result from swelling of the fauces caused by inflammatory exudation into the parts, from œdema glottidis, or from extension of diphtheria to the larynx and trachea, or it may be a result of the imperfect oxidation of the blood. The term "diphtheritic" is here used in a clinical sense, to designate a condition of coagulation necrosis in the tissues involved, and has no reference to a pathogenetic relationship with true diphtheria. This necrosis occurs simply as a result of the intensity of the accompanying inflammatory changes. There is no evidence that true diphtheria may not coexist with scarlatina, but that the commonly observed membranous pharyngitis of scarlatina represents this combination is most improbable. Many of these membranes are undoubtedly due to the action of the streptococcus and staphylococcus infections. Their differentiation from true diphtheria is now made easy by the bacteriological examination in reference to the presence or absence of the Klebs-Loeffler bacillus. J. Lewis Smith has seen four instances in which the diphtheria became dissociated from the scarlatina, and attacked other persons as idiopathic diphtheria. Such observations are exceedingly uncommon. The scarlatinal diphtheritic membrane is indeed essentially identical with that of idiopathic diphtheria in structure. The differences are etiological. The diphtheritic poison and the scarlatinal poison, differing in their specific natures, possess in common the power to excite such violent inflammatory changes in the tissues that a coagulation necrosis results. The diphtheritic membrane of scarlatina, then, is purely scarlatinal in its origin. This view has received solid indorsement. It has been adopted by Henoch. Heubner considers scarlatinal diphtheria to differ from primary diphtheria both clinically and histologically. It begins with a simple catarrhal affection, and, following his observations, changes from catarrhal to diphtheritic inflammation on the fourth day. Koven also thinks that the throat affections of more severe grade are characterized by necrosis from direct intensity of the scarlatinal process, and are not of a truly diphtheritic nature. He observes that while two acute diseases rarely coexist, of 426 cases of scarlatina 125 had necrosis faucium, although at the period of observation there was not a single case of primary diphtheria in Christiania. He further declares that diphtheritic paralysis never occurs after scarlatina, and that while true diphtheria shows the membrane at once, the scarlatinal slough usually appears after several days of increasing angina, and does not extend to the larynx. Henoch has never seen a single case of accommodation paralysis of the eye or of the soft palate, nor of the neck, nor of the extremities, after scarlatinal diphtheria. The inflammation may, often does, extend along the Eustachian tube to the middle ear, and excites changes that give scarlet fever one of its principal terrors, resulting often in more or less complete permanent deafness. These changes will be considered with the complications and sequelæ of scarlatina. In a number of these cases cervical adenitis and periadenitis occur, and prolong the fever beyond the eruptive stage indefinitely, frequently resulting in suppuration. Occasionally the pus burrows deeply among the tissues of the neck, and extensive gangrene may follow. Williams has reported a case of extensive sloughing in the left anterior triangle of the neck, with exposure of vessels, followed by recovery. Other similar cases have been recorded. In most cases in which death does not speedily occur after suppuration and evacuation of pus recovery will take place, but the patient may ultimately succumb under blood-poisoning and protracted fever. Occasionally, also, parenchymatous tonsillitis may cause rapid and enormous enlargement of the tonsil, with the formation of pus, a condition of extreme gravity, especially if associated with retropharyngeal abscess and œdema of the glottis. In favorable cases the sloughs in the fauces will cease to extend, the œdema and dusky redness will slowly subside, and the diphtheritic ulcers begin to granulate.

In many cases the faucial symptoms here described do not appear, only because life is early destroyed by the intensity of the action of the specific poison upon the blood and tissues. In such malignant cases the patients often die with the rapidity of those who succumb to narcotic poisoning; or a series of convulsions inaugurate the disease and terminate life within an hour or two. This has been called the *atactic* form of scarlet fever. At other times brief initiatory symptoms have been followed by intense fever (106°–109° F.), with uncontrollable vomiting, diarrhœa, delirium, rapidly deepening coma, and death, before the appearance of the eruption. Or, again, the disease may begin in the ordinary manner, not suggestive of a severe course, and alarming symptoms may not develop until after several days; or it may be intense from the beginning, with severe and repeated convulsions, vomiting, profound nervous depression, and the appearance of the eruption at the usual time, with steadily increasing gravity of all the symptoms, until, after a few days, death results from convulsions or coma. Finally, the malignant symptoms will appear suddenly in the midst of what has seemed a mild attack of scarlatina. An unusually protracted period of invasion is sometimes the forerunner of malignant scarlet fever, and should always be regarded with apprehension. Cases may at times exhibit at the beginning alarming symptoms. A decided apathy, in which no notice of what is passing is taken, with great apparent depression and even delirium, excites the apprehension of the attendants, yet the pulse and temperature will not show marked variation from the normal. After the second or third day such cases will very often pursue a mild course. A high temperature and very quick pulse may even be added to these symptoms and justly excite alarm, and yet the case may assume a favorable character after the development of the eruption. In such cases as these the probability of the issue in life or death seems to vary from hour to hour. All the symptoms show intensity. The fever, accompanied by more or less severe initiatory symptoms, rapidly increases, the eruption is copious and deeply colored, the pulse beats 130, 140, 160 times, or oftener, to the minute, the respiration is proportionally accelerated, the throat duly shows more or less extensively the peculiar alterations. This course may be held throughout the first week, and even longer, without mitigation, the result remaining doubtful all the while.

In malignant scarlet fever the usual course is one of intensified general symptoms. Those of the invasion period are indicative of grave perturbation of the economy. By the time the eruption appears it is already evident that the patient is dangerously ill. He is apathetic, or perhaps extremely restless, remaining in one position not an instant. The skin is hot, dry, and pungent, the temperature very high, the features are swollen, the conjunctivæ injected, the fauces reddened and dry, the thirst is intense, but water and all ingesta are often vomited as soon as swallowed; the urine is scanty, or even suppressed, from acute renal inflammation. Diarrhœa may be present. The nervous phenomena become intensified. The eruption now appears, and may at first develop regularly, but after a while will become duskier and will not completely fade on pressure. The color tardily returns to the part whence it has been pressed. Coma or convulsions may now carry off the patient in full eruption. Often, however, the eruption will recede from certain parts in whole or partially, or it may become paler universally; or in place of the regular eruption hemorrhagic exudation will appear. Ecchymoses, from the size of a pinhead to that of the palm, or larger, will replace the usual eruption, which will in great measure disappear. Then livid spots, not fading on pressure, are found, generally upon the flanks and back, but may appear anywhere. According to Mayr, the hemorrhagic eruption may appear over a large part of the surface in children, but in adults is mostly confined to the neck, upper part of the chest, the back, and about the joints of the upper and lower extremities. This hemorrhagic variety is the most formidable form of scarlet fever, and is probably always fatal. Hemorrhages from mucous surfaces are exceedingly uncommon. Mayr has described a scarlatinal dissolution of the blood, in the gravest form of which death occurs in from twelve hours to five days. "Extreme muscular depression, with slight headache and a remarkably rapid pulse, are present from the very commencement. . . . The patient lies on his back with his eyes half open, but in an unconscious state. . . . Quivering movements of the muscles of the face and of the fingers are also commonly observed in these cases, and in children general convulsions often occur. The pupils are moderately dilated; the lips and tongue are dry, the latter being usually of a bright-red color. As the disease goes on, mucous râles are heard in the large bronchial tubes; the abdomen becomes distended, but there is seldom any enlargement of the spleen; the urine becomes scanty and of a dark-red color; the pulse continually increases in frequency, reaching as many as 200 beats a minute; the features become shrunken and the extremities cold." Death speedily follows. This form resembles the so-called typhoid scarlatina, in which drowsiness, stupor, delirium, and subsultus precede the fatal issue. The life-destroying symptoms are often connected with impairment of the heart's action, attributable to crippling of the vagus, when death occurs from heart paralysis, without widespread molecular disintegration. This failure is shown by increasing weakness, frequency and inequality of the pulse, with quickened and shallow breathing, and coldness of the hands and feet. Allbutt has classified the modes of death in scarlet fever as follows: (1) hyperpyrexia (this Jenner denies positively); (2) specific blood-poisoning; (3) special malignity of the case; (4) asthenia. In the rather uncommon event of recovery from any of the most severe forms of scarlet fever, the progress is slow, the essential symptoms, complications, and sequelæ proving all very obstinate. In those cases in which extensive diphtheritic exudation precedes a rapidly fatal course, the eruption undergoes many modifications, the integument remaining pale except for some few splotches about the joints, at other times showing only a few dark-red patches irregularly distributed, and again entirely disappearing before death. At other times the eruption persists in full efflorescence.

Changes in the Blood.—The number of the red corpuscles in general is but slightly altered, more, however, in scarlet fever than in measles. The same may be said concerning the character of the red cells and the amount of hæmoglobin; in scarlet fever poikilocytes and normoblasts are occasionally found. The state of the leucocytes is much more characteristic. In measles there is either a normal number or a diminution of leucocytes; in scarlet fever there is hyperleucocytosis. In the former, as the temperature falls the leucocytes gradually increase; in the latter the temperature and leucocyte curve run parallel. In both diseases, but especially in measles, is the number of polynuclear neutrophilic cells diminished, while lymphocytes, both large and small, are relatively increased. The eosinophilic cells are diminished in number in measles, reaching their normal state long after recovery; in scarlet fever they are constantly increased.

COMPLICATIONS. — *Nephritis.* — Derangements of the kidneys are the most important complications of scarlet fever. Indeed, a number of recent writers assert that these organs are always affected in this disorder. Among these may be mentioned Frerichs, Reinhardt, Begbie, Newbigging, Holder, Böning, and Stevenson Thompson. Steiner states that evidences of kidney disorder are always present in those who die of scarlet fever. Thomas' clinical observations do not bear out this statement, and Friedländer, who examined the bodies of two hundred and twenty-nine persons dead of scarlatina, found kidney disorder in less than one-half. Though renal inflammation is not shown as yet to be a constant accompaniment of scarlet fever, it occurs much more often than is commonly supposed. Renal catarrh, which Eisenschitz declares to be as much a feature of scarlet fever as bronchial catarrh is of measles, is indeed an extremely common complication. It usually escapes detection from the general neglect duly to examine the urine. Thomas, in denying that this catarrh is at all constant, shows that it also occurs in measles, croupous pneumonia, etc., and is often only an expression of the febrile condition. Yet the catarrh is relatively so common in scarlatina that he cannot avoid concluding that the specific influence of the disease is often concerned in its production. In many cases, from the very beginning, cylinder-like masses of renal epithelium may be detected. In milder cases the urine will contain mucous casts with increased quantity of mucus, but no albumin. In more severe cases the urinary sediment will contain hyaline masses with epithelium and epithelial *débris*, and red and white blood corpuscles. Slight albuminuria will also be present. This catarrh is usually insignificant, and but rarely serves as the starting-point for the graver and characteristic forms of nephritis scarlatinosa, though doubtless many milder forms of nephritis and dropsy originate in it. Thomas concluded, however, that the cases of scarlatinal nephritis not developing from preceding catarrh, but arising suddenly, usually end fatally. Scarlatinal nephritis varies greatly in the relative frequency of its occurrence, involving from five to seventy per cent. of cases in different epidemics. In the Children's Hospital, Hillier noted its occurrence in about half of the cases. Dickinson [16] considered this rather below than above the average. Fleischmann [17] noted 95 cases of Bright's disease in 472 observations. During 1861 every third child with scarlatina had dropsy, while in 1862 it affected only one case in ten. Thomas asserts that renal alterations develop in about one-half of all cases of scarlet fever. It has been shown that there are those who assert that the renal alterations are constant. On the other hand, Jaccoud [18] declares that for fifteen years he has never had a case of nephritis among his scarlet fever patients, a result that he attributes to his treatment. Albuminuria may appear at any time during the attack of scarlatina, though its most common occurrence is during the second and third weeks. Dropsy should not be taken as marking the beginning of the nephritis, the signs of which may be present in the urine sometimes for days before this occurs. In Fleischmann's cases dropsy occurred 9 times during the first week, 30 times during the second week, 23 times during the third week, 20 times during the fourth week, and 5 times after the fourth week. Of 60 cases at the Children's Hospital, 42 began between the end of the first week and the end of the fourth week; 5 became dropsical during the first week.

Nephritis during the first week of scarlatina often escapes detection from the blending of its symptoms with those of the essential disease, and from the attendants' neglect to examine the urine. Dropsy will, of course, attract attention, but this does not often occur so early, and may be confounded with the œdema from the exanthem. Rarely, the fatal issue of what was, apparently, malignant scarlet fever, may really have resulted from uræmic poisoning due to a fulminating nephritis. The symptoms may be identical. Fever, vomiting, headache, delirium, amblyopia, coma, convulsions, may have been present. The convulsions are often very irregular. They may be general, partial, or unilateral, tonic or clonic. The patient may have them in rapid succession, or may pass into a *status epilepticus* from which death alone will release him. The urine will be completely or partially suppressed. If secreted it will be of high specific gravity (1.020 to 1.040), dark and smoky in appearance, loaded with albumin, and forming an abundant sediment of hyaline, granular, epithelial, and blood tube casts, with renal epithelium and white and red blood corpuscles in greater or less quantity. If the kidneys become implicated toward the end of the first week, the symptoms may delay the course of what may otherwise appear to be an ordinary case of scarlet fever. Microscopical research will often betray the onset of the changes in advance of chemical analysis; casts of the renal tubules will be observed, with epithelial deposits and detritus, before albuminuria is established. This will shortly appear, and in severe cases the nephritic symptoms will obscure those of the scarlatina. There will be no constant relation between the amount of albumin, the tube casts, and the general detritus, one variety of sedimentary matter being at one time copious, at another scanty. At this time vomiting may appear with returning headache, the appetite will again fail, and pain in the loins may become annoying; the patient may again become dejected and feeble, and his fever may cease to diminish—may even exceed its original intensity. At other times no apparent influence will be exerted upon the scarlatina, which will follow its usually mild course until dropsy and albuminuria reveal the state of the kidneys. When the renal disorder develops after defervescence, during the second, third, or fourth week, or later, the same series of symptoms may be observed, their severity being in direct ratio with the earliness of their occurrence. Cases developing after the fourth week may be expected to pursue a favorable course. Although it has been asserted that the renal disorder may arise several months after a scarlatinal attack, a patient will almost certainly escape it if he pass the sixth week in safety. The symptoms in cases arising during these weeks are not always gradually developed, and some of the most disastrous results of the disease may be encountered, during the second, third, or fourth week, in children apparently convalescing from scarlatina, and often in full desquamation, who, after indisposition for a few hours, with nausea, headache, confusion of ideas or stupor, with return of fever, rapidly pass into coma or convulsions, ending after a short interval in death, before dropsy has developed, but after partial or complete suppression of urine. Scarlatinal nephritis has usually a mild and favorable course. Dropsy is usually the first symptom observed, first appearing in the face and sometimes remaining confined to this locality; at other times becoming general speedily, and giving an appearance of plumpness, but with a wax like translucency of skin. The face, upper and lower extremities, body wall, and prepuce may thus become dropsical. The serous cavities are also implicated, and more or less effusion into the pericardial, pleural, peritoneal, scrotal, and intracranial cavities occurs. Œdema of the lungs and of the glottis may imperil life. Desquamation is often completely arrested upon the supervention of dropsy. The temperature is more commonly but little above the normal (38.3 to 39 C.—101 to 103° F.). The pulse, sometimes feeble and accelerated, will often become remarkably slow and intermittent, and so remain throughout the attack. The child will grow dull and listless, and extremely feeble. Pain in the belly and in the back may at times prove very distressing, or, again, it may be absent. The tongue, having lost the strawberry aspect of the eruptive stage, will become pale, flabby, and coated. The appetite will fail, and the bowels become sluggish. The urine will rapidly diminish in quantity and may deposit urates abundantly, or may present a smoky and oily appearance, due to the abundant presence of epithelial cells, white and red blood corpuscles, and tube casts. The total amount may now be reduced to a few ounces. The blood corpuscles often form a thick red layer at the bottom of the test tube. This free admixture of blood may amount to pronounced hæmaturia, is generally post-scarlatinal, and, according to Schütz, occurs most frequently during the third or fourth week. Of itself it adds but little to the gravity of the case. The patient often feels fairly well, and may eat and sleep with comfort. While the pallor and œdema may be very decided, the temperature and pulse may vary but little from the normal, or may show the variations of ordinary nephritis. With the gradual improvement of the general symptoms the hæmaturia disappears. Heubner has reported a case of nephritis after scarlatina in which hæmoglobinuria was present. The urine was brownish-black; no blood corpuscles were found. Death resulted from asthenia on the fifth day after both albumin and hæmoglobin had disappeared from the urine.

The amount of albumin in the urine in scarlatinal nephritis is usually very great. The urinary sediment is abundant, and is largely composed of tube casts, the hyaline character predominating; finely and coarsely granular, epithelial, and blood casts are, however, numerous. Later, coarse fatty granules stud the casts plentifully. These casts are often almost diffluent, and differ strikingly from the firm and sharply outlined ones of more chronic nephritis. Crystalline deposits are scanty, and are mostly of uric acid and urates; on the other hand, the amorphous urates are often very abundant. The degree of albuminuria present is of less importance than the total quantity of urine secreted, rapid and pronounced diminution of this indicating the accumulation of nitrogenous waste in the blood, and consequently the danger of uræmia. According to Glax, a lessening of the proportion of urine secreted to the fluid ingested (2:3) not infrequently foreshadows the approach of uræmic symptoms, even though the urine contain no albumin. Whether the temperature remain normal throughout the attack, or whether, after an initial chill, it become elevated, and all the symptoms of acute nephritis develop, complete recovery may reasonably be expected if the patient pass safely through the earlier phases of the disorder. But although nephritis may be mild—the dropsy lasting only a few days, and, perhaps, being limited to slight puffiness about the eyes—the disorder does not usually entirely subside in less than a month. It may endure as long as three, four, or even five months; and there is good reason to believe that chronic nephritis in young people may, in rare instances, have had its beginning in antecedent scarlatinal inflammation of the kidneys. Such a result is, however, exceedingly uncommon.

The dropsy indicates the degree of renal derangement, except in the most acute cases, and sometimes attains enormous proportions. As the urine increases in quantity the albuminuria proportionately diminishes, and the dropsy disappears. The skin, which until now has been dry and inactive, becomes softer, more elastic, and resumes its proper functions. The appetite improves, the spirits, strength, and mental activity return, and good health becomes gradually restored. Just as the microscope reveals the earliest evidence of renal derangement, so does it continue to expose the results of pathological action after chemical tests fail to do so. Tube casts continue to appear in the urinary sediment, sometimes for weeks after the cessation of albuminuria, the blood casts, epithelial, coarsely granular, and fatty casts gradually giving place to finely granular, hyaline, and mucous ones, which in turn finally disappear. When the disorder terminates fatally, the symptoms will be those of acute nephritis; suppression of urine may be followed by cerebral disturbance, headache of violent character, during which blindness may occur, with or without dilatation of the pupil, vomiting, and convulsions, partial or general, coma, and sometimes paralysis; or the fatal termination may be slowly reached through constantly increasing asthenia; or, what is more frequent, complications may arise which cannot always be definitely ascribed to the nephritis or to the scarlatina itself. Such are inflammations of the pleuræ, of the pericardium and endocardium, the peritoneum, the cerebral meninges, etc. Pneumonia, acute articular rheumatism, or enteritis, may also hasten the fatal issue.

Cases are occasionally observed in which dropsy follows scarlatina, but without albuminuria. Indeed, a tendency toward non-albuminuric dropsy after scarlatina has been associated with certain epidemics. Scarlatinal dropsy without albuminuria has been observed by Guersant, Rilliet and Barthez, Noirot, Bouchus, Löschner, Duckworth, and others. Quincke[19] tries to explain such cases of non-albuminuric dropsy as not depending upon nephritis, but as a consequence of the scarlatinal irritation exerting some peculiar influence upon the connective tissue. Cases occur probably in the experience of most practitioners. One should be cautious, however, in deciding against a nephritic origin of these dropsies, except where they can be definitely attributed to anæmia and debility. Henoch[20] has asserted that nephritis may occur without albuminuria up to the time of death. He reports a case in which anasarca was present for three weeks after scarlatina, without tube casts or albuminuria, until convulsions occurred, death resulting from œdema of the lungs. The necropsy revealed the presence of acute nephritis. He also reports the case of a child, dead on the thirteenth day, of malignant scarlet fever, in whom repeated tests during life had not shown albuminuria, and yet whose kidneys showed indubitable evidence of hemorrhagic nephritis. Steiner has seen nephritis without dropsy, but never dropsy without nephritis, after scarlatina. It is altogether probable, however, that in many cases the dropsy following scarlatina without albuminuria is secondary to concomitant anæmia. This is the view adopted by Henoch. Whatever be their explanation, such cases usually run no remarkable course. The general health is not much reduced. The urine is in normal amount, the various functions are fairly performed. With the disappearance of dropsy convalescence is established.

Scarlatinal nephritis is not associated with any especial phase or type of scarlatina. It is as frequent after mild as after severe attacks; indeed, it is possible that the care exercised over those who have grave attacks of the fever, in proper nursing and surroundings, may furnish a safeguard against renal complications. At all events, there is a widespread belief that the milder cases are more apt to be followed by nephritis and dropsy. Violent nephritis may certainly follow a scarlatina so mild as to have escaped observation. Individual predisposition and epidemic type are probably the most important etiological factors, though at present enough is not known to justify dogmatic statement. The nephritis and dropsy may occur without antecedent symptoms of scarlatina. Instances of this are not uncommon. Several members of a family or of a school or asylum in which scarlatina has been known to prevail may exhibit dropsy and albuminuria characteristic of scarlatina, without having manifested any other symptom of the disease. Such cases pursue an ordinary course generally, but at times develop a severity altogether unexpected.

Inflammation of the Lymph Nodes and Connective Tissue of the Neck.—Although Barthez and Rilliet, and others, have observed cases of scarlatina in which there was no angina, in one form or another it is nearly always present. More or less hyperplasia of the neighboring lymph nodes also constitutes part of the ordinary phenomena of scarlatina. The infection is supposed to originate in the throat, the hyperplasia being due to reflex irritation from the scarlet-fever contagium, or to the secondary streptococcus or staphylococcus or mixed infections. It has already been shown that the inflammation sometimes leads to suppuration and even gangrene of the glandular and periglandular structures. This especially occurs in scrofulous and rhachitic children, but is probably a result of septic absorption. The active symptoms become prolonged beyond those of simple scarlatina into the second, third, or fourth week, and even later, and merit some especial notice. They may not develop until as late as the third or fourth week, thus constituting true sequelæ rather than complications. Usually the fever continues after the subsidence of the eruption, the pain and stiffness of the neck increase, and deglutition continues painful and difficult, or even almost impossible. The mouth may be held open and saliva constantly dribble from it. The neck becomes hard, brawny, and swollen; the integument tense, smooth, and shining. The outline of the neck sometimes stands in line with that of the head and underjaw, and it becomes impossible to distinguish the enlarged nodes in the mass of inflammatory exudation. The patient is unable to find repose, or to swallow food or fluids, unless in small quantities and with great pain. Rest is broken and unrefreshing. Suppuration reveals itself by dark-red, livid spots which soon fluctuate; or it may be deep-seated and difficult to detect, or may point and discharge internally. The parotid gland and periglandular tissue often become involved. At times more or less widespread necrosis may lay bare important muscles, vessels, and nerves, and involve large areas of tissue. These diphtheritic and gangrenous inflammations may give rise to phlebitis or arteritis with thrombosis, and embolism with metastatic inflammation. Compression of the larynx, of the trachea, or of the jugular veins may also result. At times pus may burrow into the deeper cervical structures. Hemorrhage may also occur from exposed vessels. Baader[21] reported two cases of death from hemorrhage thus occurring. The extent of these phlegmonous inflammations of the neck varies greatly. In most cases, after the evacuation of pus, recovery follows, though slowly. In more severe cases death may result from exhaustion or from blood-poisoning. In healing, the scars may be insignificant, or, where granulation involves a large surface and is protracted, the resulting cicatrix may occasion deformity by its contraction. Retropharyngeal abscess, which has already been described, is not common. Schmitz, in the Child's Hospital in St. Petersburg, did not observe it once in 450 cases of scarlatina. Cases, however, have been reported. Bokai reported it as occurring seven times in 664 cases; of these 2 were fatal. Lewandowsky[22] reported 2 cases, both resulting in recovery.

Disorders of the Auditory Apparatus.—These are very important complications of scarlatina. Probably most cases of deafness acquired in early life are results of scarlatina. Of 85 cases of affection of the middle ear following this disorder, 18 had lost the sense of hearing in one or both ears, and 3 were deaf-mutes.[23] Milder degrees of middle-ear inflammation arise by extension from the throat, and are simply catarrhal; but the severer forms are preceded by croupous-diphtheritic inflammation of the fauces. The milder form of otitis media will cause the patient some earache, of which, if he is old enough, he will bitterly complain. Infants will indicate their sufferings by cries, by raising their hands to the ears, by rolling the head toward the affected side. If the Eustachian canal remain pervious, all inflammatory exudation may escape, and no symptoms, other than those mentioned, and slight and transitory deafness, may occur. This latter symptom may result from the pressure of an enlarged parotid gland upon the external auditory canal. But in the severer forms the pain may be excruciating, the deafness more or less complete, and the fever high. The Eustachian canal becomes occluded from inflammatory swelling, and exudation accumulates in the cavity of the tympanum. Headache may be violent. The drum membrane will be bulged outward from internal pressure, and will be reddened and swollen. The pent-up fluid, unless released by puncture of the drum membrane, finds an exit for itself by perforation. Extreme pain is often produced by pressure upon the tragus and over the mastoid process. Rarely, delirium may be followed by signs of meningitis from extension of the inflammation from the middle ear to the dura mater, along the course of the middle meningeal artery. In mild cases the inflammation will subside, with or without perforation of the drum, and hearing may be perfectly restored. In severer cases, timely tapping of this membrane may yet preserve the sense of hearing; but, unfortunately, it but too often happens that the ossicles of the ear and the tympanic membrane are destroyed; the bony walls, even of the middle ear, become carious, and irreparable damage is done. The severer inflammations involve a croupous diphtheritic process that often entails wholesale destruction. According to Green, disease of the labyrinth, involving absolute deafness, may occur within a day or two. In such cases the watch held to the skull, the ear, or between the teeth, may not be heard. Green[24] thinks that when loud "clashing," "ringing of small bells," or "musical notes" are heard during scarlet fever or cerebro-spinal meningitis, these are apt to be immediate premonitions of labyrinthine disease; whereas the subjective sounds always accompanying acute purulent inflammation of the tympanum are described as "hissing," "singing," "buzzing," or "throbbing." He also suspects that the fluid secreted in immense quantity—a clear, limpid serum, differing from the wine-yellow serum of tympanic inflammation, may be labyrinthine peri- and endolymph. Pus may form in the mastoid cells. These changes may occur either as complications or as sequelæ. Caries sometimes appears quite early, and the chronic otorrhœa thus set up may last for years, occasioning widespread disorder of both soft parts and bone.[25] In necrosis following middle-ear disease, the facial nerve may become involved with subsequent paralysis. Fatal hemorrhage from the ear may occur after scarlatina, from exposure of vessels from the diphtheritic processes.[26]

Chronic posterior nasal catarrh, and necrosis of the bones of the nasal cavity, constituting various degrees of ozæna, sometimes follow the extension of the pharyngeal inflammation to the nasopharynx. The eye may likewise be implicated in scarlet fever. Conjunctivitis may develop as a complication, or diphtheritic inflammation may extend along the lachrymal canal and involve the conjunctivæ. It may produce keratomalacia and even destruction of the eyeball. Retinitis after scarlatinal nephritis has been observed by Schrötter. Its course is favorable. Temporary blindness may be due to uræmia. Acute amaurosis after scarlatinal nephritis has been noted.[27] Transitory blindness, lasting for from twenty to sixty hours, has been observed by Ebert,[28] Henoch,[29] Tolmachew.[30] In a case of Förster's it lasted eighteen days.

INFLAMMATION OF JOINTS.—Not very infrequently inflammation of the synovial membrane of the joints appears as a complication or as a sequel of scarlet fever. The usual date of its occurrence is during the second week or later. It is often only indicated by pain without swelling, and may be limited to a single joint. In other cases a number of joints are involved, usually the ankles and wrists, knees and elbows. The hip joints may be affected, and also the smaller joints of the extremities. The inflammation may betray all the features of acute rheumatism—the fugitive character of the inflammation, the metastases, the sweating, the fever, even the tendency to implicate the other serous surfaces, the pleura, the endo- and pericardium, and the meninges. Mahomed's[31] studies showed that, as the urine increases in quantity from the seventh to the fourteenth day, it loses its deposit of lithates, and often its albumin (if this has been present). It is highly acid, and uric acid is abundantly thrown down by the nitric-acid floating test. It was at this period that he found the rheumatism most apt to occur. This rheumatism seems identical with ordinary acute rheumatism, but follows a less protracted course. Numerous writers have seen purulent arthritis as a sequel of scarlatina. It commonly occurs during the second or third week, and in most instances is monoarticular. Pyæmic arthritis usually results in suppuration, erosion, and destruction of the cartilage of the joint. According to Spender,[34] the wrist-joint is most often attacked, next in frequency the knee and hip. Recovery may take place, but usually death follows the discharge of pus and the formation of fistulous openings, from exhaustion, or from the further progress of the pyæmia. The approach of these complications, which are fortunately rare, may be recognized through the thermometer.

Affections of the Heart and Pericardium.—Cheadle[32] quotes fifteen cases from West, in which endo- or pericarditis, or both, supervened upon scarlatina. These did not occur during the acute stage, but during desquamation. He, however, considered them rather the result of uræmia and nephritis than of rheumatism. Henoch[33] relates two cases in which acute arthritis appeared during the first week of scarlatina, followed by severe chorea and loud mitral murmur. As to the cardiac symptoms, Cheadle concludes that they occur in scarlatina as results both of scarlatina and of nephritis. He also thought that "scarlatina would appear to have a special influence in causing dilatation and hypertrophy without accompanying valvular disease." Endocarditis, which not uncommonly arises, may be very insidious, and may even pass undetected if not looked for. Probably not a few old valvular affections have originated in attacks of scarlet fever. Acute pleuritis or pericarditis may accompany joint inflammation, or may occur independently. In severe cases they may result in purulent exudation and ultimately terminate fatally. Sometimes the serous inflammations are pyæmic. Endocarditis ulcerosa may begin in this manner.

In the most severe and malignant cases of scarlatina the heart muscle undergoes, first, cloudy swelling, and later, fatty degeneration, especially on the right side. This is the occasion of death from heart failure in many malignant cases.

Affections of the Respiratory and Alimentary Tracts.—Inflammation of the respiratory tract is decidedly uncommon in milder scarlatina. Bronchial catarrh is apt to complicate serious cases. Pneumonia is seen sometimes as a secondary complication following nephritis, diphtheria, etc. Disorders of the intestines are also uncommon. Diarrhœa, when present, is usually associated with severer forms. Diphtheritic enteritis was the most frequent sequel in the cases observed by Fleischmann. Peritonitis may occur as a rare complication. Henoch has seen bedsores complicate scarlatina.

SEQUELÆ.—The affections that constitute true sequelæ usually are disorders that persist after scarlet fever has completed its course, having begun as complications. Thus are encountered chronic buccal, pharyngeal, nasal, and aural inflammations, nephritis (which, as a rule, ultimately entirely disappears), or inflammation of the various serous membranes. In some cases, marked by severe eclamptic seizures, there results contraction of different groups of muscles, giving rise to permanent deformity. Chorea may develop in connection with the arthritis and endocarditis. Progressive involvement of the limbs with paralysis and wasting may rarely be met with, showing the clinical features of an ascending spinal paralysis. Cerebral thrombosis and hemiplegia rarely occur. Mania has been known to follow scarlatina.[35] Gangrene, apart from that resulting from diphtheria of the throat, is infrequent. Noma has been observed by a number of writers (Barthez and Rilliet, Heyfelder, Böning, and others), but it is notably less common than after measles. Necrosis of the nasal cartilage was observed by Henoch during convalescence.

Concurrence with Other Specific Affections.—Scarlet fever may be complicated by, or may complicate, other acute exanthemata, not to the extent, however, that many writers believe. Mayr and Hebra, indeed, taught that scarlatina never coexists with measles or smallpox. This question is involved in much obscurity. Scarlatina may be simulated by a variety of affections that may in fact coexist with the exanthemata, by various erythematous eruptions, by the roseola that often precedes and accompanies the eruption of smallpox, by certain anomalous forms of measles, and by various medicinal rashes—those caused by belladonna, copaiba, chloral, and especially cinchona and its preparations. These considerations and faulty methods of observation and recording lead to the rejection of much of the evidence adduced in favor of these coexistences. After all faulty observations are thrown out, however, there still remains strong proof that scarlet fever may coexist with other exanthems. It will be everywhere admitted that one exanthem may follow close upon the heel of another. Prior[36] noted a case in which scarlatina developed on November 18th, varicella on December 2d, and measles on December 13th. When the two exanthems develop simultaneously, there will often remain much doubt, in the absence of evidence of the double exposure of the unprotected individual and of his subsequent double protection. Where one precedes the other by a few days, the difficulties are not so great. Scarlet fever has been observed as complicating, or complicated by, other exanthemata by Steiner,[37] Monti,[38] Thomas,[39] Fleischmann,[40] Fabore,[41] Stillen,[42] Zechmeister,[43] Backer,[44] Dornig,[45] Lewis Smith,[46] Murchison,[47] and many others. The combinations and the order of occurrence have been noted as follows, viz.:

Scarlatina and measles.
Measles and scarlatina.
Scarlatina and smallpox.
Smallpox and scarlatina.
Scarlatina and vaccinia.
Scarlatina and varicella.
Varicella and scarlatina.
Scarlatina and typhoid fever.

Concurrence of scarlatina and Rötheln has not been reported. A probable source of fallacy is the scarlatiniform rash that is often observed in smallpox, and occasionally in typhoid fever; indeed, Simon asserts that Fleischmann has even made this very error. The possibility of these rashes should always be held in mind when questions of concurrence are under consideration. When scarlet fever develops after smallpox the eruption involves the parts of the skin left free by the lesions of smallpox, more especially about the chest and abdomen. When the two exanthems appear simultaneously, their course is shortened; "the second mitigates the first and becomes shortened itself," excepting, according to Fleischmann, when severe smallpox occurs in connection with scarlatina, when death usually results. The same author asserts that if scarlatina appear at the period of maturation of smallpox, the latter, in mild cases, is shortened and mitigated. When scarlatina complicates measles, the latter is shortened, but the scarlatina thus occurring may be mild or severe. Barthez and Rilliet noted that in scarlatina-measles, when the former malady predominates, bronchitis is more marked; but when measles is most severe, faucial angina is worse. All of these statements lack such evidence as would entitle them to unqualified acceptation. Very often neither disease is well developed, and the true condition may be very difficult of recognition. In America these concurrences are more uncommon than they seem to be abroad.

Whooping-cough has been known to complicate scarlatina, and a number of non-specific affections may occur simultaneously with it. These coincidences are purely accidental and present no peculiar interest. Biart[48] has reported psoriasis as following scarlatina. Barthez and Rilliet assert that tuberculous children very rarely have scarlatina. Some chronic affections partially or entirely disappear during an attack of scarlatina. Among these may be especially mentioned certain cutaneous affections, eczema, psoriasis, etc., but they usually reappear upon the establishment of convalescence.

Surgical Scarlatina.—Sir James Paget, in 1864, and again in 1875,[49] declared that patients who have undergone surgical operations are peculiarly susceptible to the action of the scarlet fever poison. This question has attracted a great deal of attention. In France, Trélat was the first to accept this view, though scarlatinoid rashes had been observed by Civiale, Germain Sée, Tremblay, and others. Similar rashes were reported by Hutchinson, Hilton, Bryant, Lee, Moore, Stirling, and others. They had generally been considered as of septicæmic origin. In 1879 Paley and Goodhart[50] and House[51] reported observations of endemics of scarlatina in the Evelina Hospital for Sick Children and in Guy's Hospital. The first-named authors based their report upon twenty-five cases of scarlatina occurring in surgical patients. Of these nineteen were known to have been exposed to scarlatina, and all the rest, save one, were known to have had possible sources of infection. House's paper was based upon four cases of surgical scarlatina. The epidemic tendencies ceased upon the establishment of isolation, and one cannot doubt their scarlatinal origin. These writers were careful not to assert that *all* such red rashes should be attributed to scarlatina, or that there is *not* "such a thing as a rose rash in a typical case of septicæmia"; but they believe that when occurring in groups they may nearly always rightly be attributed to scarlatina. Riedinger and Howard Marsh also agreed that there exists in wounded persons a predisposition to scarlatina. While Holmes coincided with these views, he, however, declared that many cases of "surgical scarlet fever" are really due to pyæmia and other causes. Most recent writers incline to the opinion that these eruptions are due to true scarlatina. When any epidemic tendency is shown, every one will agree with such conclusions. This cannot be granted of rashes occurring in isolated cases. Of 25 cases reported in Paley and Goodhart's paper, scarlet fever attacked 17 after operations; 7 were without any wound whatever, and 1 had only an old sinus. In many of the cases reported by other writers there was no open wound. These reporters, unfortunately, most rarely note whether their patients had ever previously had scarlatina. Most children, when first exposed to the contagion of this disease, become infected. Is it remarkable that they are unable to withstand it when it attacks them, weakened by injury or surgical operation? Apart from epidemic influence, it is probable that scarlatiniform eruptions in the wounded may justly, in a large proportion of cases, occur quite independently of scarlatina. Rashes of septicæmic origin are well known to occur. Various fugitive eruptions often result from emotional and nervous irritations, or from the ingestion of certain articles of food or medicines. It must be admitted that scarlatiniform septicæmic rashes are uncommon. But there is excellent evidence that they occur.[52] Attempts have been made to establish a differential diagnosis for the surgical scarlatiniform rash. Cheadle,[53] for example, claimed that it has specific characters in not often being universal, and in being confined to the body and parts covered by the clothing; that it rarely lasts twenty four hours, and that it never desquamates. He also asserted that there is no tonsillar swelling, nor glandular enlargement, nor the peculiar "strawberry tongue." Such points of differentiation do not appear to be well founded. Scarlatiniform eruptions also occasionally follow the ingestion of certain drugs. They may be evoked by belladonna, copaiba, opium, chloral, mercury, and other drugs, but, above all, by cinchona bark and its derivatives. These eruptions are much more common than is generally supposed. Quinine has been frequently given to those who have been injured or submitted to surgical operations, and beyond question eruptions evoked by it are often attributed to other causes. A number of eruptive forms are observed, but the one of especial moment is the scarlatiniform rash. At the onset it often cannot be distinguished from scarlatina. Beginning with high fever and often with sore throat, the eruption appears upon the face, chest, and neck, and within twenty-four hours the entire surface may present a bright scarlet aspect. At the end of this period the resemblance may be made perfect by the "strawberry tongue." Up to this point the diagnosis may be impossible. Rarely, it remains so throughout the attack, especially when the ingestion of the cinchona preparation is continued. Usually, however, after thirty-six or forty-eight hours the type of normal scarlatina is departed from. The fever rapidly decreases, the angina disappears, and the rash either fades or acquires features unlike those of true scarlatina. It becomes duller, more papular, and often tends to form miliary vesicles. Eventually it may resemble ordinary "prickly heat." Sometimes, however, the scarlatinal features are preserved throughout. In either case a copious desquamation is sure to follow. This is usually lamellar. Even albuminuria has been known to add to the embarrassment of the diagnostician. These medicinal and septicæmic rashes occur in isolated instances, and may at times baffle the keenest diagnostic powers. We may conclude that unprotected persons who have suffered injury or who have undergone surgical operations are rather more liable to scarlatina than the unprotected healthy. Scarlet fever is more apt than the other exanthemata to attack such persons, because its symptoms vary within such wide limits that it often escapes the attention of those who readily detect other infectious disorders and provide against them. When an epidemic tendency of the symptoms we have been considering is shown to prevail, it may be confidently concluded that true scarlatina is present. Septicæmia is occasionally accompanied by a scarlatiniform rash which does not depend upon the scarlatinal poison. These rashes are often attributed to scarlatina.

Scarlatina Puerperalis.—While pregnant women seem to enjoy a remarkable immunity from the specific eruptive fevers, it is well known that during the *puerperium* they are especially subject to them after exposure, and that the disease is then apt to pursue a grave and often fatal course. Not only scarlatina, but measles and smallpox may affect the lying-in woman with such malignity that the symptoms may not acquire the features of the maladies to which they belong, but become indistinguishable from those of malignant septicæmia. Scarlatina is especially liable to attack the lying-in woman. It may assume the virulence referred to, or it may pursue a course in which it is difficult to determine whether its symptoms are septic or really scarlatinal, or, finally, it may appear with typical and unmistakable features. Not a few writers have thought that the scarlatinal virus may produce in the puerperal woman septicæmia, pure and simple. This view is maintained by Playfair, Braxton Hicks, Leishman, and others. They assert that in these women, after exposure to the specific contagium, symptoms of acute blood-poisoning may be developed, and not those of scarlatina. On the other hand, just as in septic conditions, independent of puerperal causes, an erythematous rash and other scarlatinal symptoms may be observed in which true scarlatina has no part, so must one guard against assigning to scarlatina every scarlatiniform rash occurring in obstetrical cases. It may be septic in origin, or it may be a medicinal eruption. When a septic, or medicinal, or other form of erythema can be excluded, and when exposure to scarlatinal influence is followed by any degree of the symptoms we are considering, are we in atypical cases to look upon the results of the infection as distinctly scarlatinal? More recent writers regard the scarlatinal nature of the disorder as preserved, and as capable of further dissemination. It has not been determined to what extent women who have already had scarlatina preserve an immunity from further attacks during their lying-in period. It would appear that the intensified predisposition of the childbed carries with it an increased liability to second or third attacks. Busey[54] has related a case in which the patient had already had scarlet fever. Other such cases are upon record.[55]

In all probability the scarlet-fever contagium evokes scarlet fever, and not septic disorder, in the puerperal woman, whose systemic condition affords peculiar susceptibility to its influence, and predisposes her to a virulence of its activity that often leads to disastrous results. The less remote the date of delivery the graver the course of the malady is apt to be. If the symptoms do not appear before the seventh day, their development is no longer to be feared. Olshausen[56] collected from the literature 111 cases, of which the scarlatina attacked, during pregnancy, 7; in 8 it immediately followed delivery; in 62 it occurred on the first and second days; in 27 on the third day; in 22 after the third day. After the fifth day none was attacked. While the puerperal woman shows intense susceptibility to scarlatina, the pregnant woman enjoys a marked immunity from it. Olshausen thinks, however, that the period of incubation may last for months during pregnancy, but only a few days during childbed. This opinion he rests upon no solid basis. Primiparæ are more often attacked than multiparæ. The mortality in puerperal scarlatina is high. In the series just alluded to it was 48 per cent (3 cases during pregnancy and 64 in childbed).

In the recorded cases studied by McClintock[57] the mortality was over 66 per cent. In 34 cases at the Lying-in Hospital the death rate was 30 per cent. Of 10 deaths at this hospital, 8 occurred when scarlatina had developed within thirty-six hours after delivery. Of 18 patients attacked on the first or second day, 8 died. Of those attacked on or after the third day (16 in number), all but 2 recovered. McClintock also quotes Dr. Halahan's cases, as follows, viz.: 3 patients, ill of scarlatina at the moment of delivery, died; of 5 attacked during the first twenty-four hours, but 1 recovered; of 10 attacked during the second day, but 1 recovered; of 4 attacked during the third day, but 1 recovered. The remaining 3, attacked on or after the fifth day, recovered. Braxton Hicks'[58] contributions to this subject have been most important. He believes that in one-half of the cases the usual symptoms of scarlatina are manifested, and that the disease almost always commences after the third day after delivery. The death rate will be greater the earlier after labor the symptoms develop. Though lying-in women are peculiarly liable to scarlatina, they are frequently exposed to its influence without detriment. Women have not seldom been confined in the room, even in the bed, occupied at the same time by scarlet-fever patients, without experiencing the slightest interruption of their normal convalescence; a result that is not astonishing in protected persons if the scarlatinal virus transmits only scarlatina, but which would not be expected were the virus equally competent to communicate septicæmia in these cases. While a large proportion of cases pursue a grave and anomalous course, there are many others in which a perfectly typical scarlatina is observed, without seriously endangering life. Secondary inflammations are not unknown. Metritis, cellulitis, peritonitis, or pyæmia may be developed, but whether these are direct results of scarlatina or of the puerperal condition is undetermined.

The exact nature of puerperal scarlet fever and surgical scarlet fever will remain in doubt until a specific organism of scarlet fever can be isolated. At present this is impossible. In the mean time it is interesting to note that with the development of aseptic and antiseptic methods in surgery and obstetrics, less and less is heard and seen of "puerperal" and "surgical" scarlet fever.

Relapses and Recurrences.—There are recorded numerous instances of relapse of scarlet fever within a short period after the original attack, and second or even third attacks after a more or less prolonged interval are well known to occur. By a relapse is meant a second attack of scarlatina that is evidently due to the persistent activity of the influences that excited the first attack.

Within a short period (three days after deflorescence in a case of Woldberg's[59]) after the original attack all the symptoms are repeated; the initial disturbances, the fever, the eruption, the angina, and other phenomena, with ensuing desquamation, are developed. It is held that the second attack is but the completion of the first, that it occurs after an incomplete primary attack, and that it tends to be severe in proportion to the mildness of the first, and often to affect in eruption only those parts which were originally spared,[60] imparting thus to the second eruption the appearance of scarlatina variegata. The relapse may be accompanied by complications of throat, kidney, and other disorders, that were not present in the earlier disorder, and *vice versa*. These relapses are usually very rare, but seem to be more frequent in certain epidemics.

Thomas applies the term pseudo relapse, or *reversio eruptionis*, to those cases in which the exanthem returns before the disorder has entirely completed its course. Trujawsky found the interval between the two attacks to be from seven to ten days, with an average of eight and five-eighths days. The intermissions are completely afebrile. These relapses have been explained by, (1) a recrudescence of the original contagion, and (2) the action of a newly acquired contagion from a source different from the original one. The prognosis is often graver than in the primary attacks.

Recurrences or attacks of scarlet fever occurring after a more or less protracted interval are more common, and are due to fresh infection. They may occur at almost any period. Trujawsky[61] noted, in 300 cases of scarlatina, 18 patients who had had a former attack. Of these 4 were under ten years of age, 10 were over ten years, and 3 were adults. The interval between the attacks varied from one and a half to seven years. Thomas had personal knowledge of a case in which a second attack occurred. Willan never saw one. Many years may elapse between the two attacks, as when a mother who had the disease during childhood again develops it by contagion from her child. Heyfelder himself had a second attack twenty-seven years after the first one. Trujawsky thought that immunity is greater against contagion originating at the home or in the neighborhood of the patient than when it is brought from a distance. A third attack in the same individual may be observed (as in Richardson's case), and there are reports of repeated attacks of scarlet fever. Bernouilli,[62] for example, mentions the case of a woman, fifty years of age, who experienced in rapid succession six attacks of an exanthem indistinguishable from scarlatina. Other similar cases are on record, but their consideration suggests that they may rather have been forms of medicinal eruption.

Acute exfoliative dermatitis may also be mistaken for scarlet fever, and may attack repeatedly the same person. Rashes resembling scarlatina may occur in various other affections, such as typhoid fever, smallpox, etc. Hallopeau and Tuffier[63] saw a scarlatiniform eruption in acute rheumatism, in which there were two relapses with intense erythema, followed by copious desquamation. The possibility of all such cases being mistaken for scarlatina should be remembered. It is a rather singular fact that many persons suffer from angina whenever they are brought into close personal relationship with those who have scarlet fever. This is commonly mild, but may occasion serious discomfort. Those who suffer thus from exposure to the scarlatinal influence do not communicate scarlatina to unprotected persons. Mild desquamation is said to have been noted in some such cases. This, however, would indicate a true scarlatinal infection.

Pathological Anatomy.—In most fatal cases every trace of eruption disappears after death. After a very intense exanthem, more or less redness may remain. After malignant cases blood extravasations may present the only post-mortem discoloration. The organs primarily affected are the *skin* and the *throat*; the principal complications arise in connection with the *ear* and *cervical lymph nodes*; and the chief sequela is *nephritis*. The *heart* may be affected as a result of the general septic condition, but its lesions are more frequently dependent upon the changes wrought in the kidneys.

Skin.—Remy[64] and Neumann have investigated the histology of the skin in scarlatina. Remy found the capillaries of the papillary layer dilated and hyperæmic, and filled with leucocytes which were enlarged and of different sizes, but not so large as in leukæmia. The vascular wall was not altered. The epidermis was thickened by increase of its cylinder cell layer. The horny layer, sebaceous glands, and hairs were unchanged. The sweat glands were empty and shrunken. Neumann found the cells of the rete swollen. In many specimens the prickle cells were elongated, and here and there formed interspaces in which exudation cells were embedded, and into which small blood extravasations often occurred. Exudation cells extended abundantly as far as the horny layer, and at the orifices of the follicles they were very numerous. In measles this epidermal layer presents no marked changes; hence it is not difficult to understand why the epidermal cells are so much more liable to carry the contagium in scarlet fever than in measles. The corium was swollen, the fibres were thickened, partly separated by proliferation, partly by enormously dilated vessels that were at times bulbous. It is this exudation into the epidermal layers that causes the loosening of the horny layer from its bed, and the characteristic desquamation. Löschner and Fenwick have also noted this infiltration of the rete. The latter writer found the basement membrane of the sweat glands also thickened and the lining membrane gone in places, but in other places it was increased so as to occlude the sweat glands. The deeper layers were normal throughout. The scarlet-fever exanthem, then, consists of hyperæmia with exudation. Remy found the changes he describes regularly and uniformly distributed.

Throat.—The throat symptoms, as constant as are those of the skin, are due to lesions that are always recognizable after death. The milder alterations offer nothing characteristic; they are identical with those of pharyngeal catarrhal inflammation. In more intense degree follicular inflammation, with suppuration and ulceration, is superadded, and œdema becomes more prominent. The inflammatory changes extend beyond the pharynx into the buccal and nasal cavities, while parenchymatous tonsillitis and inflammation of the cellular tissues of the throat and neck develop, with, sometimes, extensive gangrene.

According to Härlin (Thomas), scarlatinous angina is specific, and is marked by "a deep, bluish-red injection of the mucous membrane of the tonsils and neighborhood, of the uvula, of the posterior portion of the tongue in the neighborhood of the highly swollen papillæ, of the posterior portion of the region of the cricoid cartilage, and of that portion of the pharynx which includes these different parts, and measures about two inches in breadth." This coloring is said to be sharply outlined in the direction of its transverse diameter.

Among the earlier writers on scarlet fever, and as late as the years 1883 and 1884 when the Klebs-Loeffler bacillus was discovered and demonstrated as the specific cause of diphtheria, much space was devoted to the nature of the diphtheritic membrane so often formed in scarlatinous angina. The weight of opinion was that the scarlatinal virus, acting upon the virus of the throat, caused a coagulation necrosis that resulted in the production of the membrane, although it was held that occasionally the scarlatinal process might be complicated by a true diphtheria. The result of modern bacteriological researches has shown that the diphtheritic membrane is in all probability the result of the activity of streptococci and staphylococci or of a mixed infection. There may be, of course, a Klebs-Loeffler infection as well. The influence exerted by the scarlatinal virus in the production of the pharyngeal inflammation cannot be determined in the present state of our knowledge of the specific cause of the disease.

Kidneys.—Bacteriological examinations of the tissues in scarlet fever frequently show general streptococcus infections, probably having their origin in the lesions in the throat. In a number of these cases there may be found in the kidneys extensive lesions which bear no relation to the presence or absence of streptococci; on the other hand, streptococci may be found in the kidney without any lesion of the kidney.[77] We may assume, therefore, that at times the pathological changes are a result of soluble chemical poisons produced by the virus of scarlet fever or by the activity of the associated secondary infections by streptococci and staphylococci, and at times the lesions are due to direct infection of the kidney by organisms conveyed to it by means of the blood.

Councilman, who has made recent and extensive studies in the pathology of scarlet fever, divides the kidney lesions into two classes: (1) Representing simple degeneration of the epithelium; and (2) representing marked changes in the tissues of the kidney. The lesions of the second class he divides according to their anatomical distribution into (*a*) *interstitial*, in which there is marked proliferation of the interstitial tissue of the kidney; and (*b*) *capsular glomerular*, in which the lesions are chiefly confined to the glomerulus and its capsule.[77]

The first, the purely degenerative form, appears at the beginning of the exanthem, or a few days later, and disappears in a few days or weeks. It rarely excites œdema, and hardly ever kills. It is analogous to the alterations productive of the febrile albuminuria of many infectious diseases. Cloudy swelling and proliferation of the tubular epithelium, and, later, fatty degeneration, are shown. Within the tubular lumen are hyaline and granular cylinders, round cells, and desquamated epithelium.

The second type, the *interstitial*, was first described by Wagner as the lymphoid kidney.[77] The kidney is swollen, the capsule is easily stripped from the cortex, and the surface is moist, whitish, and opaque. Usually there is no hemorrhage, although in some cases punctiform areas may be found in the cortex and intermediate zone. The epithelium may show the changes characteristic of the first or purely degenerative class. The most marked feature of this class of cases is the thickening of the interstitial tissue and the abundant infiltration with round cells, most of which are plasma cells, with some lymphoid cells and polynuclear leucocytes. This form of nephritis may be markedly developed and yet not give rise to clinical symptoms any more pronounced than are seen in the first or purely degenerative class. It is not confined to scarlet fever, but may occur in the course of diphtheria, measles, and other infectious diseases of children, but is not commonly produced in adults in the same class of diseases.

The third form of nephritis, the capsular glomerular, is a more frequent accompaniment of scarlet fever than of any other infectious disease, but is not so common as the acute interstitial form. The kidney is swollen and hyperæmic, the markings of the cortex are obscured or effaced, while the hemorrhagic areas give to the kidneys a mottled appearance. Histologically the chief lesion of this form consists of a proliferation of the capsular epithelium combined with hyperplasia of the connective tissue. The proliferation of the capsular epithelium increases the pressure upon the glomerulus so much as to interfere with the blood supply and hence with the secretion of urine. It is this form of nephritis which is especially liable to give rise to dropsy, to greatly diminished amounts of urine, or to uræmia. The clinical appearance of the urine is that of an acute diffuse nephritis, the amount of blood, albumin, and casts depending largely upon the severity of the infection. Recovery may take place even from the severe forms of capsular glomerular nephritis, but chronic nephritis is a sequela in a certain number of cases. Friedländer holds this to be the only characteristic scarlatinal nephritis.

These three forms of nephritis—the simple degenerative, the interstitial, and the capsular glomerular—may usually be recognized histologically, but transition changes occur. It is not always practicable to make sharp definitions between early and late changes. The first set of changes are chiefly limited to the cortex. They are: 1. Increase of nuclei (probably epithelial) covering the glomeruli. 2. Hyaline degeneration of the elastic intima of minute arteries, especially of the afferent arterioles of the Malpighian tufts. The intima of these vessels is swollen here and there into spindle-shaped hyaline masses, causing narrowness of the lumen. There is similar hyaline degeneration of the capillaries of the glomeruli, rendering them often impermeable. These degenerated parts become fibrous in appearance, and Bowman's capsule becomes thickened. 3. A third change is multiplication of the nuclei of the muscularis of the minute arteries, with increased thickness of their walls. This is greatest at the point of entrance into the glomeruli, but is also distinct in other arteries of the cortex and in the base of the pyramids. There are also swelling of the epithelia of the convoluted tubules and proliferation of their nuclei, especially of the tubules close to the afferent arterioles of the glomeruli. In some cases the epithelium of the large tubules of the pyramids is detached. Klein's[66] observations, (1) that the hyaline changes readily affect the arteries near their point of branching, and (2) that the hyaline substance is of the nature of elastic tissue, agree with the conclusions of Neilson concerning the arteries in various cerebral disorders and in many infectious diseases. He does not think that the anuria and uræmic poisoning in scarlatina, when the kidney does not show conspicuous change, are due to compression of the vessels of the glomerulus by the nuclear germination, as claimed by Klebs,[67] but rather to the changed state of the arterioles, and suggests that the increased formation of arterial muscular fibres, under the stimulus supplied by the disease, may cause a contractility that obliterates the calibre of the arterioles and shuts out the glomerulus from the circulation, and thus, so far as it operates, suppresses the secretion of urine. The parenchymatous changes found in the early stages are slight and difficult to detect, the cloudy swelling and granular degeneration being limited to small portions of convoluted tubules. The second order of changes begins about the ninth or tenth day. They are interstitial as well as parenchymatous. Round cells are found around the larger vascular trunks, spreading into the bases of the pyramids and into the cortex. This process begins about the end of the first week, and gradually increases until portions of the cortex, rarely portions of the bases of the pyramids, are converted into pale, firm, round-cell tissue, in which the tubules become compressed and obliterated. The parenchymatous element of the nephritis consists in crowding of urinary tubules with lymphoid cells and various kinds of tube casts, and fatty degeneration of the epithelium of the tubules. This grows more marked with the advance of interstitial changes. The round-cell infiltration of the cortex begins at the roots of the interlobular vessels, spreading rapidly toward the capsule of the kidney, and laterally among the convoluted tubes around the glomeruli, at first between the medullary rays, but later encroaching upon them. Portions of the cortex may be converted into firm, pale, bloodless cellular masses in which Malpighian tufts and urinary tubules become more or less destroyed. In one case renal embolism was encountered; both interstitial and parenchymatous inflammation was very intense. The kidney was markedly enlarged. Klein also noted deposition of lime in the epithelium and lumina of the tubules, first of the cortex and then of the pyramids, at an early stage of scarlatina, when only slight changes are otherwise shown. He concludes that cases of scarlatina which are fatal after the ninth or tenth day usually show more or less well-marked interstitial nephritis.

Lymph Nodes.—Peculiar changes have been noted in the lymph nodes by Klein. In addition to the ordinary inflammatory infiltrations which he describes as occurring in the lymphatic follicles connected with the organs of the throat and in the lymph nodes of the neck, the ordinary lymphoid cells are greatly diminished in number, and are replaced by large granular cells containing numbers of germinating nuclei.

Liver.—This viscus becomes slightly enlarged from cloudy swelling. In one case Klein noticed, after two days' illness, acute interstitial hepatitis. The middle and internal coats of some arteries show the same alterations as in the kidneys. Wagner observed lymphoid new formations and numerous collections of cells and nuclei, especially in the interacinous connective tissue.

Spleen.—In the spleen the changes are uniform and constant. They are: 1. Enlargement of the Malpighian corpuscles. 2. Hyaline degeneration of the intima of the arteries. 3. Proliferation of the nuclei of the muscular coat of the ultimate arterioles, with increased thickness of their walls. 4. Hyaline swelling and degeneration of the adenoid tissue around the degenerated arteries. 5. In the central parts of the Malpighian corpuscles the ordinary nuclei of the lymph cells disappear, and in their stead are found large hydropic cells containing pigment (Klein). Other writers assert that there is no uniformity in the splenic changes, beyond a slight enlargement. Biermer has observed enormous enlargement of the Malpighian bodies.

Intestines.—Disorders of the alimentary canal are not frequent in scarlatina, and when they occur it is usually in grave cases. They then not infrequently constitute the principal complicating lesion. In the cases of Fleischmann, diphtheritic enteritis was the most common sequel. The peculiar "shaved-beard appearance" of Peyer's patches has been at times observed, and at times these patches and the solitary glands are prominent, reddened, and inflamed, with associated tumefaction of the mesenteric glands (Harley). Barthez and Rilliet show, however, that in cases in which the typhoid-like lesions have been discovered, the symptoms shown during life did not resemble those of typhoid fever; and conversely, cases of typhoid scarlatina cannot be expected to reveal these lesions after death. Enteritis is more often catarrhal in nature. It has been asserted that in scarlatina the exanthem invades the mucous membrane to the same degree as the skin. Post-mortem evidence of this, however, is by no means constant. The glands throughout the alimentary tract are sometimes swollen, and sometimes form small ulcers and extravasations.

Brain.—It is rare that even the most intense cerebral symptoms occurring in the course of scarlet fever are due to meningitis. Hyperæmia of the brain and meninges, with great venous engorgement, is often seen, but signs of pronounced change are extremely uncommon.

Ear.—An acute otitis media is the most common affection of the ear met with in scarlet fever. The inflammation is especially likely to result in the destruction of tissue, the formation of adhesions, and the establishment of a long-continued suppurative process with accompanying necrosis.

Periostitis and osteitis occur in connection with affections of the joints, of the nose, of the pharyngeal and aural cavities, and of other parts, but afford nothing characteristic. Neither do the general serous surfaces show peculiar lesions. The condition of the blood and blood-vessels after certain rapidly fatal cases is important. Sometimes the blood is very fluid and black. At other times clots are abundant and firm; again, it may have become diffused throughout the tissues. Remy has seen all the vessels of the papillary layer of the skin filled with coagulated blood. Thrombosis of the sinuses has been noted after scarlatinal diphtheria (Thomas).

Heart.—Fatty degeneration of the heart following cloudy swelling, with dilatation, occurring particularly in the walls of the right ventricle, is a frequent result of scarlatina, as it is of other infectious disorders.

Diagnosis.—Scarlet fever must be distinguished from measles, rubella (Rötheln), roseola variolosa, scarlatiniform rashes of septic or medicinal origin, certain idiopathic erythemata, and diphtheria. From measles it differs in its shorter incubative stage, and in the character of its prodromes. In the former affection there are symptoms of coryza and bronchitis, with photophobia, sneezing, coughing, and the appearance of Koplik spots on the mucous membranes of the cheeks and lips (see *Measles*), while in scarlatina the prodromal symptoms especially involve the throat and in children are frequently associated with vomiting. In scarlatina the eruption begins to appear during the first or second day; in measles during the third or fourth day. During the course of scarlatina there is an absence of catarrhal symptoms for the most part. There are the characteristic sore throat and enlarged papillæ on the sides and tip of the tongue, the peculiar "strawberry tongue" (after the first two or three days), the well-defined eruption, the more protracted fever, the pronounced desquamation, and the tendency toward renal complications. The eruptions differ both in their development and in their distribution in the two affections. In scarlatina the face is characteristically invaded by the eruption, which entirely spares the area about the mouth, and is nowhere copiously developed in this region; while in measles the eruption is, probably, most intense upon the face. The macules in measles are large, irregular, and mostly papular. In scarlatina the eruption is punctate and more regularly distributed, not elevated; it is scarlet in color, and generally coalescent, while in measles it is more discrete, elevated, arranged very extensively in forms of crescents and segments of circles, with greater or smaller areas of healthy skin between the lesions, and is of a darker raspberry color. In measles the stage of eruption lasts for from three to four days, and begins to decline as soon as the eruption upon the lower extremities becomes complete. It occupies about thirty-six hours in attaining its acme. In scarlatina this stage lasts for from two to six days or more. It attains its acme in about eighteen hours. In measles there is a rapid return to a normal temperature in uncomplicated cases, while in scarlatina both eruption and fever decline more slowly. The conjunctival, nasal, and bronchial catarrh of measles is absent in scarlatina. In measles the tongue remains coated throughout. Sore throat is constant in scarlatina, quite uncommon in measles, and when present is almost invariably only catarrhal. The fever in scarlatina is at once more intense and more protracted. The desquamation of scarlatina is pronounced and lamellar; that of measles insignificant and branny. The presence of leucocytosis, not otherwise to be accounted for, is evidence in favor of scarlet fever and against measles. Scarlatina is frequently complicated by diphtheritic pharyngitis and renal inflammation, measles by inflammations of the respiratory apparatus.

The eruption of rubella (Rötheln) more closely resembles that of scarlatina. It is paler, more discrete, and its lesions are larger and more distinctly papular. It is more transitory, and fades almost without desquamation, which, when present, is branny. Rötheln, moreover, has a longer incubation, almost no prodromal stage, sometimes marked catarrh, and but slight elevation of temperature. It is feebly contagious, of much shorter duration, and is hardly ever followed by nephritis and dropsy. The diagnosis is difficult only when the eruption of rubella becomes confluent. Here, however, the confluence involves certain areas. It is sharply circumscribed by normal integument, and shows in contrast the outlying characteristic lesions. It is of a pale rose-red, and not of a scarlet color, and is accompanied by the peculiar symptoms of rubella, and rarely lasts more than thirty-six hours. Both measles and rubella may at times closely resemble the milder forms of scarlatina, and from the eruption alone the diagnosis may be difficult; but a consideration of all the symptoms will usually lead to correct conclusions. The presence of leucocytosis, in the absence of other conditions to account for it, is strong evidence in favor of scarlet fever.

Roseola variolosa should excite embarrassment only when it occurs before the peculiar eruption of smallpox has appeared. It is less general, is more like a simple diffuse erythema than is scarlatina, and is so speedily followed by the characteristic vesicular eruption that doubt will soon be dissipated. Its coexistence with the essential eruption may excite suspicions of a concurrence of scarlatina and smallpox. Such an error may readily occur.

Obstetrical and surgical scarlatina have already received attention. When erythema begins near a wound and becomes scarlatiniform in spreading, a septic origin must usually be allowed, though instances of scarlatina thus beginning have been reported; otherwise, septic erythema is more circumscribed and irregular. Scarlatina in the wounded and in lying-in women may be perfectly typical.

Medicinal eruptions have unquestionably been at the bottom of many errors of diagnosis. It has been shown that many drugs may excite eruptions and general symptoms very like those of scarlatina, but for the most part they are simple active hyperæmias, such as are produced by the action of belladonna upon the cutaneous arterioles. Such eruptions differ from that of scarlatina in the absence of prodromes, and, usually, of fever. They are also mostly partial and without the history, course, or results of scarlatina; but at times, and especially when they follow the ingestion of preparations of cinchona, the whole complex of scarlatinal symptoms may be accurately simulated. The conditions for diagnosis have already been pointed out. In second or repeated attacks of so-called scarlatina, due consideration of the possible influence of drugs as an etiological factor will doubtless convert some very puzzling cases into very simple ones.

Acute exfoliative dermatitis and desquamative scarlatiniform erythema[68] may well be mistaken for scarlatina upon their first appearance. The rash is more protracted than in the essential fever, and is less abrupt in its onset. The local symptoms are very marked, while the constitutional phenomena are usually insignificant. The desquamation may begin while the eruption is in full florescence. These affections are not contagious and have no specific sequelæ.

An erysipelatous eruption may be like that of scarlatina. It, however, differs markedly in its distribution, its evolution, and its course, being never universal, always progressive, and of indefinite duration. The subjective symptoms are quite different in the two affections; the erysipelatous eruption is painful both spontaneously and on pressure. Much œdema accompanies the latter eruption.

Diphtheria may complicate scarlatina, and the intensity of the local inflammation may induce a coagulation necrosis exactly corresponding to the membranous formations of diphtheria. Idiopathic diphtheria may especially resemble scarlet fever when it is accompanied by the erythematous exanthem that is sometimes developed, either early in the disorder or later, in cases of blood poisoning. At first it may not be possible to arrive at a correct diagnosis. According to Robinson,[69] in the early diphtheritic erythema there is no marked elevation of temperature. The rash may begin in any region, and rarely extends to the whole surface. The tongue is not affected, and there may be no special general disturbance. Desquamation does not occur. Bacteriological examination of the nasal and buccal secretions will almost always determine the presence or absence of true diphtheria. The late diphtheritic erythema is septic.

When the eruption of scarlatina is imperfectly developed, or when it does not appear at all, and when sore throat and fever are the only symptoms to attract attention, the diagnosis must rest upon the history of the patient and his surroundings, and upon the course of his illness. In not a few cases a retrospective diagnosis of scarlatina must be made, after the occurrence of desquamation or the supervention of nephritis and dropsy under conditions that indicate their scarlatinal origin.

PROGNOSIS.—The mortality from scarlet fever varies widely in different epidemics. From the affection that in Sydenham's time "hardly deserved the name of disease" to a pestilence of intense malignity, all degrees of fatality have been, and continue to be, observed. Epidemics have been recorded in which no deaths have occurred. Recently Whitla[70] has recorded but a single death in 133 cases of scarlatina treated in hospital. Such results are, unhappily, exceptional. The mortality has been known to reach 30 and 40 per cent. An excessively high rate of mortality is, in great part, attributable to epidemic tendencies toward grave complications, diphtheria, nephritis, etc. In private practice the death rate will not often exceed 10 per cent. In hospitals the percentage of deaths is usually much higher, the result being due to the fact that milder cases are kept at home for the most part, and not to differences in social condition, except in so far as neglect and exposure previous to admission may have aggravated an attack or have excited a complication. The death rate will be high or low in accordance with the type of the prevailing epidemic, and the average mortality of the disease should always be considered with reference to this. Neither season nor atmospheric condition appears to exert any influence upon the epidemic type. Likewise, telluric conditions do not modify it. Benign and malignant epidemics follow each other without evident cause. The mortality at the beginning and during the height of an epidemic is greater than during its decline. Barring the effects of extreme poverty and exposure, scarlet fever affects the rich and poor impartially. The sexes are almost equally attacked, but age exerts a striking influence upon the result. Children under one year of age, though less apt to be attacked, are especially liable to fatal forms of the disease. According to Fleischmann, the mortality at St. Joseph's Hospital was: under one year of age, 75 per cent. (8 cases, 6 deaths); from one to four years of age, 43 per cent.; from five to twelve years of age, 19.6 per cent.; the total mortality being 10 per cent. The majority of deaths occur under the sixth year of age; with increasing years the prognosis becomes more favorable. Fleischmann's records show a higher mortality than those of some other writers. For example, Kraus gives 4 deaths in 13 cases less than one year of age; 29 deaths in 113 cases from the close of the first to the close of the fifth year of life; 10 deaths in 106 cases from the end of the fifth to the close of the twelfth year of age; and 2 deaths in 40 cases from the twelfth to the twentieth year of age. Voit reported 1 death in 5 cases less than one year of age; 24 deaths in 166 cases from the first to the close of the sixth year of age; 10 deaths in 109 cases from the sixth to the twelfth year of age. Roset reported 16 deaths in 43 cases less than one year of age; 31 deaths in 156 cases from the first to the close of the fifth year of age; and 3 deaths in 88 cases over five years of age.[71] An exception must be noted to the favorableness of the prognosis in persons of maturer years, in the case of puerperal women, in whom scarlatina has already been shown to be especially malignant. No case can appear to be so mild as to justify a prognosis unqualifiedly favorable. From the beginning until the termination in recovery there is no period when a sudden change may not place the life of the patient in jeopardy, whether by an aggravation of the essential symptoms of the disease, or by the supervention of complications. The prognosis, however, is generally favorable if the disease pursues a regular course; if the eruption follows a brief prodromal stage and is regularly developed; if the fever, more or less intense from the first, does not exceed at the height of the eruption 40° C. (104° F.), and, steadily falling, reaches the normal on the sixth, seventh, or eighth day; if the angina do not assume a diphtheritic character, and is not complicated by parenchymatous tonsillitis, retropharyngeal abscess, or cellulitis of the throat or neck; if the kidneys remain unaffected or show only slight evidences of disorder. On the other hand, the prognosis is more grave when the eruption appears after a prolonged prodromal stage, or when the attack is ushered in by convulsions or other profound nervous disturbance; or when the temperature reaches a high degree, 40.6° to 41° C. (105° to 106° F.), at once; or when intractable vomiting is present; or when diarrhœa is a prominent feature; or when the pulse beats more than one hundred and twenty times to the minute, and is feeble, unequal, and irregular; or when the throat is ulcerated and develops diphtheritic inflammation; or when suppurative, parenchymatous, or gangrenous inflammation of the tonsils, or retropharyngeal abscess supervenes; or when the neck becomes swollen, brawny, and livid from glandular, periglandular, and diffuse cellular inflammation. Apprehension should always be excited if the eruption come out imperfectly or irregularly while the fever is intense; or if, once fully developed, it suddenly fade; or if the eruption assume a livid color or a distinctly hemorrhagic character. A coppery hue of the eruption is unfavorable, as is also a livid coloration of parts not invaded by the eruption. Small, scattered petechiæ in the midst of an otherwise normal eruption are unimportant. Miliary vesicles, developing in the ordinary course of the fever are insignificant; occurring later, during an attack of unusual severity, they are often the forerunners of death. Convulsions first occurring after the height of the fever are more ominous than if occurring earlier. Should the eruption, and especially the fever, continue unabated after the usual period, dangerous complications are to be apprehended. Coma is of grave augury, as indicating uræmia, œdema of the brain, or even meningitis. Nephritis is more serious the earlier it is developed. It occasionally happens that scarlet fever at first shows the symptoms of a mild attack, but, before the completion of the eruption, assumes a malignant character. If symptoms of malignancy occur after the completion of the eruption, they are usually attributable to complications. On the other hand, all the signs of malignant scarlatina may be present at the outset. High fever, rapid pulse, convulsions or coma, protracted vomiting, intense eruption, may all yield after the second or third day, the disease thenceforward pursuing a mild course; again, symptoms of malignancy may disappear upon the supervention of a delayed eruption. Mayer[72] observed a temperature of 43° C. (109.4° F.) on the evening of the second day. The temperature subsequently varied slightly until the fourth day, when, upon the appearance of the eruption, it subsided. The occurrence of scarlatinal diphtheria always increases the danger of death. Heubner regards its sudden extension to the soft palate and to the portals of the œsophagus and trachea as certainly to be followed by death within from twenty-four to forty-eight hours, the fatal issue occurring either through gradual progress of gangrene, by inflammation of the lymphatic glands and connective tissue of the throat and neck, or by œdema glottidis. When circumscribed spots are invaded and the lateral portion of one tonsil shows the first patch, from which the membrane gradually spreads, recovery may occur. Diarrhœa persisting during the attack greatly increases the danger. Nephritis is always a serious complication, though terminating favorably in most cases. The danger is usually proportionate to the earliness of its occurrence. Death may occur as in ordinary nephritic inflammation. Scarlatinal nephritis most rarely becomes chronic. Inflammation of the organs of hearing, while rarely imperilling life, often results in partial or complete deafness. This, according to Burkhardt-Merian,[73] depends upon croupous-diphtheritic inflammation primary in the throat. The prognosis is more unfavorable if the process be allowed to go untreated. Rheumatic and rheumatoid inflammations are not commonly dangerous complications. Endo- and pericarditis, pleurisy, peritonitis, meningitis, pneumonia, dysentery, parenchymatous degeneration of the heart, etc., are all complications of extreme danger. Purulent inflammations of pyæmic origin usually constitute sequelæ of scarlatina, and are of the gravest importance.

TREATMENT.—Mild cases of scarlatina require little more than good nursing, the regulation of the diet, and proper precautions against the spread of the disease to the other members of the household. Severe cases, on the contrary, tax the resources of the physician to his utmost.

General Principles of Prophylaxis, Hygiene, and Disinfection.—As soon as the disease is recognized the patient should be removed to a clean, well-ventilated room, preferably at the top of the house, and accessible by way of back stairs, and all persons not concerned in the care of the patient should be rigidly excluded.

The following practical rules and directions, taken in part from those issued by the New York Board of Health, for the prevention of the spread of the disease in a family in which one case exists, cover in a general way the matter of prophylaxis and disinfection. They should be followed as closely as possible, but at times may be modified to suit the requirements of the case. A copy should be given to the nurse and parents at the beginning of the quarantine, and they should be instructed to study the principles on which the directions are based in order that they may know how to meet conditions which are constantly arising in the course of the disease and which cannot be specially mentioned in directions intended for general use.

1. If possible one attendant should take the entire charge of the sick person, and no one else besides the physician and nurses should be allowed to enter the sick-room. The attendant should have no communication with the rest of the family. While in the sick-room she should wear a covering to protect her hair, and a gown, which should be removed when she leaves the room. When leaving the portion of the house which is quarantined she should change her shoes, and dress and disinfect her hands and face, and should make use of the back stairs, so far as possible in going in and out of the house. The members of the family should not receive or make visits during the illness. Other children in the family should not be allowed to go to school, if they remain in the infected house, and if sent away they should be kept from other children until the stage of incubation has passed. The physician should exercise great care not to carry the contagious elements to other patients. Disregard of such precaution by many physicians is a fault only too common, and one which deserves the most severe condemnation. A cap covering the head and back of the head, a gown reaching from the neck to the floor, and rubber overshoes should always be put on before entering the patient's room. When these are removed, they should be dipped in carbolic acid or corrosive sublimate solution, and hung up to dry in an ante-room, where they will be ready for use on the following day. Rubber gloves are also a useful addition to the articles just mentioned.

2. The discharges from the nose and mouth must be received on handkerchiefs or cloths, which should at once be immersed in a carbolic solution (made by dissolving six ounces of pure carbolic acid in one gallon of hot water, which may be diluted with an equal quantity of water). All handkerchiefs, cloths, towels, napkins, bed linen, personal clothing, night clothes, etc., that have come in contact in any way with the sick person, after use should immediately be immersed without removal from the room in the above solution. These should be soaked for two or three hours and then boiled in water or soapsuds for one hour. They should be laundried separately from the household articles.

3. Great care should be taken, in making applications to the throat and nose, that the discharges from them in the act of coughing are not thrown into the face or on the clothing of the person making the applications, as in this way the disease is likely to be caught.

4. The hands of the attendant should always be thoroughly disinfected by washing in carbolic solution, and then in soapsuds, after making applications to the throat and nose, and before eating. Rubber gloves may be worn with advantage while handling the patient.

5. Surfaces of any kind soiled by discharges should be immediately flooded with the carbolic solution.

6. Plates, cups, glasses, knives, forks, spoons, etc., used by the sick person for eating and drinking must be kept for his especial use, and under no circumstances be removed from the sick-room nor mixed with similar utensils used by others, but must be washed in the room in the carbolic solution and then in hot soapsuds. After use the soapsuds should be thrown into the water closet, and the vessel which contained it should be washed in the carbolic solution.

7. The room occupied by the sick person should be thoroughly aired several times daily, and swept frequently, after scattering wet newspapers, sawdust, or tea leaves on the floor to prevent the dust from rising. Af-

ter sweeping, the dust upon the woodwork and furniture should be removed with damp cloths. The sweepings should be burned and the clothes soaked in the carbolic solution. In cold weather the sick person should be protected from the draughts of air by a sheet or blanket thrown over his head while the room is being aired. In summer the windows should be kept open sufficiently to secure free movement of air and agreeable temperature; in winter an open wood or coal fire should be kept constantly burning. The temperature of the room should not exceed 21° C. (70° F.) nor fall below 18° C. (65° F.). The patient should be kept in bed even during the mildest attacks, with only enough bed covering to secure comfort.

8. When the contagious nature of the disease is recognized within a short time after the beginning of the illness it is advised that all articles of furniture not necessary for immediate use in the care of the sick person, especially upholstered furniture, carpets, and curtains, should be removed from the sick-room. If the disease is well advanced this should not be done without first taking precaution to disinfect them properly.

9. When the patient is beginning to recover and the skin is peeling off, the body should be washed once daily in warm soapsuds, and afterward rubbed in oil or carbolated vaseline. This should be continued until all roughness of the skin has disappeared.

10. When the patient has recovered and the Board of Health inspector has authorized his discharge, the entire body should be bathed and the hair washed with hot soapsuds, the nose, mouth, and ears should be disinfected as far as practicable with antiseptic sprays, and a corrosive sponge bath of 1 to 2,000 to 1 to 5,000, according to the age of the patient, should be given. The patient should then be dressed in clean clothes (which have not been in the room during the sickness) and removed from the room.

The Health Department should be immediately notified, and disinfectors will be sent to disinfect the room, bedding, clothing, etc., and under no conditions should i be again entered or occupied until it has been thoroughly disinfected Nothing used in the room during the sickness should be removed until this has been done.

11. The attendant or any one who has assisted in caring for the sick person should also take a bath, wash the hair, and put on clean clothes, before mingling with the family or other people, after the recovery of the patient. The clothes worn in the sick-room should be left there, to be disinfected with the room and its contents by the Health Department.

12. As contagion sometimes occurs after very prolonged intervals it is generally better to observe the rule that isolation should be practised until the completion of desquamation. Ashby[illegible] lays down the following rules in reference to the discharge of a scarlet-fever patient from quarantine. (1) If desquamation is complete scarlet-fever cases may be discharged at the end of the sixth week, although in order to secure absolute immunity it is wiser to delay until the eighth. (2) Cases complicated with nephritis, empyema, otitis, or glandular abscess, should be detained until the cure is completed. (3) While it is important that the desquamation should be as complete as possible, the detention of the patients beyond the eighth week in order that the last vestige of epidermis should be removed from the feet, etc., is unnecessary. Such detention is, however, often insisted upon by health authorities.

13. The uses of belladonna and other "specifics" as a means of prophylaxis are based upon untenable hypotheses. Scarlet fever often fails to spread even when a number of persons have been exposed and the danger of drawing incorrect conclusions from the use of drugs as prophylactics is very great.

The following are the best known disinfectants:

Heat.—Continued high temperatures destroy all forms of life Boiling for at least one-half hour will destroy all disease germs.

Carbolic Acid.—A standard solution is composed of six ounces of carbolic acid dissolved in one gallon of hot water. This makes approximately a five-per-cent. solution of carbolic acid. The commercial colored impure carbolic acid will not answer for this purpose. Great care must be taken that pure acid does not come in contact with the skin. When practicable, the carbolic solution should be used as hot as possible. The cost of carbolic acid is much greater than that of the other solutions, but generally is much to be preferred. When the cost is an important element, the bichloride solution may be substituted for all purposes for which carbolic is recommended, excepting for the disinfection of the discharges, eating utensils, or articles made of metal, and of clothing and bedding, etc., which is very much soiled. Its poisonous character, except for external use, must be kept constantly in mind.

Corrosive Sublimate (bichloride of mercury).—A standard solution is composed of sixty grains of pulverized corrosive sublimate and sixty grains of the chloride of ammonia, dissolved in one gallon of water. This solution must be kept in glass, earthen, or wooden vessels (not in metal vessels).

The above solutions are very poisonous when taken by mouth, but are harmless when used externally.

Milk of Lime.—A standard solution is made by mixing one quart of dry freshly slaked lime with five quarts of water. Lime is slaked by pouring a small quantity of water on a lump of quicklime. The lime becomes hot, crumbles, and as the slaking is completed a white dry powder results. The powder is used to make the solution. Air-slaked lime has no value as a disinfectant.

Formaldehyde.—The use of formaldehyde gas for disinfection of rooms, clothing, and furniture, after the discharge of the patient, has now become general, and has proved superior to the older methods. The simplest, most convenient, and inexpensive apparatus for this purpose is the Schering lamp in which paraform pastils are burned, two pastils being used for each thirty-five cubic feet of air space. More powerful generators for the disinfection of very large areas are now commonly used by the Boards of Health, to whom the question of disinfection is generally referred.

The proprietary disinfectants, often widely advertised, and whose composition is kept secret, are relatively expensive and often unreliable and inefficient. It is important to remember that substances which destroy bad odors are not necessarily disinfectants.

Diet.—The diet should consist in easily assimilable food; the nearer this approaches a pure milk diet the better. Cold drinks may be allowed; cold-water lemonade, raspberry vinegar properly diluted, soda-water agreeably flavored, are grateful to the patient and preferable to warm and mucilaginous drinks. Though milk should form the principal article of food, light broths and soups, beef tea, chicken jelly, and, especially during convalescence, the various appetizing and wholesome preparations of food now so abundantly supplied may be given.

Internal medication may be held in reserve, a careful observation of all symptoms being meanwhile maintained and the conditions of the kidneys systematically ascertained by daily observation.

Hydrotherapy.—By far the safest and surest agent for reducing temperature in scarlatina is cold water which should always be tried before resorting to the use of antipyretic drugs, which are often dangerous, and the use of which should be discouraged. This may be applied in various ways. The simplest method is by frequent spongings with cold or tepid water under cover of the bedclothes. At the same time cold wet cloths may be applied to the head, and the patient may be permitted to suck small pieces of ice. In most cases it is better that the water be warm. The spongings may be repeated frequently during the day and night. In cases in which, with an elevated temperature, the eruption develops incompletely, or is much delayed in appearance, the body may be immersed in water somewhat cooler than its normal temperature. A cool bath (27° C. = 80° F.) has been extolled as of singular virtue in such cases, and at times it is of the highest value. The tepid, even the warm bath, is probably of equal benefit in most cases. Recent writers have denied that efforts to "bring out" an imperfect or delayed scarlatina, eruption are of any avail. There can be no doubt, however, that treatment with this object in view is often successful. The hot bath, even with the addition of mustard, by exciting cutaneous hyperæmia, will often relieve the congestion of internal parts. Warm and hot drinks made from various vegetable substances were formerly much employed to "bring out" the eruption. They were given copiously, and often in combination with such diaphoretics as spiritus mindereri, spirits of nitrous ether, etc. This plan of treatment is not much practised to-day. The cold bath, which should be of a temperature not lower than from 24° to 27° C. (75° to 80° F.), should be reserved for cases whose temperature exceeds 40° C. (104° F.). The body should be immersed but for an instant, the benefit of the plunge consisting largely in the dilatation of the vessels of the skin through reaction. The cold pack is also of value in these cases. When the temperature steadily rises to an alarming degree, or when hyperpyrexia is developed almost at the outset; when, with or without well-developed exanthem, stupor or coma, or other grave nervous disorder, arises, and when the pulse becomes very rapid, feeble, and irregular, the maintenance of life depends upon the reduction of temperature. Here it is impossible to give hard-and-fast rules for conduct. Water below the normal temperature of the body still remains our most efficient means of reducing the excessive heat. The lower the temperature of the bath, the more rapidly is this result attained, but the shock of the sudden contact with the cold water may exert a depressing effect that may not speedily pass off. The body cannot remain in very cold water longer than a minute or so without exciting chattering of the teeth, lividity about the mouth, and a pinched appearance of the features and of the surface. The warm bath (32°–35° C. = 90°–95° F.) has been highly extolled as favorably influencing the course of scarlet fever when used at the very beginning. Thompson employed it thus constantly, and never lost a case treated in this manner. In a bath of from 27°–30° C. (80° to 85° F.) the patient may remain for five or ten minutes. These baths should be repeated as often as the temperature of the body becomes as high as 39.5°–40° C. (103°–104° F.). To avoid alarming the little patient, the bathtub may be covered with a sheet or blanket. Placing him upon this, he may slowly be lowered into the water. Upon removal from the bath the patient should be wrapped in a dry blanket. As the body soon dries under the protection afforded, rubbing with towels may be avoided. The skin should now be anointed with oil or other agreeable fatty substance. Refreshing quiet and sleep often follow this bath. In using the wet pack, a blanket may be spread upon a hard couch or bed covered with oil cloth; upon this a sheet wrung out in cold water is laid. The naked patient is stretched upon this sheet, which along with the blanket is wrapped about him snugly. The brief sensation of chilliness is soon replaced by one of warmth, and after a few moments the body breaks out into copious perspiration. This may be encouraged by hot drinks, and hot bottles to the surface. The patient should not remain too long in the pack, otherwise hyperpyrexia may rather be increased than diminished. In the intervals between the baths, in extreme cases in adults, an ice cap may be worn, and cloths wrung out in iced water may be applied to the epigastrium. The application of ice to the head in the case of infants and young children is, however, a dangerous practice owing to its depressing influence, and should rarely, if ever, be resorted to. Nothing can exceed the efficacy of the above-described method of treating scarlet fever with high temperature; but to secure its full influence, it must be pursued systematically and intelligently. The thermometer must constantly direct the actions of the physician. The prejudices of friends and attendants against the immersion of the fevered body in ice-cold water will not extend to the use of tepid and cool baths, from which, indeed, equally good results may be obtained. The baths may have to be repeated at intervals of two or three hours for days before the fever begins to yield; or they may unhappily altogether fail to control the irresistible intensity of the disease. On the other hand, they frequently exert a most gratifying influence upon the course of the malady, the temperautre becoming permanently reduced, the pulse quieter, fuller, and regular; jactitation, delirium, and coma being replaced by composure, consciousness, or natural sleep. Often an attack that appeared about to pursue a malignant course, under the influence of the bath becomes benign and terminates favorably. While exalted temperature that threatens to destroy life can, in the manner indicated, often be reduced, the course of the disease itself cannot be aborted. No remedy is known that can be said to exert a specific influence over it. Vaunted specifics have not withstood the test of experience.

Medicinal Treatment.—Probably the most popular routine treatment of ordinary scarlet fever is that of carbonate of ammonia. When in cases of very elevated temperature the heart action flags, the pulse becoming rapid, feeble, and unequal, when delirium or stupor appears, the preparations of ammonia are demanded. The carbonate, in doses of one to three grains to a child five years of age, may be given every third hour in aqueous solution with milk, which in a great measure destroys the pungent, disagreeable taste; or it may be given in solution of the acetate of ammonia, a most commendable combination. The aromatic spirits of ammonia may be employed for the same purpose. Hoffman's anodyne, whiskey, or brandy is especially indicated when the nervous system shows alarming signs of perturbation, delirium, jactitation, stupor, etc. When strong cardiac stimulants are demanded, the fluid extract of digitalis in one-minim doses, for a child of five years, or strychnine in doses of gr. $\frac{1}{200}$ to gr. $\frac{1}{100}$, should be given. Caffeine and camphor are also of use as adjuvants to the cardiac stimulants already mentioned. Purgation, which should usually be avoided, may at times become necessary. Small doses of calomel (gr. $\frac{1}{6}$ to gr. $\frac{1}{4}$) repeated every hour until the bowels are moved, generally act well. Castor oil is a harmless and safe, but nauseous agent. Rhubarb and scammony are also efficient cathartics; either may be given in doses of five grains to a child six years of age. When depression is profound, reliance should be placed on enemata in preference to active cathartics.

During the progress of the disease the expectant plan of treatment is most to be recommended. The daily bath or sponging should be continued. It is probable that renal complications are thus frequently avoided. The patient should be jealously guarded from draughts and dampness, and even the mildest cases should be kept in bed for at least ten days after the cessation of fever; nor should the patient be allowed to leave his room before the expiration of the third week. Out-of-door exercise cannot be resumed in disregard of season, or of barometric and thermometric variations. In midsummer, when windows and doors must remain open, the question of out-of-door exercise is rather one of danger to others than of personal risk; while in spring, autumn, and winter the risks of exposure are especially great. During these seasons the patient should not venture into the open air before the sixth or seventh week of perfectly normal scarlatina. During convalescence the daily baths should be continued until desquamation is completed, and daily innunctions with mild antiseptic ointments, such as carbolated vaseline or boracic ointment, will both expedite this process and minimize the dangers of contagion. No further medication besides an appropriate tonic will be required.

Nasopharynx.—If the angina does not exceed a simple hyperæmia, mild alkaline antiseptic sprays applied frequently to the nose and throat by means of an atomizer are all that are required. If the patient is young and resists vigorously this treatment, it should not be persisted in. If the nasal discharge is profuse and purulent, gentle syringing with such solutions as Dobell's, Seiler's, and alcohol is indicated. Should the throat develop the whitish curdy deposits of follicular inflammation and the erosions that so often accompany acute catarrhal pharyngitis, an antiseptic gargle will act beneficially and will correct fœtor of breath, and to some extent disinfect the secretions and exhalations. For this purpose one of the subjoined prescriptions may be employed:

℞ Acid. carbolic. cryst. . . . . ʒ ss.
Glycerin . . . . f. ʒ i.
Aq. destil. . . . . q.s. ad f. ℥ vi.
M. Sig.: Use as a gargle or spray.

Or

℞ Tinct. ferri chlorid. . . . . f. ʒ i.
Potass. chlorat. . . . . ʒ ss.
Glycerin. . . . . f. ʒ i.
Aq. destil . . . . q.s. ad f. ℥ viij.
M. Sig.: Use as a gargle or spray.

When the inflammation is more severe, and accompanied by more or less superficial ulceration, applications should be made with a probang or camel's-hair pencil. When the surface is foul and covered with offensive exudation, an excellent application is the following, first recommended by J. Lewis Smith:

℞ Acid. carbolic. . . . . gr. iij.–vi.
Liquor ferri subsulphat . . . . f. ʒ ij.
Glycerin . . . . f. ʒ vi
M. Sig.: Apply with a brush three or four times a day

Or the following:

℞ Tinct. iodinii. . . . . f. ʒ i.
Glycerin . . . . f. ℥ vij.

Diphtheritic inflammation, if associated with the presence of the Klebs-Loeffler bacillus, calls for the treatment with the antitoxin of diphtheria, in addition to the local treatment of the nose and throat by sprays and gargles. Cauterization with silver nitrate, acid nitrate of mercury, chromic acid, or other agents should not be practised.

Tracheotomy should never be performed. A case of scarlatinal diphtheria which presents the symptoms which demand this operation, in the idiopathic disorder, is beyond the resources of surgical art.

Lymph Nodes.—Inflammation of the lymph nodes of the neck and of the adjacent connective tissue may be treated first by inunction of oil or cerate. In severer forms an ice bag, and when suppuration threatens, creolin or flaxseed poultices should be applied. Points at which suppuration appears should be incised early and freely to prevent burrowing. Gangrenous inflammation may sometimes be arrested by strong caustics. Iron, quinine, stimulants, and nourishing and supporting food should be administered in these conditions with a free hand, but always with care not to derange the digestion of the patient.

Ear.—Scarlatinal aural inflammation calls for special treatment, and whenever possible it should be referred to the aurist. The nasal douche should be used and the diphtheritic pharyngeal and nasal cavities should be repeatedly syringed with antiseptic solutions, for it is by the extension of the inflammation along the Eustachian tube that the severer forms originate. When the aural inflammation is established, inunctions of mercurial ointment, or of the oleate of mercury, or of iodoform ointment, should be made about the ear several times daily. When the tympanic membrane becomes strongly injected and bulges outward, paracentesis for the release of the pent-up exudation should be performed. Timely tapping of this membrane will often preserve the imperilled sense of hearing. This operation is especially commended by Buck and Olshausen. It is simple and very easily performed. The sensitiveness of the membrane may be obtunded to a slight degree by the instillation of a four-per-cent. solution of muriate of cocaine. Pomeroy's directions for performing the operation are as follows: "A good-sized speculum is introduced into the meatus. Then an ordinary broad needle, about one line in diameter, with a shank of about two inches, such as oculists use for puncturing the cornea, should be held between the thumb and fingers, lightly pressed so as not to dull delicate tactile sensibility. The part being well under light, the most bulging portion of the membrane should be lightly and quickly punctured with a very slight amount of force. The posterior and superior portion of the membrane is most likely to bulge. The chorda tympani nerve usually lies too high up to be wounded. The ossicles are avoided by selecting a posterior portion of the membrane. After puncture the ear should be inflated by an ear-bag whose nozzle is inserted into a nostril, both nostrils being closed, so as to force the fluid from the tympanum. The puncture may need to be repeated at intervals of a day or two, provided that the pain and bulging return."[74] When pain and tenderness only are present, hot fomentations to the external ear, and to the parotid and mastoid regions, are very soothing. Laudanum and sweet oil, or a two- to four-per-cent. solution of sulphate of atropine instilled warm into the external meatus, often give relief. Frequently renewed solutions of cocaine are very efficacious. Bags of hot table salt, or of heated flowers of hops, are well-known domestic remedies. When perforation occurs spontaneously the hearing may be preserved, but partial deafness is often permanently established, and sometimes the sense of hearing is totally abolished. In such cases the ear should be frequently syringed with warm water, or with warm solutions of boracic acid followed by insufflations of boracic-acid powder. Granulations and polypi developing in the course of chronic otitis may be benefited and even cured by astringent powders and washes. Surgical interference will at times be necessary.

Nephritis.—When nephritis arises in the course of scarlet fever, or as a sequel, prompt measures for its relief must be adopted. Where it forms a feature of rapidly fatal malignant scarlatina, it may have no time to develop symptoms, or these may escape detection, or the virulence of the disease may throw the renal disorder into the background, or render attempts to treat it futile. In milder cases, and later, during the latter part of the first or during the second or third week, especial attention may be devoted to the treatment of nephritis. Slight albuminuria will occur, according to Mahomed, during convalescence, associated with constipation and a hard pulse, indicative of high arterial tension, without subjective symptoms, and remediable by a brisk purge. This author also asserts that a slight chilling of the surface is sufficient to cause transitory albuminuria. The patient should therefore be carefully protected, in the manner already indicated. Dietary management will go far toward preventing renal complications. A rigid milk diet, in all cases of scarlatina, is regarded by Jaccoud as absolutely preventive of nephritis. Though this may be an extravagant statement, it is certain that in scarlatina there is no better diet than one of milk. Should nephritis arise, it is the more important that the milk diet should be continued. From two to three or four pints may be given during the twenty-four hours, in small quantities, at brief intervals, the latter amount being sufficient for an adult without other food. If there are reasons why milk cannot be taken, light broths and soups and chicken jelly may be substituted, together with light farinaceous food. Buttermilk may at times be preferred, and bonny-clabber and slip or junket (milk sweetened and flavored and coagulated with liquid rennet) are often relished, and are excellent articles of food. Proper regard having been paid to the hygienic surroundings and nutrition of the patient, a brisk hydragogue cathartic should be administered, unless diarrhœa be already present. For this purpose there is nothing better than the compound jalap powder. For a child, from five to twenty grains of this should be ordered every night, as required, the object being to secure several watery actions of the bowels every twenty four hours. The proper dose for an adult is one drachm. The desired watery stools may also be readily secured by the saline cathartics if given in concentrated watery solution. The more drastic purgatives will rarely be required, except in uræmic intoxication and in extreme dropsy, when podophyllin, croton oil, elaterin, etc., may occasionally be employed with benefit. When dropsy is but slightly pronounced, purgation may not be required.

The action of the skin should next demand attention. Frequently during the day the body may be wrapped in flannels, wet or dry, as hot as can be borne; or the wet pack may be applied. When available, the steam bath or hot-air bath is to be strongly recommended. The hot plunge bath may also be employed most advantageously. Pilz has especially lauded this treatment. It should be used after the method of Liebermeister, by gradually increasing the temperature of the bath from 36° C. to 40° C. (96° to 104° F.), in a half-hour. Under its daily use dropsy speedily disappears. Diseases of the heart and lungs, while not positively contraindicating this plan of treatment, necessitate great caution in its application. Sudden chilling of the surface after the bath should be avoided. The imminence of the danger is usually proportionate to the degree of impairment of the function of the kidneys. In giving remedies to modify their action, none calculated to increase their hyperæmia should be employed. Exception can hardly be made in favor of juniper, which enjoys with some writers considerable reputation in scarlatinal nephritis, and digitalis has received very general approval as a most useful diuretic in acute nephritis. From one fluidrachm to a half fluidounce of the infusion (which is much the best preparation for the production of diuresis) may be given three or four times daily, the dose varying with the age of the patient. Its effects, however, are hardly as happy as when dropsy is associated with, or dependent upon, cardiac weakness. Diuretics that act specifically upon the secreting cells of the urinary tubules, the sedative or refrigerating diuretics, are to be preferred, as a rule, in the treatment of scarlatinal nephritis, and will often achieve most astonishing results. Of these the salts of potash are most efficacious—the citrate, the acetate, the bitartrate, and the bicarbonate. For slight nephritis and anasarca a lemonade made with bitartrate of potash will be taken with avidity, and will often almost magically increase the quantity of urine, reduce the dropsy, rapidly diminish the albuminuria, and cause a radical change for the better. Diuretin in five- to ten-grain doses may be combined with this with great advantage. This lemonade may be made by adding one drachm of cream of tartar to a pint of boiling water, into which a sliced lemon has been dropped. This quantity, properly sweetened, may be drunk during the day by a child five years of age. Water may be allowed freely, or any of the mild domestic infusions may be substituted for it, their virtue residing principally in the amount of fluid. The free use of water is especially to be recommended as unirritating, and tending to wash out of the tubules the exudate choking up their lumina. In more severe cases, where life is threatened through one or another form of uræmia, very energetic treatment will be required. Jaborandi may now prove useful. J. Lewis Smith, Hirschfeld, and others have commended its action highly. For a child two years of age, one-twentieth of a grain of pilocarpine may be given by the mouth every fourth or sixth hour, or the same amount may be injected hypodermically, and prove much more efficient. Both diuresis and diaphoresis will be promptly increased, and in favorble cases the uræmic symptoms will disappear. Hot saline injections, given by rectum and repeated several times a day are frequently of value in threatened uræmia. Uræmic coma and convulsions, developing suddenly or after progressive renal embarrassment, should be treated without reference to the scarlatina and upon general principles. A remedy of most undoubted value, at least for the control of convulsions, is chloral, which, if the patient be unable to swallow, may be injected in full doses under the skin or into the rectum.

After the more acute nephritis has subsided and convalescence promises to become established, iron becomes one of our main reliances, in virtue of its combined hæmatic and diuretic properties. The Mistura ferri et ammoniæ acetatis will generally be found to be the best of the old preparations. Recently many new and excellent preparations of iron in organic combination have been put upon the market. Quinine is also a remedy of great value in the treatment of convalescence from scarlatinal nephritis. During the height of the inflammation, local treatment is often of great importance. If fever is intense, the pulse full and strong, and if pain and tenderness in the back are pronounced, the abstraction of blood, by leeches or cups, from the loins will often prove beneficial. Large sinapisms and poultices may be applied over the kidneys. Besides assuaging the irritation they tend to promote diuresis and diaphoresis. For obvious reasons, turpentine should not be employed as a counter-irritant in these cases. Ascites may occasionally be so excessive that the pressure exerted upon the kidneys interferes with the action of therapeutic agents, and impedes the functional activity of these organs. Paracentesis abdominis, by relieving this compression, will often be followed by copious diuresis and the rapid disappearance of general anasarca. Cases of scarlatinal nephritis which pass into chronic Bright's disease, as rarely happens, will require the treatment appropriate for this condition. During convalescence the usual precautions will be necessary. The treatment of other complications and sequelæ of scarlet fever is not peculiar, and will require no special notice here.

Serotherapy.—In 1896 Josias, of the Trousseau Hospital, gave an account of the treatment of a case of scarlatina with Marmorek's antistreptococcus serum. The results apparently were inconclusive, and subsequent trials by other investigators have proved equally so. Quite recently the efforts to secure a specific antitoxic serum for scarlatina have received a new impetus, and have given rise to much discussion.

Baginsky, of Berlin, claims to be the first to call attention to the association of a streptococcus with scarlet fever, and he has announced that Dr. Aronson has demonstrated an anti-scarlet-fever serum, which, as he believes, will prove specific in this disease. Priority is disputed by Moser,[53] who asserts that, with Pirquet, he previously had shown this association, which was also independently found by Salge as a result of agglutinating reactions, the peculiarity of which was first demonstrated by van de Velde and Paltauf. The first antistreptococcus serum, he says, was produced by Marmorek, and Aronson's was perfected on similar lines, while his own is based on different principles. Aronson's test comprises a macroscopic, and not the microscopic agglutination reaction on the peculiarity of which Moser bases his claims of priority. Out of ninety-nine cases of fatal scarlatina, Moser has been able to cultivate [54, 55] streptococci from the blood in the heart in sixty-three cases. These results accord with those of previous investigations, and make it probable that streptococci play an important part in the disease. On the other hand, the use of ordinary antistreptococcus serum has not proved of use in treating the disease. Moser points out that this may be due to the fact that there are different varieties of streptococci. The organism isolated from scarlatina differs from other varieties found in other diseases, in being almost innocuous for rabbits, and in possessing different agglutinating properties. Moser therefore prepared a special immune serum from streptococci obtained from scarlet-fever cases. As there is no proof yet that the organism is the same in all cases, he produced a polyvalent serum by injecting horses with increasing doses of the mixture of living cultures obtained from different cases of scarlet fever. The organisms were grown on bouillon, and were not passed through animals. After months of such treatment the serum was drawn off and preserved in a sterile condition, without any addition of a preservative. The serum was tried in eighty-four cases. At first the dose was too low. Later, better results were obtained, doses of 180 c.c. being used. Possibly the serum was more potent in the later cases. The individual doses varied from 30 to 180 c.c.; the latter amount is now chiefly used. In seventeen cases classed as mild or moderately severe, there was no mortality. In sixty-two cases classed as severe and apparently hopeless there were sixteen deaths. The earlier the injection the more favorable is the result. The chief clinical result is the rapid improvement in the general condition. With early injection the rash may not fully develop, or may fade much sooner than usual. The disturbances of the central nervous system disappear in a short time, while the temperature and pulse often show a critical fall. The symptoms of heart weakness are favorably influenced. The throat clears up more quickly, and although superficial necrosis is not prevented, Moser has not observed deep destruction. As yet, nothing can be said about the effect of serum on the renal and middle ear complications. The whole course of the disease is shortened, and convalescence occurs much sooner. Injections of normal horse serum had no effect on the course of the disease. Serum rashes were often noted, but joint pains and abscess formation were rarer. A much larger number of observations must be made before a definite opinion can be held in regard to the efficacy of this form of serumtherapy in scarlatina. The results already attained certainly warrant further investigation along the same or similar lines.

Roger[87] attempted, in a single case, to treat scarlet fever by injecting into a vein 80 c.c. of serum taken from the blood of a patient recently convalescent from scarlet fever. The case was apparently comatose at the time of the experiment, and recovery took place, but no conclusion can be drawn from this single instance. Obviously it is not a method practicable for general use, and is only of scientific interest.

Preventive Inoculation.—Stickler[86] in 1897 attempted to produce a mild type of scarlet fever by inoculating children with subcutaneous injections of mucus obtained from the throats of recent cases of scarlet fever. The results of the experiment showed that the symptoms produced were practically as severe as those of the typical cases of scarlet fever, and that preventive inoculation on the principles of vaccination for the smallpox was impracticable. Incidentally his experiments showed that the secretions of the mouth and pharynx of scarlet fever are highly virulent, as all the symptoms of scarlet fever appeared, with hardly any incubation period, within from two to twenty-four hours.

SCHOENLEIN'S DISEASE.—See *Morbus Maculosus Werlhofii.*

SCHOOLEY'S MOUNTAIN SPRINGS. — Morris County, New Jersey.

Post-Office.—Schooley's Mountain. Hotel.

Access.—From New York viâ the Delaware, Lackawanna and Western Railroad, to Hackettstown, thence three miles by stage to springs; or viâ the Central Railroad of New Jersey to German Valley, thence two and one-half miles by stage; from Philadelphia viâ the Philadelphia and Reading Railroad to German Valley, etc.

Schooley's Mountain is a broad plateau in the northern part of New Jersey, 1,200 feet above tide water, overlooking the Musconetcong Valley on the north and German Valley on the south. The scenery in the vicinity is varied and picturesque, and the neighborhood abounds in beautiful walks, drives, landscapes, etc. Among the near-by points of interest are Lake Hopatcong, Budd's Lake, and the romantic Delaware Water Gap. The chalybeate spring, situated half a mile from the hotel (the Heath House), has enjoyed for many years a reputation as a ferruginous tonic. The analyses which have thus far been furnished are not entirely satisfactory. It is an established fact, however, that the iron is present in relatively small quantity. The waters are recommended in cases of general debility, and of torpor of the liver, and in renal and bladder disorders. At the Heath House is another spring, which has been analyzed by Prof. George H. Cook, State geologist. It appears from this analysis that the water is rich in mineral ingredients. Nevertheless, so far as we can learn, it is not used for medicinal purposes. The Heath House and cottages consist of several detached buildings, none of them over three stories in height, with accommodations for three hundred and fifty guests. They are situated in the midst of a beautiful lawn of twenty-five acres. It is stated that the "temperature here averages ten degrees lower during the day, and from fifteen to twenty degrees lower during the night, than at New York or at Philadelphia. *James K. Crook.*

SCHOOL HYGIENE.—The physical conditions attending the education of the child at school are quite as important as his mental training. School hygiene embraces all that pertains to the physical welfare of the child in the course of instruction, both subjectively and objectively, including his own physical condition, and the effects of his environment. That the subject is attracting increased attention is evident from the enactment of laws relating to the ventilation and sanitary condition of school-buildings, the restriction of contagious diseases among school-children, and the medical inspection of schools. About one fifth of the entire population is under instruction in the schools, either public or private, at a period of life when good health and its preservation are matters of the highest importance.

SCHOOL-BUILDINGS. SELECTION OF SITE.—The site should be chosen with reference to the convenience of a majority of the population for whom the building is intended, having in view a reasonable probability of future increase. It should be well back from the street, and not on a main street or thoroughfare. The neighborhood of noxious and offensive, as well as noisy trades, should be avoided. Nor should it be near the line of a steam railway. Proximity to liquor saloons should be avoided. Fortunately in some States, a definite distance is prescribed for such nuisances, so far as proximity to school-houses is concerned.

The location should not be overshadowed by a hill of greater height than the school-building, especially upon its western side. The size of the site, including the playgrounds, should be largely determined by the number of pupils to be accommodated, a space of thirty square feet being desirable for each pupil.

The site should be capable of thorough drainage, and should be graded to a higher level than that of the contiguous streets. The soil of the immediate neighborhood should also be dry, and there should also be opportunity to obtain a supply of pure drinking-water.

School-Building.—In the planning of school-houses, the school-room should be the unit first considered. According to Shaw, "the school-building should be a number of

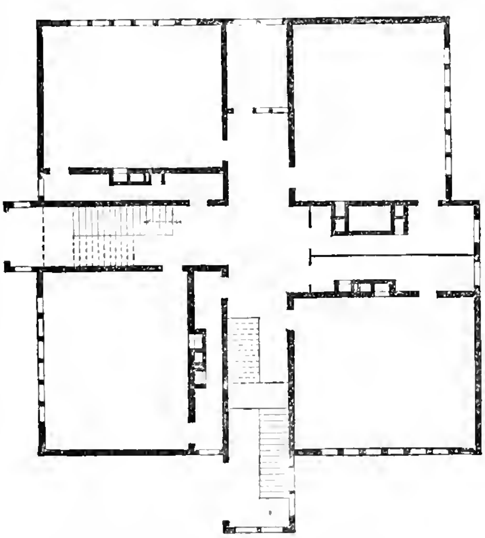

FIG. 4157.—A Good Single Floor Plan. Rooms well arranged for seating and lighting. (Shaw's "School Hygiene," The Macmillan Company.)

school-rooms properly disposed, and not a whole cut up into school-rooms, whose size and arrangement are dependent upon the size and shape of the building."

The general shape of the school-room should be oblong, with the aisles running lengthwise of the room. This allows proper lighting of the desks (Fig. 4158).

The question of the size of the school-room has received much attention, and has been made the subject of experiment until definite standards may now be recommended, depending upon the ventilation, heating, lighting, and the needs of the eye and ear of the pupil. A minimum of 15 square feet of floor space and 200 cubic feet of air space for each pupil should be insisted upon. For a room intended for forty eight pupils these conditions may be secured with a height of 13 feet, length 30 feet, and width 25 feet. A greater length than 30 to 32 feet is not admissible since the scholars in the rear row of seats would be subjected to unnecessary eye-strain when looking at blackboards or other objects at the opposite end of the room.

Lighting.—The amount of glazed surface admitting light to a school-room should be from one sixth to one-fourth as much as the floor space of the room, in order to provide sufficient light for all parts of the room in cloudy weather. This limit, however, may not be sufficient in case of obstruction by trees, houses, or adjacent hills. In crowded cities, and other places where well-lighted locations are not available, the use of ribbed glass, and Luxfer prisms is recommended for the purpose of increasing the illumination. In the Building Rules of the Board of Education (England) are the following excellent suggestions:

"The light should, as far as possible, and *especially in class-rooms*, be admitted from the left side of the scholars. All other windows in class-rooms should be regarded as supplementary, or for summer ventilation. Where left light is impossible, right light is next best. Windows facing the eyes of teachers or scholars are not approved. In rooms fourteen feet high any space beyond twenty-four feet from the window wall is insufficiently lighted. Windows should never be provided for the sake merely of external effect. All kinds of glazing which diminish the light and are troublesome to keep clean and in repair should be avoided."[1]

Rooms having a northern exposure should, other things being equal, have a more liberal provision for light than those with a southern exposure.

According to Shaw:[2] "If a school-room is insufficiently lighted and more light cannot be admitted from the left or near, the windows placed on the right should have their sills eight feet above the floor, and the amount of light admitted by such windows should in no instance be strong enough to overpower the light admitted from the left."

Spaces between Windows.—The windows should be placed with as little space as possible between them, to avoid the production of alternate bands of light and shade which are injurious to the eye.

Height of Windows.—The windows should extend as near to the ceiling as possible, since the higher they extend the better the illumination. Windows arched at the top decrease the illumination.

Height of Window Sills.—The English rules advise a height of at least four feet above the floor. Some authorities advise a height of five feet, but this would interfere too much with the amount of glazed surface. Large single panes of glass for upper and lower sash allow the least obstruction of light, and readily admit of cleaning.

Color of Walls.—No color should be used which absorbs light. Reds are to be avoided. Yellow is not restful to the eye. A pale greenish-gray, nearly white, appears to be the best suited for school-rooms.

Window Shades.—Window shades are useful in bright sunny days, and especially when the ground is covered with snow, to modify the effect of light. They should roll up from the bottom and should be somewhat darker than the walls. The direct rays of sunlight should not be allowed to fall upon any occupied desk.

Arrangement of Seats.—The best arrangement is that which allows the pupils to face one of the shorter sides of the school room, the windows being at the left of the scholars as they sit in their seats. It is also best to have the aisle at the side opposite the windows considerably wider than that upon the side next the windows. This allows some freedom of movement about the blackboards, as well as space for other school exercises (Fig. 4158).

If the seats are arranged so that the scholars face the long side of the room, those upon the outer rows are at some disadvantage in looking at objects on the wall behind the teacher, such as maps, etc.

Blackboards.—The best blackboards are made of slatestone, and should be either black or dark green. If blackboards are not used, slated paper, cloth, or walls

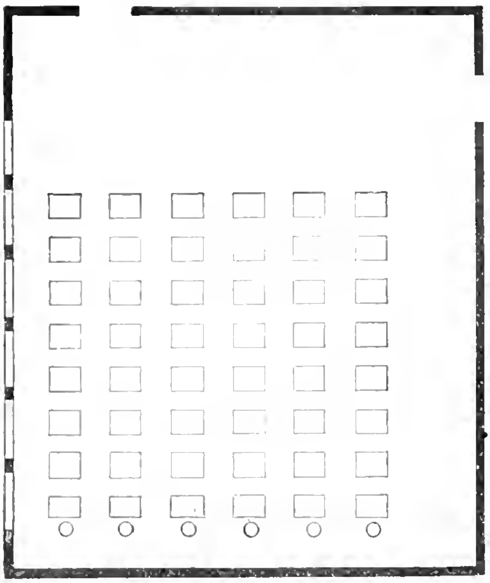

FIG. 4158. Model Arrangement of Seats; Windows at Left of Scholars. (From Shaw's "School Hygiene," The Macmillan Company.)

may be prepared. For young scholars the bottom of the board should not be more than twenty-six inches from the floor, varying from that height to thirty-six inches for the older grades. Their width from top to bottom should be about four feet.

Number of Stories.—When it is practicable, the number of stories should be limited to two above the ground. This rule is especially applicable to that class of schools in which the scholars frequently pass from one story to another during the day.

Basement.—A basement should always be provided. Its walls and floor should be so constructed as to prevent access of dampness, and the walls should rise above the ground sufficiently to permit the entrance of sunlight.

Hallways and Entrances should be sufficiently ample to allow the building to be rapidly emptied in cases of emergency.

Stairways.—All stairways should be well lighted, and should be at least five feet wide, and should be broken by landings about half-way from top to bottom. Diagonal steps, or spiral stairways should not be permitted. Steps with six-inch risers and eleven-inch treads are easiest for school children, but six and one-half inches may be allowed for stairs in high schools.

Floors.—Floors should be made of well seasoned hard wood, free from cracks. At the junction of the mopboard and the floor, a concave strip will allow better cleaning and sweeping (Fig. 4159). The floors between the occupied stories should be made as nearly sound proof as possible. Cornices, mouldings, and other projections which catch dust should be avoided.

Moist sawdust may be used in the cleaning of floors. Bad floors should be replaced, or treated by planing, and filling the cracks. Pure oil is not so good an application for floors as preparations containing a considerable proportion of wax or paraffin, since the oil darkens the floor and interferes with the light.

Cloak-rooms.—These should be provided, and furnished with shelves and hooks for clothing, hats, and overshoes. They should be so arranged as to admit of free ventilation.

Heating and Ventilation.—The importance of the proper heating and ventilation of school buildings depends largely upon the climate or region in which the school house is located. In the tropics where windows may be open throughout the year, an abundant and constant supply of fresh air can be had, and the question of heating is of little consequence. In temperate climates, however, the subject assumes greater importance.

The common modes of heating large school-houses are by hot air, steam and hot water. The two latter are generally preferable for large school-houses, since by them the rooms in different parts of a building can be warmed more equably than by hot air.

In rural districts a supply of fresh air may be introduced by means of jacketed stoves after the manner described in the nineteenth report of the State Board of Health of Massachusetts, p. 315.[3] The ventilation should be of such efficiency as to provide a supply of thirty feet of fresh air for each pupil per minute. The inlets and outlets should be of such size that the incoming warm air shall not have a velocity of more than four hundred feet per minute, and this inlet, for a room of standard size, should not have an area of less than four square feet. A wire screen of one-eighth inch wire, with meshes of one and one-half inches, is better than a cast-iron register. The inlet and outlet should be on the inner or warm side of the room, the inlet being placed about eight feet above the floor, and the outlet in the floor or very near it.

Temperature.—A temperature of 65° to 68° F. should be maintained during school hours. Dr. Lincoln recommends 66° as a proper standard. Most English authorities are in favor of lower temperatures than these.

Humidity.—Good ventilation requires a proper amount of moisture to supply the loss involved in heating the air to a sufficient degree to insure comfort. Various devices have been invented to supply this deficiency. The ordinary water-pots which are supplied with hot-air furnaces cannot be relied upon to produce a sufficient degree of humidity for health and comfort.

Carbonic Acid as an index of impurity in the air. The amount of carbonic acid in fresh outdoor air is about 3 parts in 10,000.* In order to secure the highest degree of comfort and health for the scholar who spends a portion of his time every day in the school-room, the amount of carbonic acid in the air should not be allowed to exceed 7 parts per 10,000. For the purpose of measuring the relative amount which may be present in an occupied school-room several devices have been invented, but none which have thus far been devised appear to be capable of giving as satisfactory results as a quantitative analysis of the air by a competent chemist. Dr. Haldane has recently brought to notice a new apparatus for which he claims that "the analysis after some practice can be relied on to within 0.5 volume on either side of the right result." The apparatus, however, requires very careful manipulation, since "a variation of 0.1° C. in the temperature of the water in which the air burettes are immersed would, unless compensated, cause an error of fully three volumes per 10,000 in the analysis.† A sim-

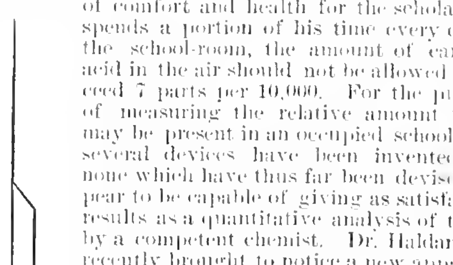

FIG. 4159. Section of Concave Strip at Corners Between Mop Board and Floor.

† *Loc. cit.*, pp. 117 and 120.

ple apparatus which can be used by the teacher in any school-room for the purpose of determining, at least approximately and with facility, the relative amount of carbonic acid present in the air of the room, under the ordinary conditions of school attendance, is very much needed.

Lavatories, Water-Closets, etc.—The best location for these appliances, sometimes by an exclusive misapplication of terms called "sanitaries," is in a separate building outside the school-house. In consequence of the severity of the winters in northern climates, and the increased cost of heating, this is not always practicable, and these conveniences are usually placed in the basement in large buildings, especially where they are connected with the public sewer system. No system, however, should be tolerated in which the ventilation of the water-closets is in any way connected with the general ventilation of the school. They should be well lighted. If latrines or troughs are used, they should be so constructed as to admit of thorough cleansing and flushing with water. Systems providing for the drying or cremation of excreta in the basement of school-buildings require the most careful janitorship, and are not to be generally recommended.

Urinals.—These can be successfully maintained only in school-buildings connected with a public water supply. Slate or asphalt is the best material for construction. There should be an abundant flush of water, and a gutter at the bottom with a sufficient inclination to carry off the water rapidly to the drain or soil pipe.

The plumbing, the care, and management of the closets, latrines, and urinals should be of such good character as not to require the use of disinfectants or deodorizers. The substances often recommended to be placed in such places for the purpose of "disinfecting" the air do not disinfect, but merely substitute one smell for another.

Outhouses in Country Districts.—In districts not supplied with good systems of water and sewers, the maintenance of convenient and cleanly outhouses is a difficult problem, since, without the strictest attention on the part of teachers and janitors, they are likely to become sources both of physical and moral uncleanliness. Such outhouses should be located at least forty feet from the school house, and there should be entirely separate buildings for each sex. These should also be separated by a tight board fence extending from the school-house, at least six and one-half feet in height. They should be provided with ample and well-cemented vaults, so constructed as to admit of emptying and cleansing without difficulty. They should be so made as to exclude all water from any source, except that contained in the excreta.

Provision should also be made for the storage of an ample supply of dry loam under cover. This can usually be obtained during the warm season. It should be applied daily during the time of school attendance, a sufficient quantity being applied each day to cover the fresh contents of the vaults.

Water Supply.—In cities it is customary to provide a supply of water from the public supply. As a general rule such water is pure and wholesome. On the contrary, instances have occurred in which the authorities have found it necessary to shut off the water of the public supply from the schools in consequence of serious pollution at the source. Lead pipe should not be used for the conveyance of water to the school-buildings nor for its distribution in them. It is desirable to have as many faucets on each floor as there are separate schools. There should also be opportunity for washing hands when coming from the closets and urinals, for which purpose soap and towels should be provided.

In country schools the supply is often obtained from wells, and special attention should be paid to their proper location in order to secure them from pollution. If there is any doubt as to the quality of the water, it should be submitted to a competent chemist for analysis. School house wells should be thoroughly pumped out at the close of the vacations in localities where the water is not used through the vacation. Water for the schools should not be kept in open pails, and the use of a separate drinking cup for each scholar should be encouraged.

School Baths.—The provision of places for bathing in connection with the public schools, as introduced recently in a few cities, undoubtedly exerts a decided influence, moral as well as physical, upon the children of those schools, an effect which extends to the homes of such children, among a large portion of whom the facilities for bathing are of the most limited character. Added to this, in schools which are provided with swimming tanks, the instruction given in this art has the advantage of being both healthful and of a life saving kind. The swimming tank adds materially to the cost of maintenance, on account of the fuel required to keep a large body of water at a proper temperature. Shower baths are now provided in connection with several of the public schools in New York, Boston, and other cities. In the town of Brookline, Mass., a public bathhouse erected in close proximity to the high school-house gives abundant opportunity to scholars in the public schools both for bathing and swimming all the year round.

School Furniture.—Since the scholar spends a large part of his school life seated upon some sort of seat, and, in all the higher grades, provided also with a desk, it is of the highest importance that these two articles of furniture should be as correctly made as possible. In an article by Dr. W. H. Burnham the following requirements are given:[4]

1. The height of the seat should be about two-sevenths that of the body.
2. The width should be about one-fifth of the length of the body, or three-fourths the length of the thigh.
3. The seat should slope downward a little toward the back, and be slightly concave, having bevelled edges in front.
4. A back rest is essential for hips and shoulders.
5. The correct "difference" or vertical distance from the seat to the edge of the desk is that which permits the child when sitting erect to place both forearms on the desk, without raising or lowering the shoulders.
6. Of equal importance is the "distance" * of the seat from the desk, which may be (*a*) "zero," (*b*) "positive," or (*c*) a "negative" distance, necessitating facility in adjustment.
7. A desk slope, preferably of fifteen degrees for writing, with capacity for adjustment to other purposes.
8. Strength, durability, and simplicity of construction.
9. Surfaces easy to clean, and unfavorable to the accumulation of dust.
10. A moderate price.

The principal objections to badly contrived school seats and desks are the liability to produce eye-strain and distortion of the spine. Almost any sort of seat may produce one or the other of these effects if pupils are kept continually sitting for long periods of time, without exercise, and especially if they are engaged in writing for lengthy periods. There is, however, a decided choice in school furniture, and the tendency is constantly in the direction of improvement (Figs. 4160 and 4161).

According to Janke the edge of the desk should be of such height above the seat as to be opposite the navel of the scholar who sits erect, so that, in placing the forearm upon the table to write, the elbow must be bent a little to one side and to the front of the scholar.[5]

Much improvement has been accomplished in the United States by means of adjustable desks, so constructed as to admit of change and adaptation to the wants of scholars at an age when growth is most rapid.

Shaw says: "Desks and seats should be adjusted vertically twice a year, at the opening of school in Septem

* Janke describes the "distance" as the horizontal interval between a vertical line touching the front edge of the seat, and another vertical line let fall from the edge of the desk. If these lines coincide, the "distance" is *zero*; if the desk overlaps the seat, the "distance" is *minus* or *negative*; if the edge of the seat falls to the rear of the edge of the desk, the "distance" is *plus* or *positive*.

ber, and again in February or March; and at whatever time during the year a pupil enters school or is transferred to another room, his seat should be adjusted to him "[2] Desks should be constructed to fit the children.

According to Hope and Browne: "Short lessons at bad desks are likely to be less injurious than long confinement at the most perfect."[3] The sitting posture is in itself bad, and should be counteracted by active exercise. Hence the use of blackboards for drawing and writing by beginners in place of copy-books is earnestly advised. In most American schools at the present day fixed seats and desks are in use, but in Germany several authorities give preference to movable seats and desks, on account of the facility thus offered for cleansing the floors[6] (Figs. 4162 and 4163).

FIG. 4160.—From Shaw's "School Hygiene."

As an instance of the serious effects produced by want of adaptation of school furniture to the ages and heights of children, Dr. C. F. Scudder reports that twenty per cent. of the girls in the grammar grades of the Boston schools were round shouldered, as a result of malpositions due to defective desks and seats.[7] In several rooms he found girls who differed seven years in their ages, and nearly twenty two and one half inches in height, seated at desks and in seats of exactly the same size. In one school eighteen per cent. of the scholars, when sitting back in their seats, could not touch the floor with their heels.

FIG. 4161.—From Shaw's "School Hygiene."

To counteract the ill effect of bad postures, even when properly adapted seats are supplied, periods of relief, together with exercises intended to correct bad habits of this sort should be given, to be repeated several times during each school day. During the first school year such periods should be more frequent than in the later years of school life. During the first year the child should not be confined at his desk more than one-third of the time.

Notwithstanding all that has been said and written in recent years about the importance of physical culture in schools, the tendency is still to train the mental faculties at the expense of the physical development of the scholar. There is consequently a decided necessity for devoting a greater share of each day's work to physical exercise. The recess should be maintained, and at least fifteen minutes in each session should be given "in which all scholars should, so long as the weather and climate permit, go out of doors, and engage in some form of physical activity" (Shaw). And this period of relaxation should be in addition to the regular systematic exercises which should form a part of the programme of each school day.

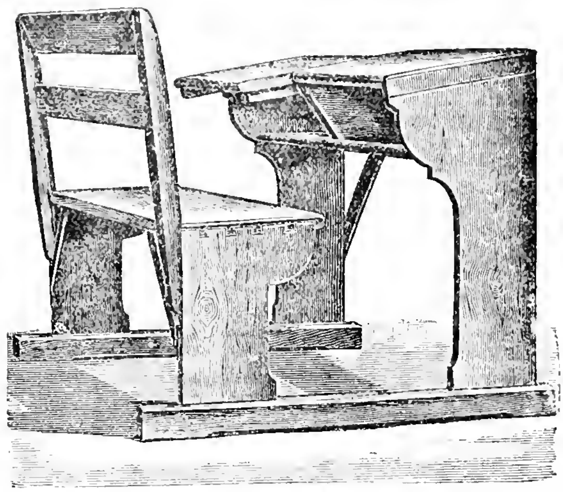

FIG. 4162.—Double Seat, used in German Schools. Movable and durable, but clumsy.

THE MEDICAL INSPECTION OF SCHOOLS.—In most European countries at the present day, the sanitary authorities exercise some sort of supervision over the public schools.[8] The well-known work of Dr. Janssens at Brussels has for years served as a model in this direction. In France, as early as 1842, it was ordered that every

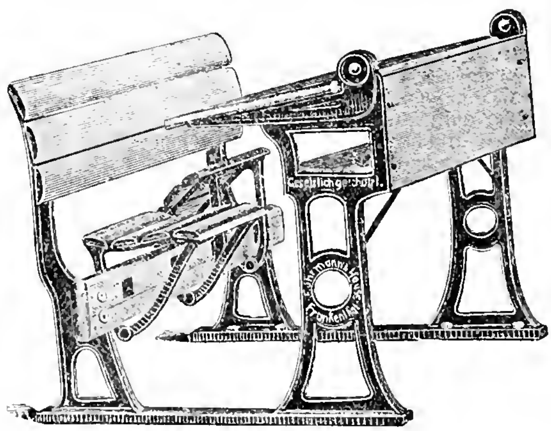

FIG. 4163.—German Double Seat. Movable.

public school should be visited by a physician, who should inspect the localities and the general health of school children. New regulations defining explicit duties of such medical inspectors in Paris were adopted, and went into effect January 1st, 1884.*

The first systematic medical inspection of schools in America was inaugurated in the Boston schools in 1894 on the advice of Dr. S. H. Durgin, chairman of the Boston Board of Health. Since that time New York, Philadelphia, Chicago, Hartford, Milwaukee, and other cities have adopted a similar course. The principal object at first aimed at was the search for unrecognized cases of infectious diseases, by which means it was believed that much could be done toward preventing their spread. Much good, however, can be accomplished in other directions toward improving all those conditions, both subjective and objective, which relate to the health of school children.

In Boston the city is divided into fifty districts, each of which is provided with an inspector who visits each of the schools in his district daily in the morning. Children who appear to be ill from any cause, and especially those suffering with incipient infectious diseases, are sent to their homes. The teachers soon become familiar with the work and render efficient aid to the inspectors.

The principal diseases detected by such inspectors, as shown by the experience of inspectors in different American cities, are the specific infectious diseases of childhood, whooping-cough, measles, mumps, chickenpox, diphtheria, scarlet fever, influenza, and tuberculosis, also laryngitis and tonsillitis, rhinitis, acute bronchitis, suppurative diseases of the ear, acute catarrhal conjunctivitis, imperfect sight, and contagious skin diseases, especially pediculosis, which often proves a serious pest among school children.

Eyesight.—Every possible means should be used to prevent impairment of the eyesight of school children, since the demands of school life impair the eyesight of a very large percentage of those who pass through the curriculum of several years.

The types employed in printing school books should produce letters of the most legible character, and the lines should be amply spaced or leaded. Cohn advises that the length of the lines should not be more than 10 cm. (4 inches).

White paper with a dull, unreflecting surface is best for the eyes of school children.

Blackboards should be kept clean and black, and should not be allowed to become gray in consequence of retention of particles of chalk. As a general rule, slates are not so good as paper. They become greasy, and the writing is generally more illegible than when it is written upon paper. Other sanitary reasons are also urged in forbidding their use.

Children should not be permitted to assume bad postures while writing, since they also injure the eyesight. The pupil should sit erect, and the book should not come nearer to the eyes than twelve inches.

Testing the Eyesight and Hearing.—Every teacher should know how to make the common tests for eyesight and hearing, which should be applied soon after the beginning of the school year, so that children who are found to be short-sighted or defective in hearing may be properly seated near the front of the room.

In schools where medical inspection is regularly made, this examination should be conducted by the medical inspector. Children are often punished or regarded as dull, when there is either a defect of the vision or of the hearing. Defects of the eyesight should be reported to the parents, so that a thorough examination may be made by an oculist and the proper glasses furnished.

Samuel W. Abbott.

SCHWALBACH is a spa situated in the province of Hesse-Nassau, Prussia. It lies in the valley of the Münzenbach, about twelve miles from Wiesbaden, and five miles from the health resort Schlangenbad. Its elevation is 972 feet above sea level, and as it is well protected against all but the southerly winds, its climate is mild and well suited for invalids. There are eight mineral springs at Schwalbach, known as the Wein-, Stahl-, Rosen-, Paulinen-, Ebe-, Neu-, Linden-, and Adelhaid-Brunnen. There is but little difference in the composition of the waters of these springs. The following is the analysis of two of the springs, as made by Fresenius. In 1,000 parts there are, of:

	Wein-Brunnen.	Linden-Brunnen.
Ferrous bicarbonate	0.057801	0.006902
Manganous bicarbonate	.009085	.004680
Sodium bicarbonate	.245345	.042317
Calcium bicarbonate	.572129	.429277
Magnesium bicarbonate	.605120	.395257
Ammonium bicarbonate	....	.002205
Lithium bicarbonate	....	.002633
Strontium bicarbonate	....	.001048
Sodium chloride	.008630	.017622
Sodium sulphate	.006193	.016156
Potassium sulphate	.006469	.006414
Sodium nitrate	....	.005541
Sodium phosphate	Trace.	.000138
Aluminum phosphate	....	.000197
Silicic acid	.046500	.032821
Organic matter, etc	.000046	.000063
Total solids	1.55871	0.963921

The gases are carbonic acid and a very small proportion of sulphureted hydrogen.

Schwalbach is a favorite health resort, and is visited by several thousand guests every year. The diseases for the relief of which a course of treatment at this spa is recommended are anæmia and chlorosis, epilepsy, chorea, progressive muscular atrophy, neuralgia, neurasthenia, hysteria, and other functional and organic nervous disorders, Bright's disease, diabetes mellitus, chronic vesical catarrh, and various affections of the female sexual organs.

The waters are employed externally and internally, according to the individual indications, and facilities are afforded for pine-needle, mud, vapor, and other baths. The season lasts from May to October. There are excellent accommodations for visitors.

SCIATICA. See *Neuralgia.*

SCIRRHUS. See *Carcinoma.*

SCLERA. See *Eye.*

SCLERA, DISEASES OF THE.—Although the sclera becomes secondarily involved in various morbid processes originating in other parts of the eyeball, primary disease of this structure is comparatively rare. Scleritis, or inflammation of the sclerotic, as a primary affection, is recognized only as originating in a narrow zone of the sclera, bounded in front by the cornea and behind by the insertion of the recti muscles. In this situation we meet with two varieties of scleritis—simple and complicated.

SIMPLE SCLERITIS (episcleritis) commences as a localized subconjunctival hyperæmia at a short distance from the corneal margin. As the episcleral tissue becomes infiltrated, a smooth swelling appears, which is but slightly elevated above the surrounding surface, and is usually of a dingy yellowish-red color, sometimes resembling a pustular formation, though ulceration or loss of substance never occurs. The conjunctival vessels over and around the swollen part are more or less engorged, but the conjunctiva in general remains normal. After a few days or weeks the nodule assumes a dull violet hue and becomes flatter, in which form it may remain stationary for a long time, or may gradually disappear, leaving a more or less permanent dull gray or ash-colored spot. Occasionally two or more such nodules are present at the same time, or as one disappears others may develop. The slow progress and tendency to recurrence of these nodules frequently render the disease tedious and protracted. One or both eyes may be affected, or as one recovers the other may undergo the same process.

The subjective symptoms are seldom severe; they consist in an unpleasant sensation of weight or pressure in the eye, undue sensitiveness to light or cold, and perhaps slight headache; rarely there may be considerable photophobia and sharp pain. This disease belongs almost exclusively to adult life, and is most common in elderly people. The gouty, the rheumatic, and the scrofulous diatheses are all credited with lending a predisposition to this form of scleritis.

Treatment.—Any special dyscrasia on the part of the patient must be taken into account and suitably dealt with; and while exercise in the open air is to be enjoined, the eye must be protected from strong light and from sudden changes of temperature. The local use of sulphate of atropine is allowable in the early stages, especially if there be marked symptoms of irritation. In the absence of these, instillations of solution of eserine—gr. ½ or 1 to the ounce—twice daily, are often very efficacious. Massage, with the employment of oxide of mercury ointment (amorphous yellow oxide of mercury 1 part, and fat or vaseline 25–50 parts), has been highly recommended. Dry or moist heat, applied to the eye in the usual way, several times daily, may be beneficial.

In regard to internal medication, the choice of remedies will depend on various circumstances. Mineral waters, iodide of potassium, salicylate of soda, protoiodide of mercury, hypodermic injections of pilocarpine, and many other remedies have been used with more or less success, according to the special indications present in the individual case.

COMPLICATED SCLERITIS (sclero-keratitis, scrofulous scleratitis). This is a much more serious affection, owing to the involvement of the cornea, iris, and ciliary region in the inflammatory process and also to the tendency which exists to disastrous changes in any or all of these parts. Sclero-keratitis, commencing in the sclerotic, begins with one or more dusky infiltrations of the sclerotic, as in simple scleritis, but close to the corneal margin, the cornea being involved from the first, or after the scleral affection has existed only a short time. The pericorneal tissues are more deeply and more generally involved than in simple scleritis, and in some cases the cornea becomes extensively opaque; sooner or later the iris may participate in the inflammation, as is shown by visible changes in its appearance and by the presence of posterior synechia, or the entire ciliary region may become intensely congested and sensitive (iridocyclitis). The special dangers to which the eye is subjected in any given case may be approximately estimated by the severity of the disease in the several parts affected—extensive changes in the cornea threatening permanent opacity of this structure; in the iris, more or less complete posterior synechia, and in the ciliary region, ciliary staphyloma. There may be one or more foci of inflammation; when there are several of these, the entire pericorneal zone may be involved, or the same thing may happen more slowly through repeated relapses, each time a different area of this zone being attacked. The low dusky swelling of the sclerotic, continuous with a patchy opacity of the adjacent cornea, is the characteristic objective sign of this disease, which, as a rule, is subacute in all its manifestations. Occasionally, however, the inflammatory process is more active, and there are intense photophobia, considerable lachrymation, and severe pain. The disease may at any time subside, leaving a dull grayish, thickened appearance of the sclerotic, and a corresponding irregular marginal opacity of the cornea. If several foci have been present, the cornea will have the appearance of being irregularly encroached upon by the sclerotic. With the subsidence of the inflammatory process the dull slaty-gray sclerotic may present a zone of thickened tissue around the cornea, which sometimes looks as if it were pushed forward, giving the anterior part of the eyeball an elongated appearance; or, more frequently, the sclerotic immediately around the cornea yields in certain places, and an irregular, nodular-looking projection (intercalar staphyloma) is formed behind the cornea. This prominence is sharply defined anteriorly, but becomes gradually flattened toward the level of the normal sclerotic posteriorly. After repeated attacks of inflammation the staphylomatous bulging may involve the entire circumcorneal zone of the sclerotic, giving rise to great enlargement and distortion of the anterior part of the eyeball; at the same time the iris may become expanded from the periphery, and the anterior chamber is often considerably enlarged. The development of staphyloma in this class of cases does not often depend on increased intraocular tension, but on a gradual expansion of the softened sclerotic. If the staphyloma is to be regarded as evidence of increased tension we must assume that the softened sclera has yielded more readily than the nerve entrance; otherwise it would be difficult to understand the well-known fact that extensive changes in the form and appearance of the eyeball are under these circumstances not inconsistent with fairly good vision.

The subjects of this disease are usually young adults, and it affects women far more frequently than men. "It is not known to be associated with any special dyscrasia, but generally occurs in persons with a feeble circulation and a liability to 'catch cold'; in some cases there is a definite family history of scrofula or phthisis" (Nettleship).

Treatment.—During the irritative stages soothing remedies are indicated. Protection from cold air and strong light is always advisable, warm fomentations are generally beneficial, and instillations of atropine are useful if there is much irritation, especially if the iris is at all involved.

In the more acute forms of this disease the writer has seen great improvement follow the use of antipyrin in doses of fifteen grains several times daily. Mercury may be used in moderation if the patient is not too anæmic. If a distinctly rheumatic or gouty tendency exists, the usual constitutional treatment for these conditions is indicated; in some cases colchicine is very useful, in others diaphoretics, such as pilocarpine hypodermically, give excellent results. Iridectomy may be performed if there are extensive adhesions of the iris and a tendency to the development of staphyloma. If vision is destroyed and the eyeball is greatly enlarged, an operation for the removal of the staphyloma may be indicated.

Staphyloma of the sclera (ectasia) occurs under the most varied conditions, but usually as the result of prolonged increase of intraocular tension.

As a *congenital* anomaly of rare occurrence there is sometimes a partial bulging of the sclerotic, associated with congenital coloboma of the choroid (scleral protuberance of von Ammon).

Extensive destruction of the cornea from suppurative keratitis is commonly followed by more or less complete corneal staphyloma, and this may extend to the sclera, giving rise to more or less general enlargement of the eyeball. Iridocyclitis and iridochoroiditis, followed by occlusion of the pupil, give rise to increased tension of the eyeball, and this in the course of time, if not relieved, causes scleral staphyloma, usually in the ciliary region. Protracted increased tension from neglected glaucoma (glaucoma consummatum), or from dislocation of the lens, is a common cause of scleral staphyloma. Under these circumstances the bulging is usually far back, behind or between the insertions of the recti muscles.

In an ectasia following inflammatory or glaucomatous processes the protruding part is lined by a corresponding portion of the stretched and attenuated uveal tract. Bulging of the sclerotic may occur at any part, during the course of suppurative panophthalmitis, prior to rupture of this tunic and the escape of the contained pus.

Intraocular growths likewise cause bulging of the sclerotic, either by softening of the tunic in the vicinity of an intraocular growth, by the increased tension which such growths induce, or by simple expansion from excessive development of the growth. For the diagnosis of these conditions, see article *Eye, Tumors of*.

Ectasia of the sclerotic at the posterior pole (sclerectasia posterior), as met with in axial myopia, is a condition of frequent occurrence. (See *Myopia*.) Its presence is easily determined, by means of the ophthalmoscope, by the existence of a crescent or irregular circle of choroidal atrophy, which nearly always commences at the temporal side of the optic papilla. *Frank Buller.*

SCLEREMA NEONATORUM.—This rare disease of early infancy, to which a number of other names have been given at various times, such as *algidité progressive*, *induratio telæ cellulosa*, *l'endurcissement athrepsique*, was first described by Underwood as a hidebound condition of the skin occurring in new-born infants. At birth, or shortly after, a peculiar induration of the skin appears, usually first upon the lower extremities, whence it spreads rapidly to other parts of the integument, involving the entire surface of the body in a few days. When the disease is fully developed the infant appears as if frozen; the surface of the body is cold; the skin is hard and wax-like at first, but later usually becomes somewhat livid; the limbs are fixed and rigid, and, owing to the stiffness of the cheeks and lips, suckling is impossible. The respirations are weak and shallow, and the circulation is feeble. Death commonly occurs within eight or ten days. The disease may be congenital, in which case the infant is either stillborn or dies within a day or two.

The affection is most probably due to malnutrition arising from improper or insufficient food, poor hygienic surroundings, or previous exhausting disease. It may follow cardiac disease, gastro-intestinal affections, disease of the lungs, or any other malady which greatly lowers the vitality of the infant. The congenital cases or those which occur a day or two after birth are of unknown origin.

According to Langer, the induration of the skin arises from solidification of the fat, brought about by the abnormally low bodily temperature, the fat of infants, owing to differences in composition, solidifying at a much higher temperature than that of adults. This explanation, however, is not entirely adequate. Parrot, who first distinguished the affection from œdema neonatorum, with which it was for a long time confounded, believes it to be a drying out of the tissues brought about by the draining off of the fluids of the body by previous debilitating disease. This author finds the skin thinner than normal, the fat diminished, and the vessels, especially of the papillary layer, greatly contracted. Ballantyne agrees in the main with Parrot's conclusions.

The only affections with which sclerema neonatorum is likely to be confounded are scleroderma and œdema neonatorum. From the former it may be distinguished by the early age at which it occurs, no case of scleroderma having yet been observed in the first few months of life. From œdema it differs in the waxy appearance of the skin, the absence of pitting on pressure, the rigidity of the limbs, and the more general distribution of the cutaneous changes, œdema being most marked in the dependent parts of the body.

The *prognosis* is extremely unfavorable, death occurring in almost all cases. In the exceptional cases in which the entire surface is not involved, recovery may take place.

Treatment consists in the employment of measures to increase the temperature of the body, which is always much below the normal, and the administration of easily digested food and stimulants. As the infant is unable to nurse, it is necessary to administer the nourishment with a flexible tube through the nose, or by enema.

Milton B. Hartzell.

SCLERODERMA.—Scleroderma (*σκληρος*, hard; *δερμα*, skin)—also known as *sclerodermia*, *sclerema*, *sclerema adultorum*, *scleriasis*—is a rare, chronic disease, characterized by a peculiar hard, leather-like condition of the skin occurring in diffuse areas or in sharply circumscribed patches. The circumscribed form, sometimes called *morphœa* and regarded by some authors as a distinct affection, has been fully described elsewhere and will not be considered here. Diffuse scleroderma begins either acutely or insidiously with slight stiffness of the skin, which usually presents a certain amount of swelling and hardness. Vague pains in the joints and muscles may precede the alterations in the skin, but marked or characteristic prodromal symptoms are usually wanting. The induration and stiffness of the skin spread slowly or rapidly (more commonly the former) over considerable areas, and in rare cases the entire integument becomes involved.

When the disease is fully developed the skin is remarkably firm and inelastic, smooth or slightly scaly, no longer susceptible of being picked up between the fingers and more or less adherent to the underlying tissues. While the color of the skin is usually white or yellowish-white, a considerable amount of pigmentation is often present in the shape of streaks and macules of various shades of brown.

Subjective symptoms are, as a rule, slight. There are a feeling of tension and occasionally more or less itching. Tactile sensibility is as a rule unaltered, but in exceptional cases there may be slight hyperæsthesia or anæsthesia.

The functional activity of the glands of the skin in mild cases is usually unaltered, but in advanced or severe ones the excretion of sweat and sebum is diminished to a greater or less degree.

When the skin about the joints is affected movement is more or less interfered with, and in atrophic cases ankylosis with consequent complete immobility may result. When the face is attacked, the features are motionless, as if covered with a mask; the nose is pinched; the mouth contracted so that it is opened with difficulty; the eyes are only half-open or staring, owing to the immobility of the lids. If the skin of the thorax is involved extensively, the movements of respiration may be considerably impeded.

The parts most commonly affected are the face, the neck, the upper portion of the trunk, and the upper extremities, but no part of the integument is exempt, although the palms and soles are rarely affected.

In some cases the morbid process is not confined to the skin, but attacks the mucous membranes of the mouth, pharynx, larynx, and vagina.

In the great majority of cases constitutional symptoms are absent, but in those exceptional ones in which the affection begins acutely with marked œdema of the skin, spreading rapidly over a considerable surface, constitutional disturbance, such as chills and fever, may precede or accompany the alterations in the skin.

The course of the disease varies within considerable limits. When it has reached its acme, it may remain unchanged for months or years, and then the induration may slowly disappear, the skin resuming its normal suppleness and softness; or, after the disease has progressed toward recovery for a time, relapses may occur and new areas be invaded. On the other hand, the skin may become more tense, thinner, and parchment-like; the subcutaneous cellular tissues and fat may disappear, and the underlying muscles atrophy. When this atrophic process affects the extremities they are greatly reduced in size, distorted, and the joints ankylosed. When the hands are affected great distortion of the fingers with marked wasting occurs, a condition which has been described as *sclerodactylia*.

Owing to the extreme tension of the skin ulceration readily occurs, especially over bony prominences. The general health is, as a rule, but little if at all affected; but in very extensive cases with atrophy, especially if accompanied by ulceration, death may take place from exhaustion.

But little is known concerning the immediate causes of scleroderma. It occurs much more frequently in the female sex than in the male. In the cases collected by Lewin and Heller (four hundred and thirty-five in number), two hundred and ninety-two, or sixty-seven per cent., were women. Age seems to have but little influence upon the frequency with which the malady occurs, although it is most frequent between twenty and forty years of age. Exposure to cold and damp appears to exert a predisposing influence. In a certain proportion of cases the affection has followed some disease of the nervous system, and in a number of instances (sufficiently numerous to indicate more than an accidental association) traumatism of some kind has immediately preceded it. In many cases, however, if not in most, the patient has been in good general health at the time of the beginning of the morbid changes in the skin.

Although the pathology of scleroderma is quite obscure, there is much in favor of the view that it is primarily an affection of the nervous system, a trophoneurosis; this, however, yet remains to be demonstrated. According to Crocker the various symptoms are produced by obstruction to the arterial and venous blood supply, and by interference with the flow of lymph, these being responsible for the alteration in the nutrition of the skin which characterizes the malady. Unna finds the chief pathological alterations in an hypertrophy of the collagenous tissues affecting all parts of the cutis, and consequent atrophy of the blood vessels and the epidermis. The changes in the epidermis are slight, consisting of occasional deposits of pigment and mechanical alterations due to pressure. A considerable exudation of small round cells surrounds the narrowed blood vessels, the sweat and sebaceous glands, and the hair follicles. The lymph spaces are narrowed, and in the cases in which atrophy occurs, an obliterating endarteritis is present.

The symptoms of a typical, well-developed case of scleroderma are usually so characteristic that the *diagnosis* is readily made. The peculiar induration of the skin characteristic of the malady is found in no other disease except sclerema neonatorum; but this latter affection is met with only in the new-born and the induration of the skin is accompanied by marked coldness of the surface.

The *prognosis* is decidedly unfavorable. While it is true that a certain small proportion of cases end in recovery, the disease usually lasts for years even when recovery does take place. When atrophy occurs, a return of the skin to its normal condition is not to be expected. In cases in which a considerable part of the integument is involved, interfering greatly with movements of the limbs, death may eventually take place with symptoms of marasmus; or, owing to his debilitated condition, the patient may fall an easy prey to some intercurrent affection.

Treatment.—Patients with scleroderma should be given an abundance of easily digested, assimilable food, such as milk, eggs, and butter. The clothing should be warm and abundant, so that there may be no danger of chill. Such tonic remedies as iron, quinine, arsenic, cod-liver oil, may be given with the view of improving the patient's general health. Massage and frictions with bland oils and fats should be systematically and persistently employed for the purpose of improving the nutrition of the skin. Mild galvanic currents may be applied to the indurated skin to improve the circulation and nutrition. Drugs have little, if any, direct influence over the course of the disease. Thyroid extract has been given with asserted good effect, but its value is doubtful. Hans Hebra has reported marked benefit from hypodermatic injections of thiosinamin, one-half a Pravaz syringeful of a fifteen-per-cent. alcoholic solution being given every second day; and more recently Neisser has recommended the same treatment. Liebreich found considerable improvement follow the internal use of cantharidin in doses of 0.0002 gm.

Milton B. Hartzell.

SCOLIOSIS. See *Lateral Curvature of the Spine.*

SCOPOLA.—(*Scopola Belladonna*; incorrectly, "Japanese belladonna.") The dried rhizome of *Scopola carniolica* Jacq. (fam. *Solanaceæ*).

This drug is chiefly of interest at the present time because of the very extensive use of its extract, like that of belladonna root extract, to substitute belladonna leaf extract, which last is officially directed to be used in the manufacture of belladonna plaster (see *Belladonna*). Scopola is, however, likely to be introduced into the forthcoming edition of the Pharmacopœia. The very similar species *S. Japonica* Maxim., of Japan, is the real *Japanese belladonna*. The Japanese Pharmacopœia is said to authorize its use, as an alternative, whenever belladonna is prescribed. This species is not with us a commercial article.

S. carniolica is a native of Central and Southern Europe. The plant somewhat resembles the belladonna plant. The leaves, which are considerably used for adulterating belladonna leaf, are not so large as the latter and are narrowly obovate, instead of broadly ovate, and have a tapering base. The underground portion of the plant is very different from that of belladonna, consisting of a tortuous horizontal rhizome from which descend, vertically, numerous roots, quite closely resembling belladonna roots, though averaging only half the size or less, and of a rather bright yellowish- or brownish-red, instead of the dull gray color of belladonna root, and usually rather evenly marked with small, transversely oblong, light colored scars. The rhizome, of which the drug almost wholly consists, is usually from two to four inches in length, as thick as the fingers, sympodial in development, shortly and sharply flexuous, and marked on the upper surface with rather closely set large shallowly cup-shaped stem scars. The outer surface is gray brown, mostly darker than that of belladonna root. Its fracture is accompanied by the emission of the same puff of dust that accompanies that of belladonna root, and the internal color is much the same, though usually somewhat darker than that of the latter.

The important constituents of scopola are its alkaloids, of which the total amount averages about the same as in belladonna root, namely, a little more than a half of one per cent. The composition of this alkaloid is as yet uncertain. It has been believed that about one-tenth of it is hyoscine (which see), but some recent analyses appear to indicate that there is much less. The remainder is a mixture of hyoscyamine and atropine. It has been believed that it is composed mostly of the former, but our ideas of the relations between these two alkaloids, both here and in belladonna, must be regarded as in a transition state.

Since the publication of our article on belladonna and atropine, a very remarkable discovery concerning this subject has been made, the conclusions having been reached independently by a chemist at Marburg and by Cushny and Schlotterbeck at Ann Arbor, the latter working along physiological lines. It has been found that hyoscyamine presents two forms, one dextrogyre, the other lævogyre, the one inert physiologically, the other acting precisely like atropine, but with exactly twice the energy. These two, combined, make atropine, of intermediate strength and optically inactive. It now remains for the percentages of these alkaloids and of the respective forms of hyoscyamine to be determined anew.

From what has preceded, it is apparent that the action of scopola will be practically that of belladonna in kind, and that their relative strengths cannot be stated positively until questions regarding the constituents shall have been more definitely settled. The present indications are that they are almost equal in strength, and that scopola can be used, in the same doses, for all the purposes for which belladonna root is used.

Henry H. Rusby.

SCROFULA.—Precisely analyzed from the standpoint of modern pathological anatomy and bacteriology, scrofula or scrofulosis may be defined as tuberculous lymphadenitis (see *Lymph Nodes, Diseases of*). Clinically it should be considered as the chronic form of tuberculosis of lymph glands. As thus defined it is evident that the term has no excuse for existence *per se*, and deserves recognition only in a synonymous sense. In fact, because of the confusion attending its proper usage, and because the principal condition to which it is applied can be more specifically designated, it would be better definitely to abandon the word scrofula as has already been advocated. In consideration of its historical interest, and on account of the persistency with which it adheres to popular parlance, scrofula still claims a passing notice.

Strictly speaking, then, scrofula is a morbid state whose chief anomaly is a tuberculosis of lymph glands, more especially the nodes of the cervical region and of the mesentery, occurring commonly in childhood, though not confined to this period. Accompanying this adenitis is a constitutional disorder formerly regarded as a distinctive dyscrasia (the "*scrofulous*" or "*strumous*" *diathesis*), but which is now known to be the anæmic, cachectic, or debilitated state attending tuberculous infection or intoxication. A broader and more ancient conception included as scrofulous such affections as tuberculosis of bones and joints, of the skin (*scrofuloderma*, or more properly, *tuberculides*), and of the mucous membranes, and even the various forms of visceral tuberculosis. A more serious misuse of the term is that which would comprise all disorders accompanied with hyperplasia or hypertrophy of lymphatic glandular structures. Thus the adenitis of other chronic infections, like the atypical pyogenic, the syphilitic, that of glanders and that of actinomycosis have been regarded as scrofula. Leukæmia, and more particularly pseudoleukæmia (Hodgkin's disease), have been classed with it at times, and the error still persists of confounding status lymphaticus (see *Status Lymphaticus*) and scrofula. So far as Hodgkin's disease is concerned, there may be some justification for its having been regarded in the same light as scrofula, especially in view of the researches of the last five years, which tend to show that the diffuse lymphadenitis of so called pseudoleukæmia is occasionally, at least, the result of an infection with the bacillus of tuberculosis in which the morbid changes have pursued an anomalous course.

Besides the more pronounced manifestations such as pertain to the glandular system, other minor affections which we now regard as secondary complications, were included among the evidences of scrofula. Examples of these are the scrofulous keratitis, conjunctivitis and blepharitis, various forms of otitis media, nasal and pharyngeal catarrh, and eczema or other skin diseases. The constitutional types once the subject of much attention, by which scrofulous individuals were classed as the "sanguine," "phlegmatic," and "pretty," are no longer regarded otherwise than indicative of a tuberculous taint either hereditary or acquired.

In fine, used in its most exclusive sense as indicating a tuberculous lymphadenitis, scrofula claims distinction only in that it refers to a sluggish, chronic tuberculous infection in which the exciting agent, the bacillus of tuberculosis, frequently seems to exist in a state of attenuated virulence. Or, it may be, that some of these infections result from other atypical members of the ray fungus group of parasites allied to the tubercle bacillus in morphology and tinctorial reactions, but endowed with diminished pathogenic powers.

Otherwise scrofula is tuberculosis, as manifested not only by its morbid anatomy and histology, and its bacteriology (as concerns the presence of the specific bacillus both in the diseased tissues and in cultures), and also by the results of inoculation experiments. This conclusion was reached by the more astute pathological anatomists, particularly of the German and Austrian schools, even before the advent of the bacteriological era, and there is no disposition to question it to-day after the critical modern studies in which the more precise methods of histological and bacteriological analysis have been employed. Hence a discussion of scrofula is based upon a study of chronic tuberculosis of the lymphatic glands, variously complicated with such anomalies as cutaneous, osseous, and synovial tuberculosis; and the scrofulous or strumous diathesis becomes the dyscrasia attending local or general tuberculosis either in its latent or in its chronic state. For the elucidation of such phases of the question as pathology, etiology, diagnosis, prognosis, and treatment of scrofula, therefore, the student is referred to the treatises upon tuberculosis in its various aspects and more especially those which refer to chronic tuberculous lymphadenitis. An exhaustive résumé of the bibliography of scrofula, mostly of interest from the historical standpoint to-day, is presented by Cornet (Nothnagel's "Specielle Pathologie u. Therapie," Bd. xiv.).

A. P. Ohlmacher.

SCROFULODERMA.—This form of tuberculosis of the skin includes those cases in which the skin is involved by infection from diseased lymph channels and nodes. Playing as it does only a secondary part, the cutaneous tissue is involved only when the breaking down glands or nodules are evacuated. This gives rise to both openings and sinuses in the skin which lead to the necrosed material. The discharge is thin and contains cheesy matter and leucocytes. The tubercle bacilli have been demonstrated both in the discharge and in the walls of the sinuses.

Oscar H. Holder.

SCROPHULARIACEÆ (the Figwort family).—A large, widely distributed and diversified family, comprising more than one hundred and seventy five genera and about twenty-five hundred species. It yields the important drugs Leptandra and Digitalis, besides which quite a large number are or have been employed to a lesser extent. Several of these, as follows, are of sufficient importance to be entitled to brief mention. The active constituents of this family appear to be chiefly glucosidal.

Mullein is a title commonly applied in this country to the fresh or dried leaves of *Verbascum Thapsus* L., an exceedingly coarse, stout herb, with a simple and erect stem, native of Europe, and now growing everywhere as a weed in the Eastern United States. The large, obovate, thick leaves are densely woolly, and are sometimes applied as a mild counter irritant, usually in the entire condition, but sometimes made into a poultice. They are mucilaginous and very slightly bitter. They are sometimes made into a tea and used as a demulcent in irritating cough. They possess slight laxative properties. In Europe the name mullein is more commonly applied to the flowers of this and related species. They possess constituents similar to those of the leaves and are similarly employed, though they contain a little volatile oil and coloring matter. Olive oil in which they have been macerated has quite a high domestic repute in many localities as an emollient.

Hedge Hyssop is the common name of a little perennial herb, *Gratiola officinalis* L., of Europe, which contains one or more glucosides, the very bitter crystalline one, *gratiolin*, being apparently the active agent. Its medicinal properties entitle it to a thorough investigation, since it is so active as to constitute a rather powerful emetico-cathartic poison, with marked diuretic properties. Its use, in doses of 0.2–1 gm. (gr. iij.–xv.), has been wholly unscientific, applying especially to gout and rheumatism.

Figwort is the dried herb of one or more species of *Scrophularia*, the genus from which the family takes its name. Like the last, the drug has not received any scientific investigation. Its bitter crystalline contituent, probably a glucoside, has been called *scrophularin*. There is also a very small amount of a volatile oil. Figwort appears to have some slight anthelmintic powers, but has been chiefly used, like mullein, in the form of a poultice. Its use is far more common in Europe than in this country. *Henry H. Rusby.*

SCURVY; SCORBUTUS.—(Including Barlow's Disease.)—DEFINITION.—Scurvy is a systemic disease dependent upon an improper or ill balanced dietary, characterized in its general expression by anæmia (secondary), hemorrhages into the skin and subjacent tissues, spongy or ulcerating gums, progressive debility and emaciation, resulting in death unless checked in its course by the necessary dietetic and medicinal treatment. The word scurvy is probably of Scandinavian origin, the Swedish *skorbjugg*, Danish *skojarbug*, being equivalent to the German *Scharbock*, meaning soft or relaxed stomach.

GENERAL CONSIDERATIONS.—Throughout all ages scurvy has been one of the classical diseases of mankind, and although it has been successfully eliminated as one of the social and sanitary problems of civilized life, yet it would be a great mistake to infer that, by reason of our better knowledge of its causation and character, it has ceased to be a possibility in our modern surroundings. Cases continue to be reported in our most recent journals. The ancient writers abound in references to it, giving in fanciful terms their theories as to its nature and cause. In his work on "Airs, Waters, and Places," Hippocrates describes the disease in an unmistakable manner, and Pliny and Strabo give us satisfactory accounts of scurvy as it appeared among the troops in the campaigns of Cæsar Germanicus and Ælius Gallus. Indeed, it has been from time immemorial the scourge of armies, ravaging the ranks of the crusaders, the soldiers of the Middle Ages in their long sieges, the cohorts of Napoleon in Egypt, and even the troopers of the last decade of the nineteenth century, in all parts of the world where warfare is carried on under climatic or dietetic conditions new and strange to the soldier. In our own country it has invalided half a garrison, at Council Bluffs (1820) resulting in a mortality of over thirty per cent., and later during the Mexican war our troops suffered from its appearance while in that country. During the civil war the statistics of this disease show a total of 46,910 cases in the Union army, of which 771 proved directly fatal, a small relative ratio, but it undoubtedly expended its force indirectly as a contributary factor in the termination of other cases with which it was concurrent. The same experience is recorded in the Crimean War, where 23,365 cases occurred in the French army, and 17,557 in the British army, while the numbers in the Turkish army were almost countless, as that force was practically decimated by its ravages. The Franco Prussian war again recorded its appearance, though with a much lessened ratio of invalidism, and the Russo Turkish War repeated the story. In the German army as late as 1897, there were seventy-four cases of scurvy and in the Russian and Austrian armies, the same year, a ratio of over one per thousand strength. But in the popular conception, as well as in the professional mind, scurvy is looked upon as a disease of the sea, and of those "who go down to the sea in ships and have their business in great waters." Beginning with the first known geographical explorations of the fifteenth century, involving long voyages in unknown oceans, the records of those famous discoverers always included with their marvellous tales of "new-found lands" the story of sufferings and death among their intrepid seamen from the disease then known as scurvy. Pierre Quirino, Vasco de Gama, and Jacques Cartier all record the ravages of this disease among the crews of their vessels. As late as the eighteenth century Anson lost more than four-fifths of his men while sailing round the world. Coming down to modern times, the experience of the Marine-Hospital Service of the United States, whose function is, in part, to care for sick and disabled seamen of the merchant marine, is the most accurate index to its prevalence among American sailors, as well as a few of other flags who are treated in our marine hospitals. From the statistics compiled for a period of twenty-eight years (1872 to 1899 inclusive) the following table has been constructed to show its occurrence and frequency:

CASES OF SCURVY TREATED IN UNITED STATES MARINE HOSPITALS FROM 1872 TO 1898 INCLUSIVE.

Year.	Number of cases scurvy.	All diseases treated.	Year.	Number of cases scurvy.	All diseases treated.
1872	18	13,156	1888	17	48,203
1873	47	13,529	1889	32	49,518
1874	59	14,356	1890	28	50,671
1875	25	15,009	1891	32	52,092
1876-77	89	31,983	1892	30	53,610
1877-79	24	39,155	1893	34	53,317
1880	39	24,860	1894	27	52,803
1881	42	32,613	1895	14	52,643
1882	55	36,184	1896	24	53,804
1883	43	40,195	1897	20	54,477
1884	27	44,761	1898	6	52,709
1885	34	41,714	1899	3	55,489
1886	18	43,822			
1887	37	45,314		824	1,066,887

This is less than one per thousand cases treated for the period stated. Dividing the twenty-eight years into three periods, the following result is obtained: 1872–1880, 301 cases; 1881–1889, 305 cases; 1890–1899, 218 cases.

These figures require but little explanation beyond stating that about half of the cases of scurvy treated by the service is reported from the stations on the Pacific coast, principally San Francisco. These cases are taken from vessels coming "round the Horn" from England or elsewhere, a long voyage of several months, in which the conditions of diet, confinement, lack of exercise, etc., aid the development of the disease. While on duty at San Francisco the writer had opportunities to study and treat about seventy-five cases of scurvy in the course of three years, and it is from this experience that he has derived his practical knowledge of the disease.

ETIOLOGY.—Scurvy—speaking in general terms—is a disease dependent on diet and occupation. It exists either in epidemic or in endemic form whenever persons subsist for a prolonged period on a dietary which does not contain fresh vegetables, or vegetables in a properly preserved state. This condition, when aggravated by an unsanitary environment, is thereby accentuated. It is still a subject of controversy what may be the precise elements in this vegetarian problem, to the lack of which are logically due the scorbutic symptoms. Everything, however, tends to the conclusion that the disease is dependent upon the insufficient ingestion or the deprivation of the potassium salts of fruits and vegetables. These salts, in which potatoes, for example, are so rich, must have a very potent influence in maintaining the alkalinity of the blood and preventing acid intoxication. When to this lack of vegetables, with their organic and inorganic elements, is added the enforced adhesion to a meat diet, especially if salted, or preserved by other similar processes, we have the ideal conditions under which scurvy begins and maintains its invasion. Resulting from this is a probable hyperacidity of the blood through the loss of the carbonates derived from the vegetable salts and the following loss of coagulability, with progressive anæmia. In this state of theoretical acid intoxication there is an increase in the ammonia-neutralized acid excreted as compared with the free acid. The blood is found to be dark and thin. The morphological changes are those of secondary anæmias, as from hemorrhage. Various observers have noted the changes in the count of red cells in proportion to the severity of the disease, the duration, and the hemorrhages. Megalocytes and shrunken microcytes have been seen in grave cases. Red cells in solution in the plasma are reported by Albertoni. The Hb index is low, according to White, while several other investigators have made conflicting statements as to the relative ratios of iron, sodium, and potassium salts and leucocytes. Altogether, the present state of knowledge of the morphology of the blood is not enlightening, and further studies are necessary to determine the significance of the conditions which are claimed by them as pathognomonic.

A recent contribution to the discussion on this portion of the subject is that made by Albertoni, who has shown in some studies of the chemistry of the blood and of digestion that there is a serious deviation from normal in the free HCl of the gastric juice, that intestinal putrefaction is excessive and that the urine furnishes abundant evidence of the absorption of toxins, while the absorption of fats and carbohydrates is deficient. He concluded that the greenish-yellow color of the serum and the excess of pigments in the urine were proofs of active destruction of the blood cells.

As a corollary to this toxic indication may be mentioned the theory, worthy of investigation, that the disease is in reality a chronic ptomaïn poisoning due to putrefactive changes in badly preserved animal food, such as salt beef and canned meats. It is held that if these provisions were properly sterilized there would be no scurvy. It is not an infrequent complaint among seamen suffering from scorbutic conditions that the "salt horse" was of an offensive odor, and this observation was made among the laborers employed on the construction of a transcontinental railroad where scurvy appeared among foreigners who used this tainted meat with a plentiful supply of flour, beans, and peas.

Scurvy is not believed to be contagious or infectious. Thus far no micro-organism has been found to be of determining value in such investigations as have been made by investigators. The field has not proved to be an inviting or fertile one for bacteriologists of admitted skill. Some experiments have been made with the blood of scorbutic patients, with portions of the spongy gums and with material taken from the hemorrhagic lesions, but the results are not satisfying nor constant. It has been noted in epidemics that children suckling scorbutic mothers did not develop the disease, and in a given ship from which cases of scurvy have been taken, except in extreme conditions, only the forecastle, where the diet was restricted to certain kinds of food, would be invaded. Isolated cases of scurvy have been found dependent upon conditions that favor either the nutritional, the toxic, or the infectious theories of the etiology of the disease advanced by various writers, but thus far the deficient vegetable dietary offers us the most practical evidence in our search for a factor that responds to all the tests of probability. Ever since Bachstrom set forth this theory in 1734—viz., the lack of fresh vegetables in the food—it has held its ground through the successive investigations of Garrod, Buzzard, and Ralfe, each carrying on by successive steps the study of this phase of the question. The last-named investigator, last in point of time as well, has formulated this theory in the following terms: The alkaline salts of vegetable acids (malic, citric, tartaric, etc.) are concerned with the normal transformation of the carbonates of the blood; the actual factor is thus a chemical alteration in the quality of the blood, a diminution of its alkalinity; that this follows the withdrawal of salts having an alkaline reaction, such as the alkaline carbonates; that this scorbutic condition is the same as that produced experimentally by injecting acid into the blood of animals, feeding with acid salts, etc., viz., a dissolution of corpuscles, purpuric spots, and other particular signs of the disease. The morphology of the blood is disappointing in so far as it fails to afford any sure index of the condition.

While scurvy is a disease of diet and occupation, it is not a disease of country, race, sex, age, or season. It is found in all zones, among all peoples where the conditions favor it; it knows no sex, though males probably contribute a greater proportion to the statistical tables, for the evident reason that they are more usually subjected to the favoring conditions; and in the matter of age it is met with from infancy to dotage. Naturally, it prevails in those countries and among those peoples whose observances of hygienic laws are "more honored in the breach," but it is found among civilized races as well. Institutions for the aged furnish cases occasionally, but on the whole it can be said that it is a disease of adult life rather than of the extremes of age. The winter season, for obvious reasons, adds to the number of cases when the disease exists in epidemic or endemic form. As to occupation it was once thought to be a disease peculiar to the seafaring life, but it is found more on land than on the sea.

Clinical History.—A progressive upward and downward curve marks the course of a case of scurvy from its onset to its finish. It has no definite attack, no crisis. Unless the patient is under conditions known to him to be causative, as in the case of seamen on a long voyage, the approach is without warning. The preliminary symptoms are those general signs of decreasing strength, mental depression, pallor, loss of flesh, anorexia, and perhaps some gastro-intestinal disturbance. This is gradually followed by the more characteristic features of the disease. The skin becomes dry, there is "pinching" of the features, the complexion becomes of a dirty hue, for want of a more applicable term, and the gingival mucous membrane at the free margin becomes swollen and spongy. This is one of the typical features of a case of scurvy. The gums bleed upon slight pressure, appear bluish in spots, and often ulcerations follow as the scorbutic condition progresses. The gums seem to develop into this soft, necrotic texture around teeth that are broken and decayed, but it is a matter of observation that in the aged who have lost their teeth and in children before the eruption of teeth, these gingival symptoms are practically absent. In severe cases the gums swell, and rising around the teeth partially cover them with a proliferated mass of foul growth, during which time the teeth become loosened in their sockets and dislodgment may follow. The breath becomes intensely fetid as a result, the flow of saliva is increased, the salivary glands sometimes enlarge, and the tongue appears red and swollen. The eating of food is, under these conditions, not only a painful but a disagreeable function, and the sufferer seeks liquid nourishment as a relief. This condition of the gums, which usually begins near the median line at the incisors, is the first characteristic symptom, and hemorrhagic suffusions into the cutaneous, mucous, and deeper tissues is the second typical development of the disease. It is usually synchronous with or later than the gingival symptoms. These subcutaneous hemorrhages appear at first in the lower extremities, about the ankles, in the form of petechial macules, varying in size and most of them having a hair follicle in the centre. They resemble ecchymoses in some cases, in others purpura and similar cutaneous disorders. While they develop spontaneously they may be excited by blows or other injuries. The larger coalesced spots show chromatic gradations of brown, green, and yellow at the periphery similar to the "black and blue" marks following a contusion, but in scurvy there is, in the severe hemorrhagic cases, a distinct elevation of surface upon which vesicles sometimes form. Ulcerations of an indolent type follow this and often destroy a large patch of cutaneous surface. The hemorrhages may be deeper-seated, giving to the limb affected a bosselated appearance, and when the intramuscular, the fibrous and the subperiosteal tissues are involved the element of pain is introduced. These deeper hemorrhages constitute the one particular symptom of an advanced case of scurvy. At first they feel like doughy masses, pitting or yielding to pressure, but later the tissues lose this resiliency and, as the suffusions become more general and uniform throughout the muscular structure below the knee, the leg, when handled, feels as if it were made of wood. This scorbutic sclerosis, of which the text-books rarely make mention, may extend to the trunk and upper extremities, but it rarely invades the face or the scalp. The joints of the upper extremity, the wrist usually, may be œdematous, and this effusion may involve the serous surfaces, the pleura, pericardium, and sometimes the meninges.

Hemorrhagic suffusions into the tissues of a mucous membrane are less constant, but, in the form of epistaxes, often resulting in syncope and exhausting anæmia, they are not so uncommon. The tissues involved do not respond to the usual remedies. When the intestinal mucous membrane is the seat of scorbutic lesions, there may be bloody stools, and in advanced cases the kidneys, spleen, bladder, and other internal organs may be included in this process.

Other symptoms noted in well-marked cases are: articular swellings, with pain and local febrile movement, and ulcerations of mucous surfaces, the cornea even being involved. Disintegration of recent callus has been reported, and other similar destructive processes, too numerous to mention, have been seen in advanced stages of the disease and are cited to show how profoundly the disturbed nutrition manifests itself in constitutional effects.

While there are no marked symptoms involving the nervous system, the mental depression is noticeable and the patient seems to be indifferent to his condition and surroundings. Hemorrhages into the meninges may produce convulsions or other abnormal cerebral manifestations. Among seamen the symptoms of hemeralopia and nyctalopia are not uncommon accompaniments.

There is no constant type of temperature. In some cases it may be subnormal. The pulse is often rapid and always weak, and the heart action and respiration are affected by the slightest exertion. Hæmic murmurs, common to all anæmias, can be detected. The urine is usually albuminous, of high specific gravity, decreased in quantity and of a high color. It may show the results of suffusion into bladder or kidneys. Obstinate diarrhœa, sometimes dysenteric in type, showing mucus and blood in the dejections, supervenes, and the loss of appetite and distaste for the foods that constitute the sufferer's diet, particularly at sea, soon give place to nausea and vomiting. These extreme conditions are not uncommon if dietetic relief does not intervene to turn the tide. The sufferer then presents a terrible picture, with sunken orbits surrounded by blackened circles, parted lips, and dingy yellow skin. He looks like a "breathing cadaver," as one writer has graphically expressed it.

Death from exhaustion, septicæmia, or some intercurrent infection terminates these advanced cases that have not had treatment.

DIAGNOSIS.—When a number of persons come from a ship after a long voyage, presenting any of the characteristic symptoms above described, or others of a similar character but less pronounced, the difficulties in the way of diagnosis are not great. Single cases seen ashore, in the early stages, might easily be classed under the general diagnosis of "anæmia" or "debility" by one not familiar with the symptoms, or not on the lookout for a disease generally believed to be peculiar to sailors. Atypical cases may sometimes confuse the diagnosis, as in all other definite morbid processes, but the differential diagnosis need only be established between it and a very few diseases. The one which resembles it most in external appearance is purpura hæmorrhagica, but this disease has none of the special gingival manifestations, the deep hemorrhages into the substructures, nor the hard brawny feel in the lower extremities. In purpura the macules are brighter and the skin not involved is of a cleaner hue, and as a further difference the articular involvement in scurvy is much less marked than in purpura. Peliosis rheumatica (Schönlein's disease), nearly allied to purpura, may give rise to similar doubts of identity. A case recently reported by Surgeon Irwin, U. S. M. H. S., in a sailor, presented a concrete example of the confusion which may result. In peliosis the purpuric spots are distributed over the entire surface, in contradistinction to what is observed in scurvy; there is hydrarthrosis of the joints in the upper extremity with general muscular pains, and there may be œdema of the face and hands. The spongy condition of the gums does not obtain in peliosis, and the character of the eruption in scurvy differs from that of purpura hæmorrhagica. Cases from ships hailing from ports where beri-beri is endemic may require a careful differential diagnosis. In a suit for damages entered by the sailors against the ship for scurvy, the defence raised this point in answer and the writer acted as expert witness at the trial. In the œdematous form of beri-beri, where there is much emaciation, with swelling of the lower extremities, it is necessary to exercise careful scrutiny of the case with particular reference to conditions existing prior to presentation. There are no gingival symptoms in beri-beri and the œdema is different from the hard nodular feel in the legs of a scorbutic patient. It may be necessary, in cases involving litigation between seamen and vessel owners charged with furnishing improper food, and thus causing scurvy, to be able to eliminate the question of the syphilodermata and specific infection complicating the case. Such allegations are usually resorted to by defendants in these cases. It will only be necessary to mention the fact, as the differential diagnosis should be easy for the medical attendant.

PROGNOSIS.—The mortality from scurvy should not reach five per cent., except in epidemics, military campaigns, or in exceptional conditions on shipboard. During the civil war the rate was sixteen per cent., which considerably exceeds that obtained in our marine hospitals. In the ordinary cases met on land a favorable termination may be expected as soon as the proper measures are instituted for correcting the diet. Recovery is naturally slow and sometimes weeks and months elapse, especially in the aged and feeble, before health is fully restored. In the grave cases seen on shipboard after long voyages, or after rescues from shipwrecks, the patients may succumb to exhaustion, hemorrhages, or some intercurrent affection, but cases which seem hopeless from their general appearance quickly rally under appropriate treatment.

PATHOLOGY.—From what has been said of the nature of the disease it can be readily surmised that the pathology is unimportant. There are no characteristic anatomical changes, beyond the subcutaneous hemorrhages and suffusions into the deep structures and occasionally into the viscera. These have already been referred to. There may be serous effusions into the pleura or pericardium, but the peritoneum is not so affected. Parenchymatous degeneration takes place in the internal organs. The stomach and intestines present the hemorrhagic patches common to the cutaneous surface. The blood flows from these suffusions, when cut, as in a living subject. The spleen is soft and quite constantly enlarged. The condition of the buccal cavity is merely that which was previously observed at the bedside. Microscopical examination of the gingival tissues has revealed nothing worthy of special mention.

TREATMENT.—Scurvy is a preventable disease, and therefore the question of treatment partakes of two phases, the prophylactic and the curative. The first may be applied in the case of ships about to proceed on long "deep-sea" voyages, whalers bound for the frozen sea, merchant ships sailing "round the Horn," or in the case of large institutions for the poor and indigent in which, for economical reasons, the diet must be restricted to the actual necessities. The United States statutes contain certain requirements respecting these matters. One relates to the supply of lime juice and vinegar (Sec. 4,569), which must be provided on voyages across the Atlantic or Pacific oceans or around Cape Horn or the Cape of Good Hope. The other (Sec. 4,612) defines what shall be the daily minimum of articles and quantities of food supplied, a not altogether satisfactory or scientific table. As each municipal institution for the care of the poor has a medical officer in attendance it will be incumbent upon him to advise the managers as to the quality and variety of food required for the proper nourishment of inmates, in order to avoid the occurrence of scorbutic symptoms among these ill-conditioned people. This can be accomplished by a judicious variation in the daily diet schedule. This diet should include not only fresh vegetables in season, but, what is equally to the point, fresh meat. In all almshouses there will be found a large proportion of persons laboring under the depressing and degrading influences of such places, persons in feeble condition or advanced life, who may confine themselves to a portion of the prescribed diet for a long period, and in whom scorbutic symptoms are inevitably set up. Osler cites a case of a woman who subsisted for many months on bread and tea, and it has been noted that in logging camps and among charcoal burners, where a diet of bread, molasses, and bacon is staple, scurvy will be found. The old maxim that "variety is the spice of life" is the keynote to the prophylaxis of scurvy when considering the dietetic question. It is not quantity nor quality, but variety that is the inviolable canon in the alimentation of mankind. Scurvy is not a disease of starvation, it is nature's revolt against lack of dietetic balance. None of the professional "fasters" ever developed the characteristic signs of the disease.

The therapeutic indication in the curative treatment of scurvy is one of dietetics rather than of medication. When the patient is first seen he should be removed from the environment responsible for the condition, whether ship, house, or room, and given such benefits as arise from change of air and surroundings. If possible, a warm bath should be given and clean clothes and a clean bed provided. These attentions are possible if the case can be removed to a hospital. The first symptom that will claim attention in an advanced case is the spongy or bleeding condition of the gums and the consequent fœtor of the breath. The relief of this is a preliminary to attractive alimentation and may be accomplished by the use of any of the mild antiseptics in the form of gargles and mouth washes. It is not necessary to enumerate them. The juice of a lemon, which possesses some astringent as well as other useful properties, is a simple and effective aid in this process. More pronounced astringents, as catechu or krameria, may be employed by brushing them on the spongy mucous surfaces. Alum may be applied in the form of a powder to small ulcerative patches, and a weak solution of lunar caustic, pencilled with a camel's-hair brush, enables the operator to reach such surfaces between the teeth.

Food is to be administered cautiously at first, and the first indication is the exhibition of fresh vegetables in the form of a strained soup. The condition of the gums and teeth may not permit the process of mastication. Lemons or limes can be given in the intervals between regular meals. Spinach, boiled, is an excellent form of vegetable, possessing highly nutritious qualities and having the advantage of softness in consistence. Sauerkraut, and vegetables used as "greens," with vinegar, are also valuable variants. To this basis may be added, as a change, fresh milk, and well-cooked beef, in judiciously graduated quantities. Occasionally the vegetable diet may be distasteful, paradoxical as it would seem, but it must be enforced until the condition of the patient shows its good effects in an improved color, increased strength, and general resumption of normal conditions. That a plan of tonic treatment is indicated need hardly be said. Iron in some form, preferably the citrate, or the tincture of the choride, is an excellent medicament in scurvy. The use of potassium in one of its salts, to replace theoretically the loss of the vegetable potassium, as advocated by Garrod, an early authority on the disease, has not given very satisfactory results. If nausea and vomiting, due to a distaste for food previously constituting the patient's diet, be present they will soon cease after the proper alimentation is instituted; but if they continue they may be stopped by such gastric sedatives as bismuth, hydrocyanic acid, or the carbonated waters. The last named are preferable. If digestion be feeble, the bitter tonics—gentian, quassia, or strychnine—may give a necessary tone to this function. Constipation and its opposite condition, either of which may be present, are to be treated with care. The changed diet should be allowed to operate for a few days as a natural stimulus to normal action. According to my experience it may be expected to act in this way. Diarrhœa, if persistent, needs some astringent, but constipation should cause but little anxiety. Intestinal hemorrhages require more active handling, and ergot, iron, lead acetate, or any approved hæmostatic must be exhibited. Calcium chloride can be advantageously given in doses of gr. xx. t.i.d. for this condition. The stiffened joints should be treated with massage and passive motion. Gentle friction over the ecchymosed regions and at points where there are signs of deeper suffusions, will prove of benefit in promoting absorption. All treatment, however, beyond the dietetic, may be classed as symptomatic.

INFANTILE SCORBUTUS. — *General Considerations.*— Within the past two decades there has been added to the list of diseases, for the special consideration of pediatrists, the scurvy of infants, following prolonged artificial feeding. To a number of English physicians, notably Dr. Barlow, who reported thirty-one cases in 1883, our knowledge is originally due, and from this physician the disease has come to be known in medical literature as "Barlow's disease," from its first reporter. Since that period it has been the subject of special study by observers in Europe and America, and scarcely an issue of journals devoted to pediatrics is wanting in some reference to the disease, its etiology, pathology, or clinical history. The American Pediatric Society considered a lengthy report on the subject in 1891 made by Dr. Northrup, and among the conclusions of the author was this: "It is a significant fact that the country which furnishes most of the literature of scorbutus in children is the same which is posted from end to end with advertisements of proprietary foods." Indeed it may be said that the appearance of this disease has a close relation, chronologically, to the development of the industry of artificial feeding of infants and the growth of the sentiment for sterilization following the diffusion of knowledge concerning bacteria.

Etiology.—Like scurvy in the adult, this disease of infancy is due to the continued use of an artificially prepared food which lacks some essential element required for nutrition. It is a disease found oftenest among the children of the rich and well-to-do, because in their homes are found the mothers who cannot, or will not, nurse their children, and who are able to provide themselves with prepared infant foods and the apparatus for the sterilization of milk. It may be stated as a general proposition that infantile scurvy is a disease of affluence and rachitis a disease of poverty, for though having some general resemblance to each other, these affections are distinct. As scurvy is a disease due to improper feeding, it may be further said that neither age, sex, race, nor season has any causal relation to its manifestation. It may occur at any age, but is oftenest found in infants between the eighth and twentieth months, or during the period of the eruption of the teeth and before the child is put on the enlarged diet which follows the ability to masticate. Children who are fed on the bottle later than this may also have the disease. In nearly all the cases that have been reported the patient has been fed on some one of the following foods: Proprietary or cereal foods, condensed milk, peptonized milk, sterilized milk, any of the cereals (as barley water), or milk too much diluted with water. Of these causes it seems pretty safe to say that the sterilization processes enjoined by many physicians and adopted by the laity as a tribute to bacteria, in the preparation of these various foods, is responsible to a great extent for the conditions which follow. From observations made in cases which have developed in infants it has been found that the scorbutic symptoms will begin to manifest themselves in from six to eight weeks after the institution of the improper diet. As in scurvy of the adult the exact etiological factor is still undetermined, but it would seem that fresh milk when ingested possesses antiscorbutic properties not unlike those possessed by the vegetable elements when administered to adults.

Clinical Symptoms.—An infant fed on artificial food, and especially on sterilized cow's milk (brought to 212° F.), will begin to show, after six weeks or more of this diet, the general signs of systemic disturbance, pallor, restlessness, disinclination to be moved. This is followed by particular evidences of pain in the lower limbs, usually localized in the femur, and in an increasing immobilization of the legs as the disease progresses. The pains grow more intense, the knees are drawn up, held motionless, or rotated outward and fixed, simulating paralysis. It will be seen that there is a cylindrical swelling of the lower end of the diaphysis of the femur, due to hemorrhagic suffusions into the subperiosteal space, either in one or in both thighs, and as a result in advanced cases this condition is often accompanied by fractures of the bone underneath. Swelling and softening of the gums presents the typical scorbutic feature almost synchronously with the above condition, but this manifestation is not usually seen in infants in whom some of the teeth have not erupted, and this gingival symptom is usually most pronounced about the incisors or about the teeth that may have pierced through. The condition of the gums is the same as in adult scurvy, with this exception: If teeth are in the upper jaw and not in the lower, the latter will not show the spongy and bleeding and ulcerated condition surrounding teeth that are present in the former. This symptom is usually followed by another characteristic scorbutic sign—subcutaneous hemorrhagic suffusions showing purpuric spots and coalesced macules of greater or less size and the appearance of multiple tumefactions of the deeper tissues. The picture is not so different from that of the adult disease, viz., the ashen hue, the foul breath, the circles about the eyes, the swollen, tender joints, and the listless mental condition. There is no temperature characteristic of the disease unless it be subnormal. Examination of the blood affords no more satisfactory results than in adult scorbutus. Hemorrhages into the cavities of the body occur. Diarrhœa is more frequent than constipation.

Diagnosis.—From the description above given the recognition of this disease in a developed case should not be difficult. It may be confounded in the early stages with rheumatism, rachitis, purpura, acute anterior poliomyelitis, infantile paralysis, and possibly syphilis. The first named may offer the greatest field for error. In rheumatism the joint itself is affected; while in scurvy the tissues about the joints, especially the knee, are involved. In scorbutic hemorrhages the blood escapes practically always into the diaphysis of the long bones. With proper protection of the femur the knee-joint can be moved without discomfort in scurvy. The differentiation from purpura is made in the same way as it is in scurvy of the adult type. In purpura the maculations are more evenly distributed over the entire surface, in scurvy the lower limbs are mostly affected. In infantile paralysis and poliomyelitis the immobility of the limbs is due to palsy of the muscles, while the failure of movement in scurvy is because of pain. The disease may be distinguished from rachitis by the absence of the rosary and by the typical skeletal signs of that disease. The characteristic scorbutic signs in the gums should always enable the observer to exclude rachitis from the problem. Dietetic treatment will usually settle a diagnosis in a few days. Other diseases to be borne in mind are hæmophilia, erythema nodosum, leukæmia, and local periostitis.

Pathology.—The special lesions found post mortem are those relating to the hemorrhages occurring in the course of the disease, but differ in no way from those observed in the adult type. Up to the present time no characteristic signs have been found which add to our knowledge of the pathology of the disease.

Treatment.—Being a preventable disease it has its prophylaxis as well as its cure. The first relates to the use of proper food. If a child must be given artificial alimentation, it is necessary that it have the nearest succedaneum to human milk that can be readily procured. This to a certain extent involves the whole question of infant feeding, which cannot here be considered. This much may be said, that cow's milk is the best substitute because the cheapest and most easily procured, as well as because it contains all the necessary elements. The proportions of the constituents differ from those of human milk, but a scientific effort to "follow nature" has not been productive of happy results. Properly diluted with water and raised to a moderate degree of heat, not over 170° F., for ten or fifteen minutes, cow's milk is the most available and natural food for infancy. This heat will effectually dispose of all bacteria that need give cause for anxiety. The "pasteurization" of milk renders it truly a sterile product—a dead liquid—in which either the antiscorbutic properties are rendered inert or the low proportion of proteids favors the characteristic signs of scurvy. The effect, upon milk, of heat sufficient to sterilize it, is not entirely understood. It is a delicate complex form of protoplasm, and the effects which "pasteurization" produces upon the caseinogen, nucleins, and the calcium salts by which their combinations are disturbed, have undoubtedly to do with their efficiency as antiscorbutic agencies. This much has been learned by practical experience and points the way to the preventive treatment of the disease.

The curative treatment is upon the same order as that of the adult type—the restoration of the food that the infant has been deprived of, viz., *fresh* milk in properly diluted form. This milk may be given in alternation with a teaspoonful or two of orange juice every hour throughout the day. Raw beef juice, salted, may be used for a change, and barley water can afford a satisfactory alternative. But the main reliance must be upon fresh milk fed with due consideration to the condition of the infant's digestive apparatus. All other forms of treatment are symptomatic and need not be detailed. As in the adult type the most desperate cases, so far as may be judged from external signs, recover rapidly when proper food is furnished.

Charles E. Banks.

SEASICKNESS, or **NAUPATHIA** (*ναῦς*, a ship; *πάθος*, sickness. French, *Mal de mer;* German, *Seekrankheit;* Dutch, *Zeeziekte;* Spanish, *Mareo;* Italian, *Male di mare*), is the name applied to a definite syndrome group that occurs usually in persons on board a vessel at sea—but also occasionally when the subject is in a rapidly moving railway or trolley car, on the back of a camel, in a balloon, an elevator, a swing, a merry-go-round, etc.—and of which nausea and vomiting are the most marked phenomena. It is said that not more than five per cent. of human beings are entirely exempt from it; but while I have no statistics to offer, this proportion seems to me much understated. The same individual may differ in his susceptibility at different times. As a rule, those who make frequent voyages become acclimated; but some persons are always sick on board ship, even in smooth weather. As a rule, weather and the motion of the ship make considerable difference in the number of sick persons on a vessel, and in the severity of the attack in the individual. Age has some influence upon resistance. Very young children are rarely affected, and children below the age of puberty are not nearly so susceptible as adults. Lower animals differ in their susceptibility to seasickness; dogs, horses, cows, sheep, and chickens have been affected; but hogs, ducks, and geese are said to escape, as a rule. The attack varies in both degree and duration, according to the idiosyncrasy and the physical condition of the individual. Merely uncomfortable sensations may be experienced, or the condition may be one of mental and physical collapse.

Seasickness is not in itself dangerous to life—very few deaths having been recorded—nor, on the other hand, is it beneficial, as is sometimes stated.

Symptomatology.—Definite symptoms are presented by this affection. Abnormal increase of appetite may be the first sign, but anorexia—even active disgust for food—is more common. Headache is the rule, and is in many cases attended with a sense of fulness or congestion. It is often most intense, and usually constrictive, over the forehead or temples; sometimes the severity is greatest on the top or in the back of the head. Usually there are pain and a feeling as of pressure in the eyeballs. Often there is pain in the back of the neck. Soreness in the back and neuralgic pain in the extremities may also be present. Nausea and vomiting are, as a rule, most obstinate. Their onset may be preceded by general chilliness with pallor of the face and lips. Ptyalism occurs at times, and there may be a foul taste in the mouth. Constipation ordinarily accompanies the general disturbances; diarrhœa is less frequent. Chilliness and flashes of heat are sometimes complained of. Mental depression, despondency, and even despair are frequently observed. In addition there may be complete loss of will power and of the faculty of concentration. The pulse presents a diminished resistance, being small, feeble, and easily compressed. The skin is pale, cold, clammy, and often moist. The urine is diminished in quantity.

Causation.—Numerous theories have been advanced as to the cause of seasickness. All writers agree, however, that the complaint is aggravated by the physical and mental fatigue caused by the preparations for the voyage, by the emotional excitement of parting, by previous imprudences in diet, by constipation, and by want of proper food. The cause of naupathia is believed by some to lie in disorders of certain senses. It is given as visual disturbance caused by the constant mobility of surrounding objects; irritation of the semicircular canals caused by the frequent and varied movements of the ship, and confusion of the muscular sense, or a disturbance of the feeling of the relation of the body to surrounding objects, caused by the unstable conditions prevailing on board a vessel.

Irwin regards seasickness—or motion seasickness, as he calls it—as a disturbance of a supplementary special sense whose function is to determine the position of the head in space and to govern and direct the æsthetico-kinetic mechanism by which is maintained the equilibrium of the body. He holds that motion produces sickness by disturbing (*a*) the endolymph in the semicircular canals, (*b*) the viscera in the abdomen, and possibly (*c*) the brain and the subarachnoid at its base. The true primary cause of seasickness he believes to be irritative hyperæmia of the semicircular canals. By some the stomach has been regarded as the seat of the trouble. The view taken is that by the shaking of the contents of the stomach digestion is stopped and fermentation sets in, the undigested fermented food being thrown off by an effort of nature. According to this theory the headache, depression, and vertigo are due partly to the absorption of bile, or of some or many toxic products of metabolism or of fermentation, into the circulation, and partly to irritation of the pneumogastric nerve terminals. Some suppose that the play of the diaphragm and abdominal organs, caused by the movements of the ship, induce spasms and convulsions of the stomach. Another theory attributes the symptoms to a severe intramolecular shaking and irritation produced in the cells of particular organs by rapid movements arising from sudden change of direction of motion. The direct mechanical effects produced on the nervous tissues by the movements of the ship are given by many as the cause of seasickness. These include repeated slight concussions of the brain produced by its being shaken up and down in its bony case; a centrifugal jarring of the brain as a result of motion along the two arcs of a circle described by the axis lines of a ship; shocks inflicted upon the brain and spinal cord by the violent flux and reflux of the cerebro-spinal fluid, induced by the movement of the vessel.

Beard believed naupathia to be a functional disturbance of the central nervous system, the cause being purely physical or mechanical—a series of mild concussions—the agitation of the nervous system by the movements of the ship. Other theories ascribe the cause to effects produced on the nervous system by disturbances of the circulatory apparatus. It has been supposed that the irregular variations of barometric pressure produced by the rising and falling of the waves cause oscillations of the column of blood within the larger vessels. Seasickness has been attributed also to sudden and recurring changes of the relations of the fluids to the solids of the body, both of which obey the law of gravity when the body is subjected to alternate movements of ascent and descent; the blood, however, descending more rapidly and ascending more slowly than the solids. Pollarin believed the condition due to the lessening of the ascending force of the blood in the aorta and in the arteries springing from it, caused by the movements of the body and resulting in anæmia of the brain. Wallaston, on the other hand, ascribed it to cerebral congestion. Chapman held that the proximate cause of seasickness consists in an undue amount of blood in the nervous centres along the back, and especially in those segments of the spinal cord related to the stomach and the muscles concerned in vomiting. Skinner believes that the motions of the ship cause movements, slight or considerable, and repeated displacements, collisions, and stretching of various organs of the body, especially of the abdominal organs, and unequal and alternate increase and lessening of pressure exerted by the column of blood on the walls of the arteries and veins. This starts a reflex nervous act, an inhibitory influence, causing a paresis of the cardio-accelerator and vaso-constrictor centres. Thus are brought about enfeeblement of the heart's action and frequently a diminution in the number of cardiac pulsations, and a consecutive loss of vascular tone with relaxation of the walls of vessels of medium calibre. This results in a general lowering of the arterial blood pressure, which is the cause of naupathia, giving rise to anæmia of the medulla, anæmia of the brain, anæmia of the skin, diminution of the blood pressure in the kidneys, and the diminution or the absence of action of the sympathetic nervous system upon the unstriated fibres of the intestine and of the arteries, and also upon the intracardiac nerve ganglia. A vicious cycle is thus established.

Gilon considers seasickness a neurosis, and says that while the onset of mild attacks may determine a temporary increase of blood in the cerebrum, it is certain that the lessened arterial tension due to the vaso-motor disturbance later deprives the nerve cells of their proper stimulus, and the consequent anæmia of these centres results in weakness of the heart and dilatation of the vessels. Even miasmatic intoxication has been made responsible for seasickness (Lemonas).

The theory that seems to me the most plausible is that which attributes to *rupture of labyrinthine compensation* the principal phenomena; thus partially allying the condition to mountain-sickness and aëronauts' sickness, in which this factor plays a subsidiary part. *Concussion of nerve elements* probably adds to the sum total of disturbances; while *auto-intoxication* is added as a result of the failure of digestion and derangement of metabolism. *Lowered vascular tone* is both a symptom and a cause of other symptoms. Psychopathy (morbid suggestion) is not to be excluded entirely, but is not in itself a sufficient explanation.

Prophylaxis and Treatment.—Different forms of treatment—physical, physiologic, and medicinal—have been recommended, in accordance with the various theories as to the cause of naupathia. The exciting cause in every case being the motion of the vessel, a stateroom should be selected near the centre of the vessel, away from the engines. An inside room is said by many to be preferable, but in my opinion the lack of ventilation more than counterbalances its supposed advantages. As prophylactic measures, it is advised that all preparations be concluded at least twenty-four hours before embarking, so that the system may not be exhausted by overwork and want of sleep, and that as hearty a meal as possible be eaten before going on board. Those especially liable to seasickness are told to go to bed before the vessel gets under weigh, having previously arranged within easy access such things as may be needed for the first day or two; to eat regularly and heartily, but without raising the head for at least one or two days; to take a mild laxative on the first night out and to keep the bowels open; and, after being able to go on deck and to the table, not to rise in the morning without first eating something. If the sea should become unusually rough, they are to go to bed before getting sick. Some have advocated a spare and dry diet, one full meal being indulged in, and soup, pastry, milk puddings, and sweets being avoided. I have seen good results apparently due to the following prophylactic régime: (1) A calomel purge followed by a saline, one week before sailing, and again two days before sailing. (2) A saline irrigation followed by complete rest, the morning before sailing. (3) Saline laxatives or enemas daily for the first few days on board. (4) Spending all the time possible on deck. Those very susceptible should maintain a reclining posture in a steamer chair, but out of the direct sunlight. Those but slightly affected should try to move around from time to time, walking a little more each day. (5) Taking for the first day or two light, easily digested food at short intervals. (6) Sponging or bathing daily with cold water or with hot water preceded by cooling of the head and neck and followed by a cold friction rub or shower. (7) Taking minute doses of picrotoxin (gr. $\frac{1}{100}$ hourly) for ten hours daily during the week preceding the voyage, and for two or three days at sea. I should now advise instead epinephrin (commercially known as suprarenalin) in doses of from gr. $\frac{1}{24}$ to gr. $\frac{1}{12}$, absorbed from the tongue. For this purpose a fraction of a grain of sugar of milk may be added, and either powders or tablet triturates be dispensed.

It is usually advised that the horizontal position be assumed. Various physical expedients have been tried to lessen the motion of the vessel but without success. The twin ferry-steamer, the *Calais-Douvre*, the Bessemer suspended saloon, swinging state-rooms, swinging berths and bunks, and the always upright easy-chair, *fauteuil-de-mer* of Dr. Neveu Derotrie, have all proved failures. Various preparatory exercises to be practised by those intending to go to sea have been suggested. Swinging, turning around upon one foot, the use of rocking-horses, oscillating planks, gyratory chairs, and the like, have been advised. Dr. Hewitt devised a mirror, so hung as to swing on its oblique axis over a swinging platform provided with a seat and movable at will up and down, from side to side, backward or forward, or in a combination of these movements. The person contemplating a voyage was advised to use this contrivance daily for some time before tempting the winds and waves. Various expedients based on the visual theory are recommended. Thus, patients are instructed to keep their eyes closed or covered; to wear smoked glasses or blue or red glasses; or to fix their eyes on some object away from the vessel. The wearing of red spectacles has been advocated on the theory that the effect of the color on the blood-vessels of the brain would be to send the blood to the brain, relieving a cerebral anaemia. To lessen the irritation of the semicircular canals, Dr. Minor suggests dropping cocaine in the ear. To keep the intestines quiet, to support the abdomen exhausted by incessant retching and vomiting, to determine the flow of blood to the head, or to provide a substitute for the stimulus and distention of food, abdominal compression by means of a bandage, handkerchief, towel, or napkin has been advised and is really useful. If the abdomen be hollow, a soft folded blanket may be fitted into the depression. Inflating the lungs and holding the breath as long as possible have been suggested as a means of fixing the diaphragm. Hovent, indeed, advocates systematic inhalation and exhalation against pressure by means of my pneumatic resistance valves. In my own person the experiment was unsuccessful.

The *dietetic management* usually recommended after the onset of seasickness is that a moderate amount of easily digested food be taken at short intervals. Beard says that one should keep something in the stomach all the time, if possible. Thin soups, broths, and gruels usually may be given. Junket, matzoon, kumyss, clam juice, beef juice, curry, preparations of blood, and predigested preparations of milk, beef, peptones, and the like can often be taken in small quantities, even after nausea and vomiting have occurred. Many experienced ship surgeons advise against the exclusive or excessive use of liquid food and prescribe solids or semi-solids; they believe that liquids encourage vomiting. Some writers recommend mulled wine, grog, Curaçoa, eau de menthe, iced dry champagne, cider, and brandy. Acid or effervescing drinks, such as seltzer, ginger ale, and sweetened water, with the addition of lemon juice or a little citric or tartaric acid, are often refreshing when taken in moderation. Draughts of ice-cold water, or pieces of ice held in the mouth, may give comfort. Coffee and tea as hot as possible, and in small doses, are sometimes soothing and invigorating.

As *curative agents* various forms of counter-irritation have been employed, the commonest being a mustard leaf over the epigastrium. Electricity has been applied, chiefly as faradization of the epigastric and hypochondriac regions, in some instances combined with the painting of the parts with a solution of atropine sulphate for cataphoretic effect. Chapman advocated the application of an ice-bag to the spine, believing that thus he could lower the temperature of the spinal region. Baruch, however, asserts that cold applied to the surface of the body, instead of penetrating deeply, calls into action the heat-regulating machinery of the body for the purpose of resisting the invasion of cold into the interior. The success Chapman met with may have been due to stimulation of the spinal centres with increase of vascular tone. The spinal coil would probably be more comfortable than an ice-bag and more easily arranged. If the benefit lie in the elevation of depreciated nerve tone, the best hydriatic application would appear to be the douche. The Winternitz combination compress, so efficacious in cases of obstinate vomiting, should be of service in seasickness, though it will rarely be available. It consists of a stimulating cool trunk compress enclosing an epigastric coil through which circulates water at a temperature of from 122° to 132° F. The cold wet compress at first produces an anaemic condition of the skin beneath, with contraction of the cutaneous vessels and irritation of the peripheral nerves. Reaction quickly follows with tonic dilatation of the vessels, the part covered by the coil becoming hyperaemic. Dr. Edward Miller, in 1814, recommended the warm bath alone, or alternating with the cold bath, friction of the skin with oil and camphor, or dry friction with powder of mustard.

Various *drugs* and classes of drugs have been employed to meet certain supposed indications. Laxative treatment is usually recommended, and should be commenced as early as two weeks previous to the night before the contemplated journey. Podophyllin, aloes, rhubarb, and the salines have been used. Drastic cathartics, however, should not be administered. Various sedatives, analgesics, and hypnotics have been employed. Bromides (ammonium, potassium, sodium, strontium) are often given in doses of from ten to thirty grains three times a day. Beard advocated mild bromization and prescribed large doses of sodium bromide for three or four days before starting, keeping this up while at sea, until there is well-grounded reason to believe that all danger is over. Chloral hydrate, in doses of five or ten grains, has been used alone or in combination with the bromides. Chloroform is sometimes employed. Charteris prescribes "chlorobrom," a solution of chloralamid and potassium bromide, for three nights in hypnotic dose—a tablespoonful for women and a tablespoonful and a half for men, or a teaspoonful every ten minutes until the full dose has been given. Nelken gave half a grain of morphine twice a day. Cannabis indica, in doses of half a grain, has been employed. Antipyrin has been given in doses of from five to fifteen grains. Chloralamid, chlorodyne, paraldehyde, sulphonal, and the like, have also been used. Personally, I have seen benefit only from the bromides—of which strontium is the best—and morphine when needed.

Certain so-called neuro-muscular agents have proved useful. According to Skinner, they increase the activity of the nerve cell and of the unstriated muscular fibre, as well as that of the striated, and thus cause an elevation of the arterial blood pressure. The theory is of dubious worth, but the practice is useful. Cocaine, caffeine, strong black coffee, thin and strong infusion of black tea constitute this group. I have seen much good from fluid extract of erythroxylon coca and from wine of coca. Other remedies that act in a similar manner are theobromine, guaranine, kolaine, and preparations of kola Strychnine and atropine have been used. Skinner employed them simultaneously in order to raise the blood pressure by acting upon the nervous centres and the unstriated muscle fibres. On account of the frequent vomiting in seasickness he preferred the hypodermic method of administration, giving to an adult from 0.5 mgm. to 1 mgm. of atropine, and 1 mgm. of strychnine, dissolved in mint water. This he repeated in two hours if the patient was not well, and even again two hours later. He never exceeded three injections in one day. Amyl nitrite has been lauded by some writers. I have seen benefit from strychnine arsenate, 0.5 mgm. (gr. $\frac{1}{125}$) hourly by the mouth, and also from picrotoxin—which acts like a combination of strychnine and belladonna—in about the same dose. Crude adrenal preparations have failed in my hands, but it is probable that epinephrin absorbed from the tongue may be useful in many cases.

Agents used for their supposed effect on the stomach are dilute chloroform, hydrocyanic acid, tincture of iodine in drop doses, cerium oxalate, cocaine, sodium bicarbonate in doses of ten to twenty grains, creosote in drop doses given every hour, eucalyptus rostrata, the digestive ferments, the dilute mineral acids, Worcestershire sauce in teaspoonful doses, and preparations of Peruvian bark, calumbo, and quassia. The older writers gave emetics on the advent of vomiting, using infusion of chamomile, peppermint or ginger, or even sea-water. Lemonas recommended quinine to combat the hypothetic miasmatic intoxication. I have seen no recommendation of specific serum—neither of an antitoxin from an acclimated human being or lower animal, nor of an artificial combination of chemical salts!

As a rule, if patients keep on deck, keep their bowels clean, do not overeat, sponge or bathe daily with cold water—or with hot water, if preceded by cooling of the head and neck and followed by a friction or by a shower or general douche of cold water—and are subjected to cheerful rather than to depressing suggestion, they will recover quickly without medicines. I have seen attacks cut short by a calomel purge followed by thorough saline irrigation of the bowel. *Solomon Solis Cohen.*

SEA VOYAGES.—Therapeutically sea voyages may be divided into three groups:

1. A voyage *incidental* to a change of residence or climate, or to a business or pleasure trip. Voyages of this class are usually, though not always, short, and apart from perils or discomforts of the particular voyage, need to be studied only from the view point of possible counterindications in the special case of a weak or delicate person, or one who has borne previous sea trips badly, or of an invalid affected with some lesion rendering the voyage hazardous. Such counterindications will be mentioned in the general discussion.

2. A voyage undertaken as a *restorative measure* in the case of an individual patient. Voyages of this class are to be studied from all possible view points, meteorologic, geographic, climatic, epidemiologic, therapeutic. The time of year, the special trip, the ship, the disease, the patient and his companions, must be given careful consideration, and indications and counterindications weighed against each other. Thus, voyages around Cape Horn in the winter of the southern hemisphere are to be avoided for invalids; and similar questions of route and season are always to be examined in detail. In this article space will not permit more than casual allusion to a few special voyages.

3. A voyage forming *part of a scheme* of climatic or other treatment. Voyages of this class stand midway between the other classes, and certain discomforts or other counterindications, not otherwise permissible, may be outweighed by the benefits expected from the measures to which it is a necessary introduction.

Ocean Climate.—The climate of the open sea possesses characteristics not to be found elsewhere: a peculiar equability of temperature due to absorption of thermal rays and surface evaporation in the day, and to convection with surface heating and diminished radiation at night; an abundance of light; a favorable degree of relative atmospheric humidity (the mean being 73.5 per cent.); and freedom of the air from dust, microbes, and other impurities. It is not necessary to call upon the presence of chemical factors in the atmosphere, ozone, iodine, or salines, to explain its beneficial influence; yet independently of chemical analysis the sense of smell finds an agreeable quality in the sea air, which doubtless indicates properties acting in an equally acceptable manner upon all nervous tissues, and possibly upon all cells. The breezes are always refreshing, and except in certain regions of latitude or current the midday temperature seldom exceeds 85° F., and is usually very much less. When the temperature is high upon the sea it is less distressing than an equal degree of heat upon the land; thus, at the tropics it is rarely oppressive even in the absence of wind. Similarly cold is often better borne at sea than on land, though from a therapeutic view point extremes of either heat or cold should be avoided. Against these qualities the depressing and distressing effects of storms—to say nothing of their dangers—must be taken into account.

Factors Other than Climatic.—The prolonged mental rest and the complete change of surroundings incident to a sea trip of moderate length are factors of no mean value in the sum total of restorative effects. On the other hand, in very long voyages, the monotony may become wearisome, and this contingency must be provided against. Ship, time of year, proposed voyage, and cost may not always correspond to desire. Light and air, while abundant and pure on deck, are not always so in the cabins. The food may not be suited to the needs of invalids, and the absence of fresh milk, fresh fruits, fresh vegetables, is often a serious drawback. Some individuals are peculiarly susceptible to seasickness, and others suffer with deranged metabolism during the greater part of the trip. Women generally feel the discomforts of life on shipboard more than men do, and can seldom be advised to take prolonged voyages. It is necessary in every case to exercise great care in the selection of ship, master, and route, to inspect the sleeping cabins and general accommodations, and to be sure that the dietetic arrangements are good. Other things being equal, well-equipped sailing vessels are to be preferred to steamers for therapeutic voyages. There should always be a trustworthy ship's doctor, and in many cases the invalid must be accompanied by a special attendant or a physician. When the patient owns a seagoing yacht, most difficulties vanish; and Sir H. Weber has suggested ships, specially built and equipped as ocean sanatoriums, to be sent on well-selected voyages according to season.

In the consideration of *seasickness*, the general precautions necessary to therapeutic voyages were considered. Here it may be emphasized in repetition that the pure air of the deck is preferable to the stuffy atmosphere of cabins; that exercise is necessary; that exposure to the sun is usually beneficial; that the skin should be cared for by regular and systematic baths, frictions, etc. In addition to the care necessary in choosing vessel and cabin, the provision of congenial companionship and of sources of intellectual interest as the inclination to mental activity returns, demands attention.

Indications.—Short voyages of from five to twenty days are useful chiefly to give mental and physical rest and recreation, and to prevent relapse or other accident after convalescence from depressing affections, as influenza. Voyages of moderate length, twenty to sixty days, are sometimes followed by strikingly good results in cases needing more prolonged rest, as in breakdowns from overwork, irritable conditions of the nervous system, even actual neurasthenia when the patient has good resisting power. In certain cases of asthma, in the conditions termed "scrofulous," in chronic tendencies to "catching cold," in suspected or actual pulmonary tuberculosis, such voyages are often beneficial.

In chronic catarrhal conditions of the upper air passages, in chronic rheumatic states, and sometimes in chronic rheumatoid arthritis, voyages to warm climates, as a winter trip to Mediterranean or Caribbean waters, may be advised. Hay fever has been reported to have been observed at sea, but the occurrence is so rare that its possibility may be disregarded and the general tonic effect of the ocean climate upon those susceptible to this affection is highly desirable. Some chronic forms of diabetes mellitus in middle-aged or elderly patients are ameliorated by ocean trips, especially those to warm climates in the winter.

Prolonged voyages, three months or more, are to be advised only when the patient is known to be a good sailor, is not too severely ill or too weak to undergo some discomforts, and has a fair degree of resisting power, as well as good digestive and eliminative functions.

The special trips of three and four months to north European waters in the summer and to Mediterranean and Oriental waters in the winter, made by well-equipped vessels and including in their itinerary stops at various important ports are, however, to be classed therapeutically with voyages of moderate duration, and are especially to be commended to convalescents and those needing rest and recreation. Long voyages on the open sea, as to Australia, for example, are to be advised chiefly for those who enjoy the sea, for dipsomaniacs and drug slaves, and in cases of pulmonary tuberculosis. It is especially in suitable cases of pulmonary tuberculosis that well chosen voyages are to be urged, sometimes as a means of recovery, sometimes as a means of palliation and of prolonging life. Some patients can "rough it" on sea and land with benefit; others must be carefully protected. The stage of disease, too, and the general characteristics of the patient make considerable difference. Hence general rules cannot be laid down. Certain main factors, however, may be presented. In febrile cases the temperature usually subsides after a few days upon the sea. In cases which show much general tendency to recovery, but in which limited areas of persistent activity remain, the local processes diminish and finally cease under the influence of the aseptic sea air and the general stimulation of nutritive processes. In cases of erethic temperament, unsuitable for mountain cures, especially those with a tendency to excessive cardiac action at altitudes, the sea exerts a beneficial sedative influence. No other measure is of equal value in early cases in robust males, especially in young men infected by chance, or when weakened by overwork, worry, or acute disease. In quiescent cases of a more advanced stage the general health and hence the local conditions are usually much improved. In certain far advanced cases with extensive softening and persistent fever, a voyage in equable waters—say upon the Pacific, as from San Francisco to Japan and return by way of Hawaii—has been known to mitigate symptoms and to prolong life. Sometimes such patients can even benefit by excursions into cooler regions, as to Alaska, Iceland, or Spitzbergen. When patients are to be sent to a special land climate, as from Europe to Colorado, or from America to the Alps, or from either to Australia or South Africa, the sea trip may be made a special feature of the cure; and, similarly, sea trips may be directed to well-chosen objective points, invigorative or protective as may be, where the patients may remain for a time before coming home.

Counterindications.—Grave lesions of the heart and blood-vessels interdict any ocean trip; nor should a longer voyage than the week between Europe and America be permitted in the great majority of cases of far advanced tuberculosis, chronic gastro-intestinal disorders, cholelithiasis, or chronic diseases of the abdominal viscera. Gouty patients may suffer more severely at sea than on land; neuralgias are often aggravated; hemorrhoids may become troublesome. Among other conditions necessitating caution, or even the prohibition of a voyage, are a marked tendency to hæmoptysis, great general weakness, special liability to seasickness or loss of appetite, epilepsy, maniacal tendencies, periodic insanity, suicidal inclinations, marine photophobia, and marine insomnia.

Solomon Solis Cohen.

SEBORRHŒA.—Definition. — For the purposes of this article seborrhœa may be defined as a functional disorder of the glands of the skin, characterized by the production of an excessive amount of fatty material, normal or abnormal in quality, which manifests itself upon the skin as an oily coating, scales, or crusts.

History.—The investigations of recent years have done much to determine the true limitations of this disease. Many points, however, remain unsettled, especially in the domain of etiology and pathology, and it is very probable that the future will render possible a definition of greater precision. The process of evolution of the present-day conception of seborrhœa is of interest, as showing the gradual differentiation of species from genus. The old Greek and Roman observers—Hippocrates, Galen, Celsus, Actuarus, and others—recognized the occurrence of falling of the hair; and by the Greeks the expression πιτυρίασις, *pityriasis* (that which is winnowed, *i.e.*, husks, bran), was used to designate a condition of the skin and scalp characterized by the formation of scales. This was, in the light of our present knowledge, a very broad application of the term, and probably included, among other morbid states, that disease which we know to-day as *seborrhœa sicca*. The name *porrigo* was given by the Roman writers, notably Celsus, to pathological conditions of the skin attended by scale formation. It was not, however, until the latter part of the eighteenth century that any suggestion of a differentiation of the general class into specific types was made. Plenck, in 1783, described, quite concisely, a condition very similar to, if not identical with, our *seborrhœa sicca*, and stated that the flaky material was to be regarded as a product of the sebaceous glands of the scalp. His view was not generally accepted by his contemporaries; the term *pityriasis* continued to be used in its comprehensive sense—including practically all squamous conditions—until well into the nineteenth century. A few investigators, however, seemed to have followed Plenck in the endeavor toward scientific differentiation. The terms *Teigne* (or *Tinea*) *amiantacée* and *T. furfuracée* were applied by Mahon to conditions apparently seborrhœic. Brett noted the occurrence of oily, scaling lesions upon parts of the body not covered with hair, and coined therefore the expression *acné sebacée*.

The terms *sécrétions morbides des follicules sebacées* and *flux sébacé* were used by Rayer in 1827, referring to morbid conditions of the sebaceous glands. In Hebra's time and during the period immediately preceding him, dermatologists were still seeking a better separation of *seborrhœa* from the general class *pityriasis*, with varying success. Fuchs, in 1840, it is said by Sabouraud, was the first to make use of the term *seborrhœa*.

In more recent years, largely as a result of the work of Unna, those cases formerly regarded as seborrhœa, in which an inflammatory process is present, have been set apart in a class by themselves, under the caption *eczema seborrhoicum* (which see). Unna himself would draw the line more closely, and would include in the class mentioned practically all types of *seborrhœa sicca*, since, he believes, inflammation is always present in these. His conception is not unanimously accepted in its entirety by dermatologists. The exclusion of the inflammatory process from seborrhœas, and their limitation strictly to functional disturbance, has greatly narrowed the field; it has imposed an added burden upon the diagnostician: that of determining where functional disorder ceases and organic change begins.

Symptomatology.—The classification of seborrhœic conditions clinically is not a settled one, especially as regards minor distinctions. For practical purposes, however, two general types may be considered: *seborrhœa oleosa* and *seborrhœa sicca*. These have been variously designated by authors; the former has been called *stearrhœa, steatorrhœa, seborrhagia, sebaceous flux, acné sébacée fluenté, hyperidrosis oleosa* (Unna); the latter, *pityriasis simplex, seborrhœa furfuracea seu psoriasiformis, erythema capitis, acné sébacée sèche, eczema seborrhoicum squamosum* (Unna).

Seborrhœa oleosa may affect both the hairy and the non-hairy parts of the body. It most commonly appears upon the face and scalp, but it may occur on the chest, back, pubes, genitals, and in the axillæ. Obviously, in these latter regions it is seen much less frequently by the physician. When the scalp is involved the hairs are covered with an excess of oil; they are greasy to the touch; tend to mat together into bunches and strands, and in the uncleanly an offensive, rancid odor may be present. The scalp itself is generally pallid and cool, and is covered with an oily secretion; when the head is bald this gives the skin a shining, though sometimes muddy appearance. Itching is either absent or of a very mild grade; redness is not commonly present; when these are found to any pronounced degree, it is a fair presumption that some irritating factor has entered in to modify the classical type. Neglected cases of this type of seborrhœa affecting the scalp generally result in a severe alopecia.

Upon the face, the parts most involved are the nose (especially the alæ nasi), the adjacent parts of the cheeks, the chin, and the forehead. The unusual flux of fatty material gives the face a yellowish, oily appearance; in addition, a dirty, "smudgy" quality is imparted, owing to the ready adherence of dust and soot particles to the greasy surface. The orifices of the sebaceous glands are large, and are generally filled with a visible, yellowish-white plug. Upon pressure these are discharged upon the skin surface, and oily material exudes from the patulous ducts. Some redness may be present, more frequently about the alæ nasi, but usually the skin is cool and without inflammatory changes. Should these appear the condition can no longer be considered a simple seborrhœa.

The domain of *seborrhœa sicca* is disputed territory. Inasmuch as the questions concern largely the matter of classification, the writer will seek to give that symptomatology which has been accepted by the majority of dermatologists of the present time.

The most frequent type of *seborrhœa sicca* is seen upon the scalp in the condition commonly known as "dandruff." It is here characterized by the formation of fine, pulverant or flaky, and slightly oily scales, grayish- or yellowish-white in color, about and between the hairs. They may be scanty, requiring the use of the nail or a blunt toothpick to demonstrate their presence; or so abundant, especially upon the vertex and the regions immediately anterior thereto, as constantly to shower the patient's shoulders with a flaky dust. Underneath the scales the scalp is pale, dry, and non-inflammatory. The hair appears to be deprived of its natural unguent, loses its lustre, becomes dry, thin, and atrophic, and eventually falls, the resulting alopecia being generally symmetrical and permanent. The subjective symptoms in mild cases are absent or very slight; if the scale formation is profuse there may be considerable itching and burning. This leads frequently to a modification of the clinical picture. The constant trauma from scratching in neurotic individuals who have neglected treatment soon induces a dermatitis, which, combined with already existing conditions, produces a type approaching *eczema seborrhoicum*. In these cases excoriated areas may be seen, usually small, upon which are formed yellowish, moist, friable crusts, distinctly greasy; beneath, a reddened, slightly exuding base may be found. The crusts, when removed, are quickly renewed; subjective itching and burning are quite pronounced.

Conditions similar to the characteristic *seborrhœa sicca* of the scalp are not uncommonly found in the eyebrows, eyelashes, mustache, and beard; it is more rarely seen in the pubic region. Upon non-hairy portions of the face, *e.g.*, the nose and adjacent parts of the cheeks, a continuous desquamation sometimes occurs; the scale is thin, grayish-white, and greasy; the skin is usually reddened and hyperæmic. The relation of this condition to *rosacea* is very close. However, upon non-hairy portions of the body the crusting forms are more commonly seen. These are best exemplified along the edge of the scalp, about the ears, upon the nose and adjacent folds, between the shoulders, and in the sternal region. The secretion over the diseased areas forms crusts, which are yellowish, greasy, friable, and often rather bulky; the skin beneath is pale or, more often, reddened slightly. If a crust be removed with care, prolongations may be seen extending from the under surface into the gaping sebaceous openings. The crusting forms frequently exhibit a serpiginous border, slightly raised, and somewhat more reddened than the central portions. The periphery, too, bears a bulkier crust, while the centre is either clearing or entirely free from scales. This form is best seen upon the chest, the back, and along the frontal hair border. The terms "flower-leaf" and "petaloid" have been used to designate the type.

Seborrhœa may occur upon the genitalia. In the male it is manifested by the formation of quantities of white, cheese-like, glandular secretion, and epithelial débris about the posterior portion of the glans, the corona glandis, and the sulcus behind the latter. In the normal and cleanly individual functional hyperactivity of the glands of these parts is practically without symptoms; but in the filthy, from want of proper ablutions, and in the phimosed, from the anatomical conditions present, the retention of this secretion leads to various reflex nervous disturbances, and very frequently sets up a severe local inflammation. In the female, the secretion forms about the clitoris and the folds of the labia minora. If the individual be cleanly, there are no symptoms; in neglected young children and in the uncleanly, a vulvo-vaginitis may develop.

A form of crusting *seborrhœa sicca* occurring in infants is called *crusta lactea*, "milk crust." Imperfect removal of the vernix caseosa from the head is the probable cause, though it is stated that the condition may arise after perfect cleansing of the new-born child. The crusts may cover nearly all the scalp or be confined to a small area. As to physical character, they are variable; they may be bulky or thin, moist or dry, tough or friable, and present a color dependent upon the complexion and surroundings of the child. Generally they are greasy and rather adherent; the surface beneath is reddened and moist. It is probable that these cases should be regarded as instances of *eczema seborrhoicum*, since they present the picture of a dermatitis planted upon a seborrhœic base.

Kaposi, under the caption *ichthyosis sebacea*, has described a condition of the skin in infants which he regards as a true seborrhœa, arising from the continued excessive production of the vernix caseosa. The skin is reddened, tense, and covered throughout with a greasy coating; it fissures readily, especially about the mouth, and subsequent inability to nurse leads to inanition and early death. That this is a seborrhœa is extremely doubtful. The same author has mentioned a seborrhœa occurring in the aged and marasmic, *pityriasis tabescentium*, characterized by scaling of the trunk and extensor surfaces of the limbs. The pathological position of this is also in doubt.

Neuman was the first to call attention to a peculiar seborrhœic condition found in the aged, which he designated as *verruca senilis*. Unna gives it the name of *verruca seborrhoica*. By the French it is known as *acné sébacée concrète*. The lesions are found upon the face, including all parts, the neck, the arms and hands, the trunk, and lower limbs. They vary in size and outline, may be single or grouped, are yellowish-brown or darker in color, sometimes nearly black. The skin between may be atrophic. Upon close inspection each lesion is seen to be raised, slightly verrucous, rough to the feel, and covered with a scale or crust, which is adherent and beneath which a reddened papillomatous surface is found. There may be slight itching. Hyde has called this a *pre-epitheliomatous seborrhœa*, an expression which is peculiarly apt, for if malignancy has not yet shown itself among the lesions it may be expected to appear in time; and the condition is almost invariably an accompaniment of cancer of the skin in those of advanced years.

ETIOLOGY AND PATHOLOGY.—*Seborrhœa oleosa* may occur at any age, but is most frequently seen in the second and third decades of life. The puberal epoch, so especially characterized by rapid growth of hair and hyperactivity of the sebaceous glands, often develops this form of seborrhœa. The disease occurs more commonly in women than in men, and brunettes are more susceptible than blondes. A tendency to oiliness of the skin is decidedly more marked in some races than in others; that shining, greasy condition of the negro's skin, which in him may be considered physiological, would be, in the white man, an evidence of abnormal glandular activity. Among certain classes of European immigrants to this country, *seborrhœa oleosa* is common. Various predisposing causes may be mentioned; disordered blood states, derangements of the digestive and assimilative functions, chronic constipation, convalescence from acute diseases, improper hygiene and habits of life, excesses in eating and in the use of alcohol; and, in women, menstrual disorders. Factors having a purely local action are sometimes efficient, as continuous exposure of a part to heat, local pressure tending to produce congestion, rosacea, etc. Elliott reports having observed its development on the site of a recently healed erysipelas.

Uncomplicated *seborrhœa oleosa* may be regarded as a functional disease, and pathological changes in the skin glands are not to be expected, though microscopic foci of inflammation are doubtless often present. It must not be forgotten, however, that the presence of an oily film upon the skin favors the entrapment of micro-organisms, and thereby predisposes to the implantation of an inflammatory process upon the pre-existing functional disturbance. Thus one may see a seborrhœa attended or followed by acne, folliculitis, furunculosis, sycosis, eczema, etc. Unna has ably championed the view that the coil glands participate in the formation of fatty secretion. He therefore proposes the term *hyperidrosis oleosa* as more accurately expressive of the true condition present when an excess of oil is poured out upon the skin.

Seborrhœa sicca, both the scaling and the crusting forms, may occur at any time of life. Blondes are more often affected than brunettes; men exhibit the disease rather more frequently than women, the probable reason being that with the former the pilary growth upon the body is more pronounced, their daily toilet of the hair is less thorough, and their headdress less hygienic. The same predisposing factors hold as for *seborrhœa oleosa*. Especially to be mentioned are convalescence from acute disease, syphilis, and the local influence of pressure and lack of ventilation about the head. A seborrhœic element is quite commonly found in the syphilides of the scalp and face, and one may see most typical forms of crusting *seborrhœa sicca* and *eczema seborrhoicum* beneath the stiff, unventilated head-dress of the nun.

The pathology of *seborrhœa sicca* is much in dispute. While there may be no clinical evidence of inflammatory action, the latter may be demonstrable microscopically. The view commonly held as to the origin of the scales is that they result from an imperfect metamorphosis of the epithelium lining the sebaceous glands into sebum, which abnormal product is extruded upon the skin, mixed with fat and horny epithelial débris. According to this conception, the essential process is found in a pathologic physiology of the glandular epithelium.

The most radical dissenters from this theory are Unna and Sabouraud, both of whom, for their originality of work, are entitled to great credit. The former's teachings may be summarized as follows:

All forms of *seborrhœa sicca* should be classed as *eczema seborrhoicum;* the coil glands are the source of fat in the scales (since seborrhœic catarrh with greasy scales may occur in the palm of the hand and sole of the foot), which fact he has repeatedly demonstrated by osmic-acid staining; the sebaceous glands and their secretion are normal, or the glands are filled with fatty cells and show no undegenerated epithelium; exit from the glands is blocked by an excess of horny cells in the follicles; the flow of fat from the coil glands is chemotactic; a definite tendency to acanthosis and parakeratosis is present within and without the hair follicle; the morococcus is practically always found, the bottle bacillus frequently; when the scalp is concerned, the openings of the hair follicles are choked and dilated with horny cells extending to the ducts of the sebaceous glands; there is a tendency, from pressure effect, to early separation of the papillary hairs, with failure of their new formation, hence the alopecia; after permanent fall of the hair, the sebaceous glands hypertrophy, and often form true sebaceous cysts.

Sabouraud's pathology, which is a still greater departure, is as follows:

There are two forms of seborrhœa: a moist type, *seborrhœa oleosa*, and a cystic type, *acne comedo;* of the first, the elementary lesion is a fatty sebaceous plug; this plug contains an enormous number of very small bacilli, which are constantly present in pure culture and are characteristic; the comedo is the cystic transformation of the sebaceous plug, the change occurring in relatively few of them; eventually the comedo becomes infected with ordinary cocci of the skin, among them the "gray-cultured" coccus, producing various types of acne; baldness is a microbacillar seborrhœa, each follicle from which the hair has fallen having been invaded by colonies of the bacilli; this bacillus grows on acid media, forming red colonies, and stains with Gram's method; the different forms of pityriasis are separated and distinct conditions from seborrhœa, but may be superimposed upon the latter; their lesion is the scale, an exfoliation of horny epidermis; this scale is produced by a special micro-organism, the bottle bacillus.

A description of the various organisms mentioned by these two observers would require greater space than the limits of this article will permit. It will suffice to state that dermatologists and pathologists are not at all agreed that these micro-organisms are specific for the conditions named, or even that they exist as distinct varieties.

DIAGNOSIS.—The recognition of *seborrhœa oleosa* presents no difficulties. *Seborrhœa sicca* must be differentiated from the following:

Eczema. In a pure eczema there is always evidence of inflammation, either in acute weeping or chronic infiltration; crusts are non-greasy, of coagulated serum; scales are dry, free from oil (unless treated with ointments,) and rather adherent; burning and itching are always present. However, the dividing line between *seborrhœa sicca* and *eczema seborrhoicum* is often very difficult to draw, since the former frequently merges into the latter.

The feature of greatest importance in the differentiation is the absence in the one and the presence in the other of visible evidence of inflammation and of itching, though these may be present only in a slight degree.

Psoriasis. Psoriasis of the scalp is seldom seen unaccompanied by patches elsewhere. In mild cases affecting the scalp the lesions are generally small, more or less isolated, covered by an adherent, silvery, non-greasy scale, beneath which an easily bleeding surface is found; between the lesions the scalp is normal or a true seborrhœa may exist. If the psoriasis is severe, parts of the head may be covered with a thick, dry, non-oily crust, through which the hair is growing vigorously; other regions of the scalp are clear. Alopecia, as a rule, does not result in a pure psoriasis, even though the scalp be severely and chronically affected. Psoriasis is not commonly seen upon the face, and very rarely about the nose, a frequent site of seborrhœa. Upon the body it is easily distinguished if it be remembered that the outlines of the lesions are more distinct, the scales copious, lustrous, and non-greasy, and the surface beneath reddened and easily torn.

Lupus Erythematosus. The *seborrhœa congestiva* of Hebra was probably *lupus erythematosus.* The differentiation is made by considering that in this disease the site of lesion is generally the face; the outlines are distinct and elevated; the scale is very adherent, non-greasy; the skin beneath is reddened to a marked degree; scar tissue may be present in the vicinity; and close inspection of the lesion will reveal atrophic changes in progress, for in *lupus erythematosus* structural alterations occur which lead to cicatrices on healing.

Ichthyosis. This disease is generally present from birth. The scale is universal, dry, non-oily; the skin reddened, dry, and tends to fissure readily along the lines of flexure and cleavage. Frequently, but not always, malnutrition is present, sometimes to a marked degree, especially in the young.

Syphilis. Seborrhœa often complicates well-defined syphilis, but cases are not common in which an absolute exclusion of the latter disease must be made. When such is the case, recourse must be had to the past history of the individual as to exposure, initial lesion, adenopathy, exanthem, mucous patches, headaches, alopecia, etc., and to careful searching for the relics of an ancient syphilis upon the skin and mucous membranes. The crusting lesions of syphilis about the face and scalp are more defined in outline, and generally present the copper hue about their borders, which is so characteristic in specific disease. It must not be forgotten that any ulcerating lesions upon the scalp may produce enlargement of the nearest lymph nodes, a knowledge of which fact will help in the avoidance of mistakes in diagnosis.

Tinea Tricophytina. Here the decisive proof is the demonstration of the fungus. Upon the scalp the lesions present a dull gray, non-greasy, adherent crust, through which broken, fragile hairs project.

TREATMENT.—In the management of *seborrhœa* due regard must be had for the patient's general condition. Much can be accomplished by a careful regulation of the diet, attention to personal hygiene, and such general measures as shall restore and maintain a normal physiology of the various bodily functions. Especial attention should be directed to the digestive tract.

Seborrhœa oleosa may be treated locally with mildly stimulating applications, the object being to restore the normal function by purging the glands. Such applications, however, should not be continuously used. The medicaments of most value are sulphur, resorcin, tincture of benzoin, and white precipitate. The first three may be used in pomades or in weak alcoholic lotion; the last in an ointment only. To accomplish results the application should be strong enough to produce a reaction with scaling, after which a milder treatment should be followed. The use of astringents is of doubtful value; if resorted to it should be certain that the secretions from the glands are thinner than normal.

Since the *x*-ray has a selective action on the more highly differentiated cells of the skin, causing atrophy, it has been suggested that conditions due to glandular hyperactivity were amenable, theoretically, to *x*-ray therapy. *Seborrhœa oleosa* would therefore be included in the category. The consideration is purely theoretical; the writer knows of no published reports of cases so treated.

Seborrhœa of the genitals disappears with cleanliness.

In the scalp *seborrhœa sicca* requires rather elaborate and persistent treatment. In severe cases crusts and scales must first be removed by maceration with an oil, followed by a shampoo; in mild cases by the shampoo alone. The official *tinctura saponis viridis* or Sarg's fluid soap will serve well as material for the shampoo. When the scalp is thoroughly cleansed a stimulating pomade should be applied. For this precipitated sulphur, resorcin, and the red sulphuret of mercury are most efficient, either singly or combined, the ointment base used being soft.

℞ Sulph. præcip.	1.00
Hydrarg. sulph. rubr.	.05
Ung. petrol. alb.	30.00
M. Sig.: Pomade for scalp.	

In severe cases this should be rubbed into the scalp every day for a week or more; afterward less often. Patients generally object strongly to the greasy condition of the hair following the frequent use of an ointment. It is advantageous in such cases to prescribe a lotion, which may be applied six days in the week, the shampoo and pomade being used on the remaining day. Sulphur, being insoluble in water and alcohol, cannot be made an ingredient of the lotion; resorcin and bichloride, combined with other stimulants, as tincture of cantharides, are the most efficient compounds available.

℞ Hydrarg. bichlor.	.10
Tr. cantharid.	20.00
Spts. vini. rect.	80.00
Aq. rosarum. ad	200.00
M. Sig.: Lotion for scalp.	

To this, if indicated, a small proportion of oil may be added; the amount should rarely exceed 10 gm. in 200.

Resorcin is credited with producing a slight change in the color of blond hair. For such the bichloride lotion is preferable.

For the crusting forms of seborrhœa of the face and body, sulphur and resorcin are the remedies *par excellence.* Crusts should be removed by softening with oil and the careful use of water in which some borax has been dissolved. A pomade containing the above-mentioned drugs in suitable proportions may then be applied. Care must be taken in treating these cases that an acute dermatitis be not awakened. Should this happen, soothing measures must be used until the skin will permit further treatment of the original condition.

The *crusta lactea* in infants may be avoided in the vast majority of cases by a gentle but thorough cleansing of the child after birth. Should characteristic crusts develop later, a mild course of treatment following the lines mentioned above will bring about a cure.

The *verruca senilis,* or the pre-epitheliomatous seborrhœa of advancing years, requires careful watching for epitheliomatous developments. For the purpose of keeping the lesions soft, a mild pomade may be used. Cauterization is not advisable. If an extensive removal of the lesions be contemplated, resource must be had to *x*-ray therapy.

The two forms of Kaposi—*ichthyosis sebacea* and *pityriasis tabescentium*—require careful attention to the general nutrition of the patient, and the use of such ointments locally as will keep the skin soft and pliable.

PROGNOSIS.—The outlook for *seborrhœa oleosa* is dependent largely upon the strictness with which the patient carries out general instructions. *Seborrhœa sicca* of the scalp requires faithful treatment; if it is neglected, recurrence is probable; alopecia is generally permanent. The seborrhœas of the body are more easily controlled. The same is true of *crusta lactea* in infants. *Pre-epitheliomatous seborrhœa* is not so unfavorable since the introduction of the x-ray as a therapeutic measure in skin diseases. In Kaposi's forms the prognosis is undoubtedly grave.

Stelwagon calls attention to the frequent presence of hypertrichosis in those suffering from seborrhœa of the face. It should be remembered that the prolonged use of greasy applications is certain to add to the hair growth already present. *Ernest Lewis McEwen.*

SECRETIN.—It has long been known that the introduction of acid into the intestine (duodenum) provokes a flow of pancreatic juice. Popielski and Wertheimer and Lépage demonstrated that this result may follow even after the exclusion of nervous impulses from without these organs. The secretion has therefore been attributed to the effects of a peripheral reflex brought about independently of central nervous influences. Since this flow of pancreatic juice will apparently follow even after inhibition of all nervous elements by atropine, it has been ascribed to a chemical stimulation of the pancreatic gland cells. The name *secretin* has been given by Bayliss and Starling to the chemical substance, as yet not isolated and identified, which is the direct stimulant to the gland. Wertheimer does not believe, however, that secretin acts independently of any nervous relations; and like Pflüger he points out the difficulty in obtaining complete isolation of an organ from nervous elements. The specific substance is obtained by extracting the mucous coat of the jejunum with 0.4 per cent. HCl. A very small portion of such an extract injected into the circulation suffices to call forth a copious flow of pancreatic juice. The active agent is not the HCl, since this alone does not provoke secretion when introduced directly into the blood current. Secretin is not present as such in the intestine, but is formed from a precursor, *prosecretin*, by the action of the acid. The transformation of prosecretin into secretin can also be accomplished by the action of boiling water or salt solution. The acid secretin solutions can be boiled and neutralized without undergoing a diminution in activity. The active substance thus does not behave like an enzyme. It is not precipitated by alcohol or ether; and presumably further investigation will demonstrate it to be a definite chemical individual of relatively low molecular weight. Camus has found that secretin may be formed in all animals examined by him, viz., the dog, cat, rabbit, guinea-pig, pig, pigeon, and frog. *Lafayette B. Mendel.*

SECRETION, PHYSIOLOGY OF.—By secretions we mean the products of the activity of gland cells. Usually these products are liquid or semi-liquid in character. In recent years a distinction has been made between internal and external secretions. By the latter term we designate a secretion that is discharged upon a free epithelial surface that communicates with the exterior. Such, for example, are the secretions of the glands of the skin or of the mucous membrane of the alimentary or respiratory tract. The name internal secretion is used to designate those secretions that are discharged into the blood or the lymph. The term is used especially in connection with the so-called ductless glands, such as the thyroids or the adrenal bodies, but it happens that in some cases a gland possessing a duct may form an internal as well as an external secretion. A good example of this combination of functions is found in the case of the pancreas. The external secretion of the pancreas, the pancreatic juice, is emptied through its duct into the duodenum, while its internal secretion, of an unknown character chemically, is discharged into the blood. As will be described later, the two secretions in this case are formed in all probability by two different kinds of gland cells. It will be convenient to consider these two kinds of secretion separately.

EXTERNAL SECRETIONS.

The composition of the external secretions varies greatly, but in general we may say that they consist of water, inorganic salts, and certain organic constituents. The organic elements in the secretions have aroused the greatest interest since they may be characteristic of the secretion. They are found in some instances (for example, the urea of the urine) preformed in the blood, and the function of the gland cell is a selective one, picking out this particular constituent and discharging it into the lumen of the gland. In other cases the organic element is not present in the blood or lymph, and must therefore be formed within the substance of the gland cell. In both cases there is a general agreement, speaking broadly, that the gland cells take an active part in the secretion and that the production or elimination of the organic products involves the expenditure of energy on the part of these cells. We picture this energy as dependent upon the chemical changes, the metabolism within the gland protoplasm, and naturally the character of these changes may vary greatly. General theories of secretion have concerned themselves chiefly with the physiological mechanisms by which the secretion is excited, and the means by which the inorganic constituents of the secretion are produced, whether in response to purely physical forces such as filtration, osmosis, and diffusion, or by means of unknown activities of the living protoplasm. The general nature of the theories proposed and the modifications suggested for the different secretions can be given best by describing the physiology of the most important secretions.

SECRETION OF THE SALIVARY GLANDS.—Under the designation salivary glands we must include all the glands whose ducts open into the mouth cavity and whose secretions contribute to the formation of the saliva. Ordinarily, however, the term is applied to the three large pairs of glands, the parotid, the submaxillary, and the sublingual. The duct of the parotid, duct of Stenson, opens opposite the second molar tooth of the upper jaw; the duct of the submaxillary, duct of Wharton, opens at the side of the frænum of the tongue; the duct or rather ducts of the sublingual, open into the floor of the mouth and are usually known as the ducts of Rivinus; although in some animals, and sometimes it is said in man, one of these ducts, the duct of Bartholin, may be especially conspicuous and runs parallel with the duct of Wharton. The portion of this gland which empties into the mouth by the duct of Bartholin is designated by Ranvier by the separate name of the retrolingual gland. Histologically these large glands show certain differences in structure. The secreting cells of the alveoli may belong either to the albuminous or to the mucous type. In the former the cells are relatively small and densely granular in appearance, so that in fresh sections of the living gland the outlines of the individual cells cannot be distinguished readily. In the mucous type the secreting cells are larger and much clearer. In the living condition they present a homogeneous ground-glass appearance, but on appropriate treatment display a few large granules much less opaque than those in the albuminous cells. These two types of cells may be found in the same gland or even in the same alveolus; but, speaking generally, the parotid in man contains chiefly albuminous cells, and the submaxillary and especially the sublingual, chiefly mucous cells. This difference in histological structure is associated with a chemical difference in the secretion. The saliva from the submaxillary and the sublingual contains mucin and is thick and stringy, while the parotid saliva, although it contains some albumin, is free from mucin and is thin and limpid. Each of these glands receives a double nerve supply one set of fibres coming from the cervical, sympathetic and the other directly from the cranial nerves. The parotid receives its cranial nerve fibres by a very indirect path. In the dog in which their course has been worked out experimentally the fibres arise from the brain in the glossopharyngeal, pass into the tympanic branch of this nerve, also known as the nerve of Jacobson, and thence to the small superficial petrosal through which they reach the otic ganglion. In branches from this ganglion they pass to the auriculo-temporal branch of the inferior maxillary, and thence by several small branches to the gland. This path is supposed to involve two nerve units, the first which may be designated as the cranial or preganglionic neurone ending in the otic ganglion; the second, the sympathetic or postganglionic neurone, arising in the otic ganglion and ending in contact with the gland cells. The cranial fibres for the submaxillary and sublingual are found in the chorda tympani nerve. They arise with this nerve from the facial and pass with it to join the lingual branch of the inferior maxillary. After running in the lingual for a short distance the secretory (and vaso-dilator) fibres branch off in several small strands which pass toward the hilus of each gland following the course of the ducts. This path also involves two nerve units. The cranial or preganglionic neurone ends in nerve cells of the sympathetic type, which, in the case of the submaxillary, are found in its hilus or along the duct, while in the sublingual they form a collection, conspicuous enough to be seen with the eye, and located in the angle made by the strands of fibres as they leave the lingual nerve. This collection of nerve cells was formerly designated as the submaxillary ganglion, but since Langley has shown by the use of the nicotine method that they are intercalated in the course of the nerve path to the sublingual gland, it is more appropriately named the sublingual ganglion. These sympathetic cells constitute the second or postganglionic neurone which ends in the gland cells. The sympathetic nerve supply to the three glands is in general the same. The fibres emerge from the spinal cord in the upper thoracic nerves, pass over to the sympathetic chain in the corresponding rami communicantes, ascend in the neck in the cervical sympathetic, and terminate, so far as the first neurone is concerned, in the cells of the superior cervical ganglion. From this ganglion sympathetic neurones pass out in strands that form a plexus in the coats of the arteries supplying the glands. These fibres are usually stimulated while in the cervical sympathetic or by applying the electrodes to the superior cervical ganglion.

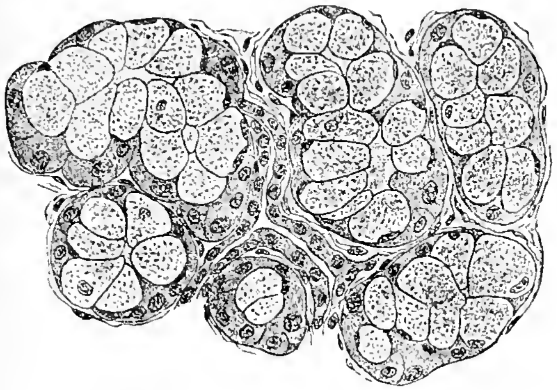

FIG. 4164.—A Section Through the Human Sublingual Gland. (Böhm-Davidoff.)

Composition of the Saliva. The saliva of the mouth consists, or may consist, of the mixed secretions from the large salivary glands together with the secretions of the small unnamed glands of the buccal mucous membrane. In addition to accidental constituents, such as epithelial cells, it contains mucin, a small proportion of albumin, an amylolytic enzyme known as ptyalin, and inorganic salts. The saliva of each gland may be collected separately by inserting a cannula into its duct. By this means it can be shown that the secretion of each gland has its own characteristics, the parotid saliva, for instance, being free from mucin, while the sublingual and the submaxillary saliva have varying proportions of this substance, but contain little or none of the ptyalin. Experiments by Pawlow indicate that the secretion of each gland may be excited differently under normal conditions. He found that in dogs the submaxillary secretion is readily excited by sapid bodies in the mouth, or by the sight or smell of food, while the flow of parotid saliva is especially marked when dry substances are placed in the mouth.

Secretory Nerves.—The discovery that these glands are supplied by secretory nerve fibres, we owe to Ludwig. In 1851 he found that stimulation of the lingual nerve causes a flow of saliva from the submaxillary gland. Bernard showed that the fibres in question belong to the chorda tympani, and discovered in addition that during the stimulation of this nerve there is a greater flow of blood through the gland. We now know that the chorda tympani conveys both secretory and vaso-dilator fibres to the submaxillary and sublingual. The natural suggestion that the increased secretion on stimulation of this nerve is due to the greater blood flow has been disproved by a series of experiments. It has been found, for instance, that after administration of atropine stimulation of the nerve is followed by a vascular dilatation without any secretion, and, on the other hand, that injection of quinine may cause a dilatation of the vessels without a secretion, which, however, is readily obtained if the nerve is stimulated. Evidently the glands possess true secretory fibres capable of starting and maintaining a secretion from the gland cells. It was found, subsequently, that stimulation of the cervical sympathetic nerve gives a small flow of saliva which is characterized by its large amount of solids and by the fact that during the stimulation the blood flow through the gland is diminished in consequence of the simultaneous stimulation of vaso-constrictor fibres. Corresponding to these facts, Heidenhain found for the parotid gland that stimulation of the cranial nerve fibres in the nerve of Jacobson, gives an abundant secretion of thin saliva, while stimulation of the cervical sympathetic gives little, or, in the case of the dog, no secretion. In the latter case, however, it was discovered that stimulation of the sympathetic fibres has an effect on the gland, although no visible secretion is produced. Sections of the gland, for instance, after

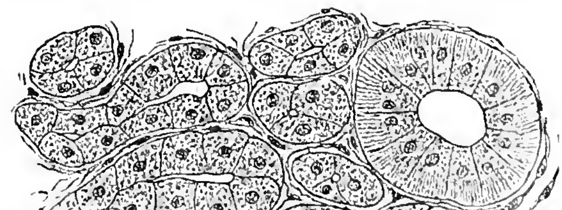

FIG. 4165.—A Section Through the Human Parotid Gland. (Böhm-Davidoff.)

such a stimulation show that the lumina of the alveoli and the ducts are distended with secretion, and if the cranial fibres are stimulated simultaneously with or subsequently to that of the sympathetic fibres, the secretion that forms instead of being thin and watery is thick, and on chemical examination shows a much larger percentage of solid matter. We are justified therefore in stating for all the salivary glands that each receives a double nerve supply, and that the sympathetic saliva, as it is called, is much smaller in amount and much richer in solids than that obtained by stimulation of the cranial fibres, the chorda or tympanic saliva. The physiological significance of this double supply of secretory fibres is not understood at present. The evidence that we have shows that reflex stimulation of these glands takes place through the cranial fibres alone, and, on the other hand, that injury to or experimental section of the cranial fibres is followed by a loss of function of the glands. In what way the sympathetic nerve supply participates in their functional activity is not explained.

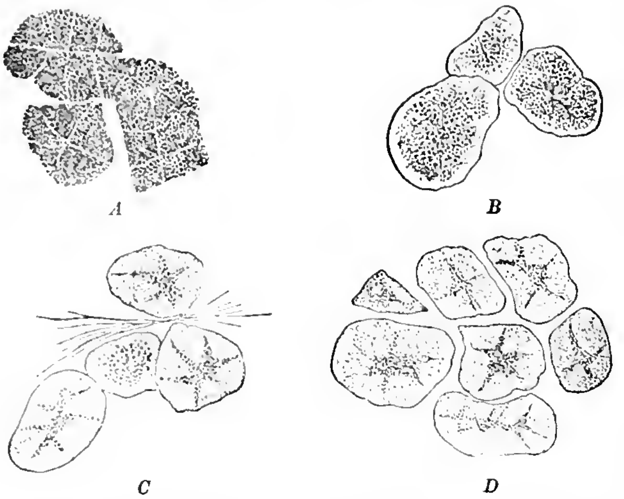

FIG. 1166. Parotid Gland of the Rabbit in a Fresh State, showing Portions of the Secreting Tubules. *A*, In a resting condition; *B*, after secretion caused by pilocarpine; *C*, after stronger secretion, pilocarpine and stimulation of the sympathetic; *D*, after long-continued stimulation of the sympathetic. (Langley.)

Relation of the Secretion to the Strength of the Stimulus.—As in the case of the neuromuscular apparatus, it is found that the extent of the secretion varies with the intensity of the stimulus, or, in other words, we can get a series of submaximal secretions by varying the stimulation. The experiments upon this relationship have been made in connection with the cranial nerve supply. According to Heidenhain, the quantity of water and the percentage amount of inorganic salts increase as the stimulus increases up to a certain maximum, while the percentage amount of organic substances shows a more variable relation. If the gland is unfatigued at the beginning of the experiment the proportion of organic substances increases rapidly as the stimulus grows, but the maximum reached is not maintained if the stimulation is continued. On the contrary, continued stimulation may give a saliva containing less and less of the organic constituents, although the water and salts may continue to show a maximal proportion. The absence of parallelism under these conditions led Heidenhain to conclude that the conditions controlling the secretion of the organic material are different from those governing the formation of the water and salts. This conclusion is expressed in his theory of salivary secretion which will be mentioned briefly below.

Normal Mechanism of the Secretion of Saliva.—The secretion of saliva may be excited reflexly by stimulation of various sensory nerves, particularly those of the mouth. The action in this case is, of course, reflex, and, as said above, the efferent path to the glands is through the cranial fibres, for if these fibres are cut a reflex secretion cannot be obtained. Although this reflex secretion may be obtained by electrical stimulation of the sensory nerves of the mouth, it may be produced most easily and abundantly by the chemical stimulation caused by sapid substances. We may assume therefore that under normal conditions the sapid substances of the food stimulate the sensory endings of the lingual and glossopharyngeal nerves in the mouth cavity and start afferent impulses to the medulla which reflexly stimulate the motor cells giving origin to the cranial secretory fibres. We have abundant evidence that the same motor cells may be stimulated reflexly through other sensory paths. The idea of food, for instance, or the sight or smell of agreeable food to a hungry person may make the mouth water, and, on the other hand, gastric irritation may give the same reaction, as is shown by the disagreeable flow of saliva that accompanies an attack of nausea. Under normal conditions the large salivary glands in man secrete only when reflexly stimulated; the secretion, in other words, is not continuous but is dependent on stimulation through the nerves. Since, however, the mouth cavity is always more or less moist even in sleep, it is probable that there is a continuous secretion from the smaller unnamed glands embedded in the buccal mucous membrane.

Histological Changes in the Gland during Secretion.—Much experimental work has been done upon the changes in microscopic appearance of the gland cells during secretion. This work was of great importance in proving that the gland cells take an active part in the secretion. Sections made of the fresh or of the hardened gland show that after prolonged secretion the gland cells are smaller than in the resting state. Moreover, in the gland at rest granules are formed within the cells, and during active secretion these granules slowly disappear. The most interesting observations are those made by Langley on sections from the living gland. He finds that in the parotid gland the cells during the resting stage are densely granular throughout. As the gland is made to secrete the granules begin to disappear first from the outer border, and after prolonged stimulation they may disappear almost entirely, the few that are left being clustered round the margin of the cells bordering on the lumen. In the mucous glands the granules are larger and clearer and much less numerous. They swell and disappear on the addition of water, and it may be assumed that they represent the mucin found in the secretion, or a preparatory material which during secretion is dissolved by the water formed, and is thus discharged from the cell.

Action of Atropin, Pilocarpin, and Nicotin on the Salivary Glands.—The three alkaloids named exert an interesting and typical action on the secretion of the salivary glands. Atropin injected into the circulation or into the gland directly through its duct will destroy its power of secretion. The gland cannot be made to secrete either by direct or by reflex stimulation. Inasmuch as the gland refuses to secrete when the stimulus is applied directly to the hilus, we may conclude that the action of the drug is either upon the gland cells themselves or upon the ending of the nerve fibres in their cells. Since stimulation of the sympathetic nerve supply may produce the usual flow of sympathetic saliva, we may conclude that the gland cells are still functional, and that the effect of the atropin is to paralyze the endings of the cranial secretory fibres. Pilocarpin or muscarin has a directly opposite effect. In proper doses each sets up a continuous secretion of saliva, and this effect may be prolonged by repeated injections of the drugs. It is assumed that these alkaloids stimulate chemically the endings of the nerve fibres in the gland cells. Atropin and pilocarpin exhibit toward these and many other glands the same antagonistic action that they exert upon the inhibitory nerve fibres of the heart. The action of nicotin has been studied chiefly by Langley. He finds that injection of this alkaloid causes first a slight stimulating effect followed soon by a temporary paralysis of both the cranial and the sympathetic fibres. After the stage of paralysis is reached it is found that stimulation of the second or post-ganglionic neurone of each path will give the customary secretion. It would seem from this result that the nicotin paralyzes the connection between the first or pre-ganglionic and the second or post ganglionic neurone. This action of nicotin takes place for other kinds of nerve fibres in which the path involves the union of a cerebro-spinal with a sympathetic neurone.

Paralytic Secretion.—After section of their cranial nerve supply, chorda tympani and nerve of Jacobson, the salivary glands give a slow continuous secretion which may keep up for several weeks. Eventually, however, the glands undergo atrophy and lose their normal structure in spite of the fact that they still possess a connection with the central nervous system by way of the sympathetic nerve fibres. This paralytic secretion occurs only when the cranial secretory fibres are destroyed, injury to the sympathetic supply alone has no such effect. The cause of the continuous secretion is not evident. Langley is inclined to the view that it is dependent upon a continuous excitation of the nerve cells within the gland, the post-ganglionic neurone. Section of the chorda, or the nerve of Jacobson, would be followed in a few days by a total degeneration of the pre-ganglionic neurone, but the second or post-ganglionic neurone would probably retain its structure and irritability for some time. Langley's view is not very satisfactory, inasmuch as it throws no light on the nature and origin of the supposed excitation.

Theory of Salivary Secretion.—Some of the constituents of saliva, *e.g.*, mucin and ptyalin, do not occur in the blood and must therefore be formed within the gland cells as a result of a special metabolism. The histological changes in the gland cells during secretion corroborate this conclusion. Heidenhain has suggested the hypothesis that the metabolism giving rise to the organic products in the secretion is under the control of a special variety of the secretory fibres for which he proposed the name of trophic fibres. A second set of fibres which he designated as secretory fibres proper control the formation of the water and salts. The action of the trophic fibres is readily understood. Like the motor fibres to the muscles, their impulses set up katabolic changes which result in the formation of mucin, ptyalin, and the peculiar proteid found in the secretion. The action of the fibres supposed to control the production of the water and salts is more difficult to explain. When the gland is at rest there is no flow of water through the gland cells from the blood and lymph. In this condition therefore the protoplasm of the cells is impermeable to the water and salts. When the secretory fibres are stimulated the flow begins promptly, and we might suppose that the action of the impulses conveyed by the nerve fibres causes a physical alteration in the gland cells, in consequence of which they become permeable to the water and salts. Since, however, under continuous stimulation of the secretory fibres the hydrostatic pressure in the occluded ducts may exceed the pressure in the capillaries and arteries, it is evident that mere filtration through the cells will not explain the flow of water. There must be some substance within the gland cells possessing a high osmotic pressure and capable therefore, if we may use the expression, of attracting the water. Heidenhain makes such an hypothesis. He assumes that normally the gland cell at rest contains water under tension in consequence of the osmotic pressure of its substance, but that this water cannot escape into the ducts in consequence of the impermeability of the limiting layer of the cells bordering upon the lumen of the alveolus. The effect of the secretory impulses is to alter the structure of this limiting layer so as to make it permeable, and the stream of water and salts will continue as long as this permeability is maintained. It would seem necessary for the completeness of the hypothesis to assume that the border of the cells resting upon the basement membrane is constantly permeable to the water, but only in one direction, that is, from the lymph toward the interior of the cells. Langley is inclined to believe that the hypothesis of two kinds of nerve fibres is unnecessary, and that it is preferable to assume that one and the same set of fibres may cause the katabolic changes leading to the formation of the organic products and at the same time control the flow of water and salts. On the histological side it may be said that there is no indication of two kinds of fibres or two sets of nerve-endings in the gland.

THE SECRETION OF THE PANCREAS.—The pancreas has much the same general histological structure as the salivary glands. The alveoli contain granular cells belonging to the albuminous type, but characterized in the resting stage by a clear non-granular zone on the basal side. The histological changes during secretion are especially distinct and resemble those described for the parotid gland. During active secretion the size of the cells is diminished, the granules disappear from the basal side, and the non-granular zone extends farther toward the inner margin of the cells. In the resting stage, on the contrary, granules are again formed within the cells, and the non-granular zone is reduced in size. Physiological evidence indicates that the granules within the cells consist of a preparatory material from which the several enzymes of the secretion are formed, and they are therefore designated usually as zymogen granules. In addition to this type of cell, which is undoubtedly responsible for the formation of the pancreatic secretion, the pancreas contains an entirely different kind of cell found in groups that are known as the islands of Langerhans. These cells seem to be connected with the production of the internal secretion of the pancreas, and will be described more fully under that head. The chief duct of the pancreas in man, the duct of Wirsung, opens into the duodenum together with the common bile duct at a distance of 8–10 cm. below the pyloric orifice. The nerves of the pancreas are derived from the solar plexus, but physiological experiments indicate that ultimately the gland receives nerve fibres from two sources, the vagus and the sympathetic nerves.

Composition of the Secretion.—The pancreatic secretion is an alkaline liquid, which in some animals is clear and limpid and in others thick and glairy. From a physiological standpoint the most important constituents are the enzymes of which three or four have been described. These are trypsin, a proteid-splitting enzyme; lipase, a fat-splitting enzyme; amylopsin, a starch-splitting enzyme, and in some animals chymosin, a milk-curdling enzyme. The strong alkaline reaction of the secretion is due to sodium carbonate. A number of organic substances may also be present in small amounts, such as albumin, peptones, leucin, tyrosin, xanthin, soaps, and fats.

Secretory Nerve Fibres.—Direct observations on animals like the dog, in which the processes of digestion are not continuous, have shown that the flow of pancreatic juice is intermittent and related to the periods of digestion. This fact would indicate that its secretion, like that of the salivary glands, is caused by reflex stimulation. Direct experimental attempts to prove the existence of secretory fibres were unsuccessful until the beautiful work done by Pawlow and his pupils. These workers found that stimulation of the peripheral end of the cut vagus or splanchnic under proper conditions causes a secretion of the juice. The latent period between the stimulation and the beginning of the flow from the pancreatic duct is quite long, from three to five minutes, and has been explained on the hypothesis that the nerves stimulated carry secretory as well as inhibitory fibres, both of which would be stimulated by the method used. The existence of inhibitory fibres is made probable also by the fact that when a secretion is in progress stimulation of the peripheral end of the cut vagus may bring the flow to a standstill. If the existence of both secretory and inhibitory fibres to the gland be accepted, recent work, which will be described in the following paragraph, makes it probable that these nerve fibres have only a regulating control over the secretion. Even when all the extensive nerve connections are severed the gland may secrete in connection with the digestive processes. Unlike the salivary gland the secretory fibres from the central nervous system are not apparently essential to secretion, but regulate it after the manner that the extrinsic nerves regulate the movements of the stomach or the heart.

Normal Mechanism of the Pancreatic Secretion.—After Pawlow's discovery of the secretory fibres to the pancreas the natural supposition was that the mechanism of secretion is analogous to that of the salivary glands, that is, some peripheral sensory stimulus in the intestines stimulates these secretory fibres reflexly. It was supposed, in fact, that the acid chyme ejected from the stomach acts upon the sensory fibres of the mucous membrane of the duodenum and sets going the normal reflex that causes the pancreatic secretion. This view was founded upon the fact, demonstrated by several observers, that acids applied to the duodenal membrane will start the pancreatic secretion. Popielski, however, asserts that the same reaction is obtained when the vagi and sympathetic are cut on both sides, so that if the reaction is effected by a nervous reflex this reflex does not involve the central nervous system. More recently an entirely new light has been thrown upon the subject by some most interesting investigations made by Bayliss and Starling. These authors find in the first place that acid (0.4 per cent. HCl) placed in the duodenum or jejunum will cause a secretion of the pancreatic juice when the loop of the intestine used (jejunum) has all of its nervous connections severed. Moreover, if the mucous membrane from the duodenum or jejunum is scraped off and treated with the acid, the solution so obtained when injected into a vein causes an active secretion by the pancreas, although the acid alone or the extract of the mucous membrane without treatment by acid is ineffective. The authors apparently have proved that normally the acid from the stomach or the acid formed (lactic) during digestion acts upon the mucous membrane and produces a substance which they designate as secretin. The secretin is absorbed, carried to the pancreas, and either stimulates the pancreatic cells directly, or, possibly, acts upon the intrinsic nerves of the gland. Secretin is not an enzyme; boiling or the action of absolute alcohol does not destroy it. According to this new and interesting discovery the secreting nerves play no necessary part in the normal mechanism of pancreatic secretion, and if this turns out to be the case we shall have to attribute to them merely a regulating influence upon the secretion. The flow of pancreatic juice caused by secretin is characterized by the fact that it does not contain an active trypsin, but recent experiments go to indicate that any normal flow of pancreatic juice possesses the same peculiarity. It would seem that in the normal secretion the trypsin is contained in the form of zymogen or pro-enzyme, and that it becomes converted to the active enzyme when it comes in contact with the intestinal mucous membrane. The conversion is made by the peculiar enzyme found in the intestinal secretion by Schepowalnikow and to which Pawlow has given the name of enterokinase (see heading of Intestinal Secretion). The normal sequence of events, then, in the secretion of pancreatic juice is, first, the formation of secretin by the action of the acid of the gastric juice on the mucous membrane of the small intestine; second, the action of this secretin, after absorption into the blood, upon the pancreatic cells; third, the conversion of the zymogen of the secretion into the active enzyme by the enterokinase of the succus entericus. This last act may be necessary only for the trypsin.

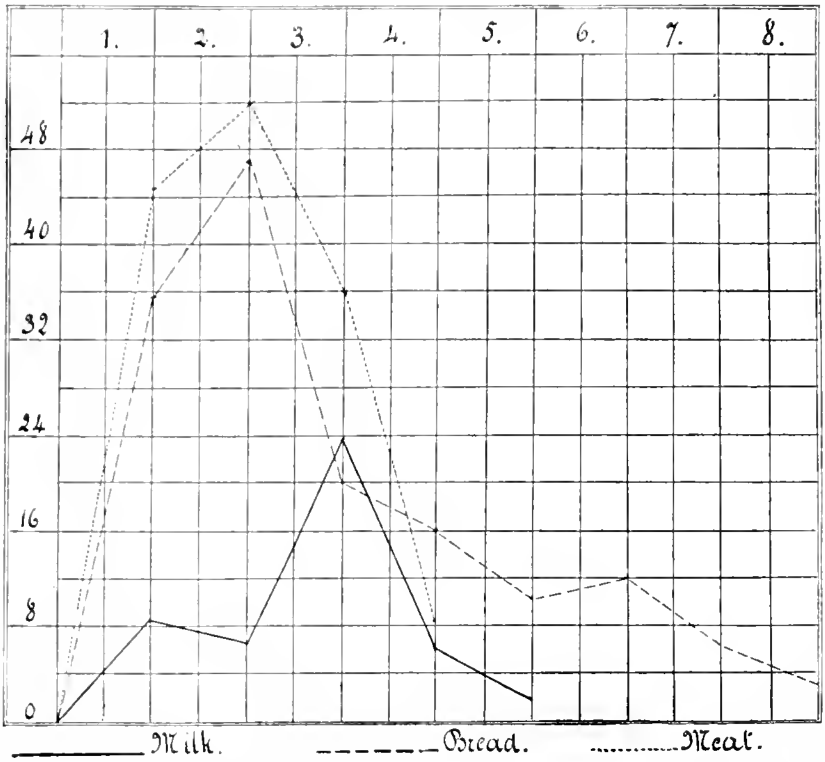

FIG. 4167.—Three Curves showing the Secretion of Pancreatic Juice upon a Diet (1) of 600 c.c. of milk; (2) of 250 gm. of bread; (3) of 100 gm. of meat. The divisions along the abscissa represent hours after the beginning of the meal; the figures along the ordinate represent the quantity of the secretion in cubic centimetres. (Walter.)

The curve of secretion of the pancreatic juice has been determined with care in the case of dogs. According to experiments made upon animals with a pancreatic fistula, the secretion begins shortly after the introduction of food into the stomach, and increases in volume to a maximum, which is reached between the first and the third hours. The curve then falls again more slowly to the base line, although there may be a second smaller rise from the fifth to the tenth hour. The general character of the curve is shown by the accompanying figure (Fig. 4167).

Relation of the Composition of the Secretion to the Character of the Food.—The work from Pawlow's laboratory indicates that the composition of the secretion varies somewhat with the character of the food, and that the variation has the appearance of a beneficial adaptation. That is, proteid foods cause in some way the secretion of a juice rich in proteolytic enzyme, and oily foods a secretion with an increased amount of lipase. This statement needs further experimental confirmation. If correct it shows a kind of biological reaction between the food and the secretion which it is difficult to explain satisfactorily. Pawlow maintains that similar specific stimuli in the food influence or control the composition of the gastric and salivary secretions. We have here a relationship which, when more fully investigated, may prove to be of much practical importance in dietetics.

Secretion of the Gastric Glands.—The accepted method of obtaining the gastric secretion dates from the famous work of Beaumont. His use of an accidental fistula in the case of St. Martin indicated at once that similar fistulas might be established upon animals for experimental purposes. Operations of this kind were performed first by Basson and by Blondlot in 1842, and were used subsequently by many investigators. At first, metal cannulas were placed in the fistulous openings to facilitate the collection of the secretion, but modern surgical technique has enabled experimenters to avoid this clumsy and often injurious device by converting a portion of the reflected mucous membrane into a tube opening on the surface of the skin. With a fistula of this character the stomach contents cannot escape to the exterior and yet can be drawn off at any time by the insertion of the catheter. The difficulty in such experiments is that the secretion becomes contaminated with the food, and its analysis is therefore difficult or impossible. Heidenhain obviated this difficulty and opened the way to successful investigation of the secretion by his device of cutting off a portion of the stomach, especially the fundic end, so as to form an isolated sac opening to the exterior. The remainder of the stomach was closed off by sutures so as to maintain the continuity of the alimentary canal. In such animals the food does not enter the isolated fundic sac, but nevertheless starts a secretion in it which may be obtained through its fistulous opening entirely free from mixture with the food. By this means the quantity, rate of flow, and composition of the secretion may be studied satisfactorily under various conditions. This operation was subsequently improved by Pawlow, who introduced a variation by means of which the nervous supply, as well as the vascular supply of the isolated sac, was maintained intact. The character of this operation is shown in the accompanying diagram (Fig. 4168). Pawlow devised also a secondary operation which in his hands has led to important results. In this operation the œsophagus was divided in the throat, and both upper and lower ends were brought to the surface of the skin to form permanent fistulas. After such an operation the food that the animal chewed and swallowed did not enter the stomach, but escaped to the exterior through the upper œsophageal fistula. By this means the effect of the act of eating upon the gastric secretion was determined. It was found that a fictitious meal of this character causes an abundant secretion of gastric juice in spite of the fact that none of the food enters the stomach, and this fact in turn led to the discovery of secretory nerves to the gastric glands.

Composition of the Secretion.—In addition to the mucus formed by the columnar epithelium on the surface of the mucous membrane, the secretion as collected contains water, inorganic salts, hydrochloric acid, pepsin, rennin, and usually a trace of peptones. The amount of the hydrochloric acid may be as great as 0.56 per cent. in the dog, but in the human gastric juice is usually given as 0.2–0.3 per cent. The secretion does not decompose easily—in fact, specimens may be kept for long periods without undergoing any putrefaction and without losing their digestive action. Evidently the secretion has marked antiseptic properties which are doubtless due to the free hydrochloric acid it contains. There has been considerable discussion as to the composition of the secretion from different parts of the stomach. The marked difference in histological structure between the glands of the cardiac and those of the pyloric end would suggest that their respective secretions might vary in character. According to most observers, the pyloric mucous membrane, when isolated from the rest of the stomach, gives a secretion that is alkaline in reaction but contains some pepsin and rennin. The hydrochloric acid, therefore, must be formed in the glands of the cardiac end. As far as is known, the glands of the pyloric end add nothing that is characteristic or essential to the secretion.

Nervous Control of the Secretion.—Much experimental work has been done to ascertain whether or not the flow of gastric juice is under the control of secretory nerves. The earlier experiments were inconclusive and need not be recalled, since in recent years Pawlow has obtained positive evidence of secretory nerve fibres. With the aid of his pupils and co-workers he has demonstrated the following facts: When a dog is given a fictitious meal by means of the œsophageal fistulas described above, there is a flow, often an abundant flow, of gastric juice, although no food gets into the stomach. If, however, the two vagi are cut previously, the fictitious meal does not cause a secretion. Evidently, therefore, the act of eating must occasion a reflex secretion of gastric juice, and the efferent paths in this reflex must pass to the stomach by way of the vagi. By the same means it was shown that the sight or smell of food will cause a reflex secretion in a hungry animal. After these preliminary experiments had indicated the existence of secretory fibres positive proof of their existence was obtained by direct stimulation of the peripheral end of a cut vagus. Under proper conditions of stimulation a flow of gastric juice can be obtained in this way, although the latent period of the secretion is unusually long, from four to ten minutes.

Normal Mechanism of the Gastric Secretion.—Beaumont and later observers held that mechanical irritation of the gastric mucous membrane is capable of provoking a secretion, and that the food therefore acts in part, especially in the beginning of digestion, as a mechanical stimulus. Pawlow, however, states positively that this belief is erroneous, and that mechanical stimuli are entirely ineffective. Heidenhain gave convincing evidence that the normal stimulus is a chemical one derived from the food, and this fact was afterward confirmed by the more detailed and satisfactory experiments made by Pawlow, who has given us a nearly complete account of the means by which the flow of gastric juice is started and maintained during digestion. According to this author, the first flow of the gastric juice is caused reflexly by the sight or smell of food, or more especially by the act of eating, and constitutes what he calls the psychical secretion. This term is used because the sensory nerves stimulated are the gustatory, olfactory, or optic nerves and the reflex is accompanied by the conscious and agreeable sensations associated with eating. The term seems to imply also that the reflex arc involves the cerebral cortex, and is thence continued to the secretory fibres in the

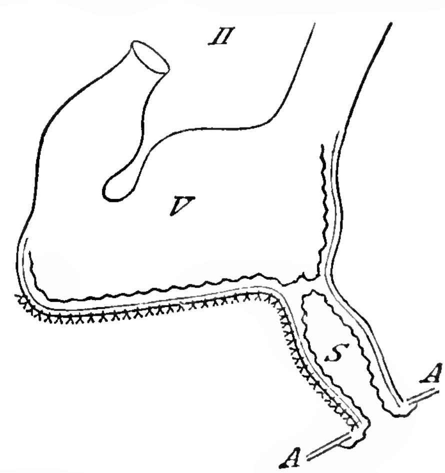

Fig. 4168.—Figure from Pawlow to show the Operation of Forming an Isolated Fundic Sac (S) and its Opening at the Abdominal Wall, A, A; V, cavity of the stomach.

vagus. The secretion produced in this way appears promptly, and under favorable conditions may be abundant in quantity. In one experiment in which the fictitious feeding was continued for several hours, it is stated that about 700 c.c. of pure gastric juice were obtained. A further flow of the secretion is caused by the action of the food upon the stomach itself. According to the experiments reported, there are some foods which contain substances capable of acting chemically upon the mucous membrane and arousing a flow of gastric juice, probably by a nervous reflex; such foods are the meats, meat extracts, milk, gelatin, and water. Other foods, such as bread or white of eggs, do not possess this power. If introduced into the stomach through a fistula without the animal's knowledge so as not to arouse a psychical

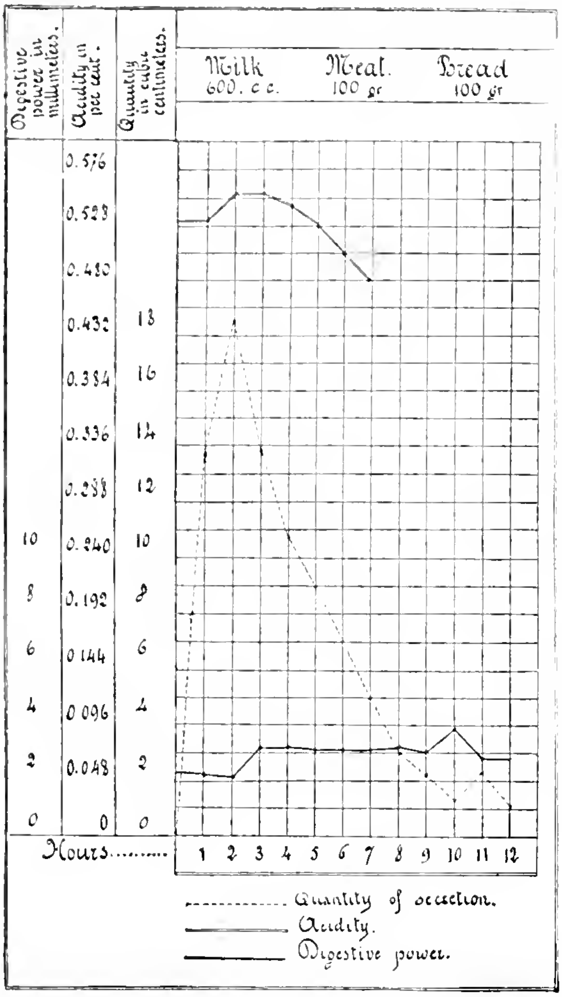

FIG. 4169.—Curve showing the Flow and Composition of the Gastric Secretion in a Dog Fed upon a Mixed Diet. (Klugine.)

secretion, they remain undigested. If, however, these foods are digested for a time they then acquire the power of stimulating a flow of gastric juice. Under the normal conditions of eating, such foods would first start a psychical secretion, and after they had begun to be digested by this secretion the flow would be maintained by the chemical stimuli developed from them in the process of digestion. These chemical stimuli upon which the flow of gastric juice depends mainly, which are present already formed in some foods and are developed in others by digestion, Pawlow groups under the general designation of secretogogues. He has not been able so far to ascertain their chemical nature. The dietetic value of meat extracts seems to lie largely in the fact that they contain much of these secretogogues and thereby favor the digestion of other foods.

Curve of Secretion and its Variation with the Character of the Food.—In its general features the curve of gastric secretion, so far as its quantity is concerned, resembles that of the pancreatic juice. The flow begins promptly after the act of eating, increases somewhat rapidly to a maximum, which in dogs fed on a mixed diet is reached at about the second hour, and then falls slowly toward zero as the stomach is emptied. The composition of the secretion during this period varies somewhat, the first flow being relatively weak in the two important constituents hydrochloric acid and pepsin. The illustration (Fig. 4169) gives an example of the way in which the secretion varies in a dog fed upon a mixed diet. Pawlow states that in a general way the quantity of secretion varies with the amount of food, a relation which is easily understood when we remember that the food itself supplies the stimulus for the secretion. The same worker has given some proof that the composition of the secretion is related to the composition of the food, and that it may be possible, when the relation has been more completely investigated, so to modify the food as to increase one or the other of its important constituents.

Histological Changes during Secretion.—The gastric glands in the cardiac end of the stomach contain two types of cells, the chief cells, and the cover or border cells. The latter vary in number in different regions, but in most cases form a discontinuous layer along the length of the tubes, and in the pyloric region they are lacking entirely. Histological and experimental evidence indicates that the chief cells are responsible for the secretion of the enzymes of the juice. During the resting stage these cells are filled with zymogen granules which disappear to a greater or less extent during active digestion. In accordance with this histological fact it is found that aqueous extracts of the mucous membrane in the resting stage may contain but little active pepsin or rennin, but that if this extract or the mucous membrane before extraction is treated with certain reagents such as dilute acids, an abundant yield of enzyme is obtained. In normal secretion the presence of the hydrochloric acid is sufficient in itself to convert the zymogen to enzyme, so that in the normal gastric juice no zymogen or proferment is found. With regard to the enzymes, therefore, we may assume that, as in the other digestive glands, they are formed within the cells as a result of their metabolism, that they are stored during rest as zymogen granules, and that, during or immediately subsequent to their secretion, the zymogen is changed to the active enzyme. With regard to the secretion of the acid prevalent theories are much less satisfactory.

Origin of the Hydrochloric Acid.—It is not known definitely which of the two cells found in the gastric tubules gives rise to the hydrochloric acid. The fact that the pyloric glands do not contain border cells and that their secretion is alkaline instead of acid suggests the view that these border cells are concerned in the formation of the acid, hence they are sometimes designated as oxyntic cells. No direct proof, however, has been furnished to show that these cells have anything to do with the production of the hydrochloric acid. On the chemical side also the mode of origin of the acid is still obscure. In general, it is believed that the hydrochloric acid must arise ultimately from the chlorides, especially the sodium chloride of the blood, and, according to one hypothesis, the acid is formed by a reaction between the chlorides and the phosphates of the blood according to the formula $NaH_2PO_4 + NaCl = Na_2HPO_4 + HCl$, the reaction being effected in some way through the activity of the gland cells. Another hypothesis is that the chlorides are decomposed by the mass action of the CO_2 formed in the metabolism of the gland tissue, and that the reaction is facilitated and the liberated base combined by an acid nucleoproteid known to exist in the gastric mucous membrane. Neither hypothesis helps us much to understand why the hydrochloric acid is formed only in this particular tissue and not elsewhere in the body. Acid indicators, such as acid fuchsin or a solution of ferric acetate and potassium ferrocyanide, show that the free acid is present only on the surface of the membrane and not within the substance of either the border cells or the chief cells. In view of this result it has been supposed that the acid is not actually formed within the cells, but in the secretion after its discharge; or if formed within the cells, it is eliminated as rapidly as it is formed, so that there is no accumulation within the cell itself as in the case of the zymogen. In accordance with this hypothesis it has been suggested that the hydrochloric acid is actually formed outside the mucous membrane from the chlorides of the stomach contents. This view assumes that the mucous membrane is impermeable to the chlorine ions, but permeable to the hydrogen ions, and that the latter passing through the mucous membrane from the blood, combine with the chlorine of the dissociated chlorides of the stomach contents. The hypothesis can scarcely be considered a probable one, since an abundant secretion of acid juice may be obtained by stimulation of the vagus nerve or in the isolated fundic sac when the stomach is entirely empty. Nor does the hypothesis help us to understand at all the part taken by the secretory cells. We must, in fact, confine ourselves at present to the general statement that the chlorine of the hydrochloric acid is derived ultimately from the chlorides of the blood.

Secretion of the Small Intestines—the Succus Entericus.—Although there is no question that the cells of the small intestine form enzymes which take an active part in the digestion of the food, there is some doubt whether these substances are actually discharged in a liquid secretion upon the inner surface of the intestine. Some mucus is formed and secreted by the epithelial cells, particularly those of the large intestine, but this mucus is not known to have any digestive action of a chemical nature. To ascertain whether a liquid secretion other than the mucus is formed in the small intestine, recourse has been had usually to experiments with a Thiry-Vella fistula. In this operation a loop of the intestines is isolated and the two ends are sutured into the skin of the abdominal wall, giving thus a portion of the intestine whose contents can be examined without possibility of contamination from the food or from the secretions of the pancreas or liver. Experiments of this kind agree in showing that an alkaline liquid forms in the loops, and indeed more abundantly in loops from the lower than in those from the upper portions of the small intestines. From experiments of this kind Pregl estimates that as much as three litres may be secreted in twenty-four hours from the entire intestine. The estimate must be received, however, with caution. Most observers agree that this liquid has no digestive action on proteids, but may contain an amylolytic enzyme. Extracts of the walls of the small intestine, on the contrary, give solutions that contain four or possibly five important enzymes. There are, first, the essential group of sugar-splitting enzymes capable of converting the disaccharides to the monosaccharides, namely, maltase which converts maltose to dextrose, invertase which converts cane sugar to dextrose and levulose, and possibly lactase which converts lactose to dextrose and galactose. In addition it has been shown recently by Cohnheim that these extracts contain a powerful proteid-splitting enzyme, erepsin, which splits the peptones and proteoses into simpler crystallizable substances—leucin, tyrosin, arginin, etc. Whether or not these enzymes are actually discharged into the intestines as a liquid secretion, they must be regarded as formed within the substance of the intestinal epithelial cells by a metabolism peculiar to these cells and analogous to the process of secretion in other glands. We must place the intestinal epithelium among the important digestive glands. Quite recently also the intestinal secretion from the upper part of the small intestine at least has been found to contain an enzyme-like substance, enterokinase, which, while it has no digestive action of its own, seems to be able to increase greatly the activity of the enzymes of the pancreatic juice. This effect is particularly marked in regard to the important proteolytic enzyme trypsin. Apparently this latter enzyme is secreted entirely in the form of a zymogen and can have no effect upon the food until it is "activated" by the enterokinase. We owe this important addition to our knowledge of intestinal digestion to Schepowalnikow, working under Pawlow's directions. This work has since been confirmed by several observers, and it is claimed by Delezenne that the enterokinase can be obtained also from leucocytes and lymph glands, and in the small intestine is found most abundantly in the mucous membrane overlying the Peyer's patches.

Secretion of Bile.—As in the case of the other glands many efforts have been made to demonstrate the existence of secretory fibres to the liver controlling the flow of bile. The secretion of bile is continuous, the metabolic processes in the liver cells leading to its formation and discharge are in progress at all times, although the velocity of the flow varies. Experimentally the velocity of the secretion may be increased or decreased, but the variations are so strictly parallel to the concomitant changes in the circulation that a causal connection between the two is rendered most probable. Stimulation of the spinal cord or the splanchnic nerves diminishes the flow of bile in proportion as it causes a diminution in the blood supply. Section of the splanchnics, on the other hand, which causes a dilatation in the blood-vessels of the abdominal viscera, is said to increase the secretion of bile. The usual view, therefore, is that the velocity of secretion of the bile varies with the volume of the blood flow through the liver. This belief seems to imply that the secretory activity of the liver cells as regards the bile is controlled by the composition of the blood. With regard to the excretory products of the bile, the bile pigments, lecithin, and cholesterin, one can understand that the greater the quantity of blood flow through the organ the greater will be the excretion. It is more difficult to comprehend the relationship between the blood flow and the increased secretion of water, salts, and bile acids, and no satisfactory hypothesis has been suggested to explain the relationship.

Curve of the Secretion of Bile.—Owing to the ease with which a biliary fistula may be established in man as well as in the lower animals, our knowledge of the daily curve

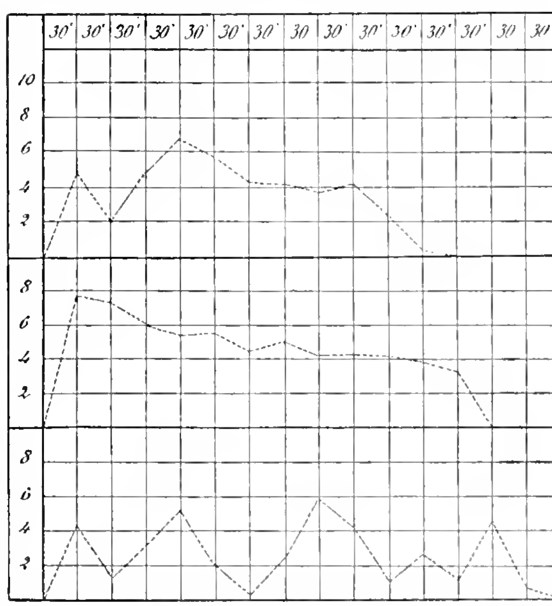

Fig. 4170.—Curves showing the Rapidity of Secretion of Bile into the Duodenum on (1) a diet of milk, upper curve; (2) a diet of meat, middle curve; (3) a diet of bread, lower curve. The divisions on the abscissa represent intervals of thirty minutes; the figures on the ordinates the volume of the secretion in cubic centimetres. (Bruno.)

of the secretion is fairly accurate. In man the quantity secreted varies between 500 and 800 c.c. in the course of a day, or taking into account the weight of the individual the secretion averages from 8 to 16 c.c. per day for each kilogram of body weight. Although the secretion is continuous, it shows a marked acceleration during the period of digestion between the third and the fifth hours after the ingestion of food, that is, during the period of maximal activity in the small intestine. Upon the general theory of secretion stated above, this increase in the secretion should be related to the greater blood flow through the liver at this period, and the altered composition of the blood following absorption of the digested products. Absorption, which is at its maximum during this time, must lead to a greatly increased metabolism in the liver cells, and the augmented secretion of bile is one expression of this increased activity. Although the secretion is continuous, the actual injection of bile into the duodenum through the common bile duct is intermittent in those animals which possess a gall bladder. The secretion in such animals is stored in the gall bladder, and by means of a definite nervous mechanism this reservoir is emptied at intervals during the course of digestion.

Ejection of Bile into the Duodenum.—The mechanism by which the bile is emptied into the intestine does not seem to have been investigated by recent observers. According to Bruno, the ejection through the common bile duct is dependent upon the passage of chyme from the stomach into the intestine, and varies with the character of the food. As long as the stomach is empty no bile is found in the duodenum. The chyme therefore must contain substances which, acting upon the sensory surface of the duodenum, lead to a reflex contraction of the gall bladder. Bruno thinks that the digested proteids (proteoses and peptones) and fats furnish the efficient stimuli. Acids, alkalies, and starches were found to be ineffective. There seem to be no data regarding the frequency of occurrence of these contractions during digestion or the action of stimuli other than the chyme. The nervous mechanism involved in this reflex has been studied by Doyon and by Oddi. It appears from their work that the afferent fibres for the reflex run in the vagi, since stimulation of the central end of a cut vagus causes a reflex contraction of the gall bladder together with an inhibition of the sphincter supposed to exist at the opening of the common bile duct into the duodenum. The efferent path, on the contrary, is through the splanchnics. Stimulation of the peripheral end of a cut splanchnic causes a contraction of the gall bladder and bile ducts.

Modification of the Bile in the Gall Bladder.—It is well known that the so-called mucin of the bile is not formed in the liver cells but from the epithelium of the mucous membrane of the gall bladder and ducts. The chemical nature of the substance seems to vary in different animals; in some cases it is a glyco-proteid of the general nature of the mucin of the salivary glands, but in most cases, according to Hammarsten, it is a form of nucleoproteid. According to Naunyn, the cholesterin of the bile is also added through the epithelium of the bile passages, and does not constitute a portion of the bile as secreted by the liver cells. According to the analyses published, the bile of the gall bladder (bladder bile) contains more solids than that of the hepatic ducts (hepatic bile). As this increase affects the constituents known to be furnished by the liver cells, it may be supposed that the bile undergoes a certain amount of concentration while in the bladder in consequence of the absorption of water.

Cholagogues.—Numerous experiments have been made upon the effect of various drugs upon the secretion of bile. These experiments have shown that substances which cause a destruction of red corpuscles increase the flow of bile. Direct injection of dissolved hæmoglobin into the circulation has the same effect. The increase in the secretion in such cases is said to be transient. The substance that has the most marked and prolonged effect upon the secretion of bile is bile itself. Bile fed to an animal or injected into the circulation accelerates the secretion of bile, and the same effect may be obtained by using solutions of the bile acids alone. Since the so-called bile acids have a distinct hæmolytic action it might be supposed at first that their effect as cholagogues is due to this action on the red corpuscles; but their effect is so much greater than that of other hæmolytic agents that we must believe that they exert a specific stimulating effect upon the liver cells. Many other substances seem to occasion a slight increase in the flow of bile, but no direct cholagogue of importance has been discovered other than the bile salts themselves. Perhaps an exception will be found to this last statement when further investigations are made upon the physiological action of the secretin formed in the duodenum and jejunum. Attention is called to this substance under the head of pancreatic secretion, and there is some indication that it may play a part as a normal chemical stimulus in the secretion of bile. At the present writing no more precise statement can be made.

Secretion of the Kidney.—None of the secretions of the body has been studied with more care than that of the kidney. The especial interest which this secretion possesses for pharmacology and internal medicine as well as for physiology accounts in large part for the attention it has received. In addition it has seemed to offer the best opportunity for testing one of the fundamental questions of secretion, namely, the extent to which the physical processes of filtration, diffusion, and osmosis participate in the act of secretion. Most of the discussion on this point has been along the lines of the two main theories of urinary secretion which have been under discussion now for many years. One theory, proposed first substantially by Bowman and afterward supported vigorously in a modified form by Heidenhain, holds that the water and salts of the urine are actively secreted by the epithelium of the capsule surrounding the glomerulus, while the urea and the other specific organic constituents of the urine are secreted together with some water by the epithelium of the convoluted tubules. The other theory we owe to Ludwig. According to him all the constituents of the urine are formed by filtration through the glomerulus. The two layers of epithelium through which this filtration occurs, the capillary or vascular, and the glomerular epithelium, act simply as a membrane through which the constituents of the urine are filtered off from the blood by the excess of pressure in the blood capillaries. The urine so formed is very dilute, and as it passes along the convoluted tubules it becomes concentrated by absorption. In both theories a difference of function is supposed between the capsule and the convoluted tubule. It will be convenient to discuss the functions of these two parts separately.

Function of the Glomerulus.—The arrangement of the glomerulus and the capsule presents a structure peculiar to the kidney and suggestive of a special purpose. The glomerulus is a knot of capillary vessels which do not form a plexus but rather a rete mirabile with a single afferent and a smaller efferent vessel. For physical reasons the blood in passing through the glomerulus suffers a diminution in velocity, on account of the sudden increase in the width of the stream bed, and yet maintains a high hydrostatic pressure on account of the resistance offered by the narrow efferent vessel and the capillary plexus with which it connects. Moreover, there are no lymph spaces round the glomerulus. The epithelium of the blood capillaries is directly adherent to the epithelium of the capsule into which the glomerulus is inserted, so that the cavity of the capillaries is separated from that of the uriniferous tubules by a double layer of endothelial cells. The arrangement suggests a filtering mechanism, and Ludwig's theory supposes that it acts in this way for all of the constituents of the urine. Bowman's theory supposes that only the water and salts are formed here, and Heidenhain, moreover, has given reasons for believing that the water is not formed by mechanical processes, but by an active secretory process on the part of the glomerular epithelium. If attention is paid only to the water and salts it is evident that if Ludwig's theory is correct the pressure tending to force them through the epithelium may be expressed by the formula $P - p$, in which P represents the pressure in the glomerular capillaries and p the pressure of the urine in the capsular end of the tubule. According to this theory, the amount of urine formed should vary directly with P and inversely with p. It is obvious that the factor P may be increased by raising arterial pressure in the renal arteries or by obstructing the flow in the renal veins, and, according to theory, each change should cause an increased flow of urine. Experiments of this kind have been made. It has been found that raising arterial pressure in the kidney arteries does increase the flow of urine, and vice versa. However, it must be borne in mind that this relationship holds only when the pressure in the glomerular capillaries varies in the same direction as in the renal arteries. All experimental variations which may be safely assumed to raise the pressure in the glomerular capillaries are followed by a greater flow of urine. The reverse experiment, however, of raising P by blocking the venous outflow fails entirely to support the theory. When the renal veins are compressed the capillary pressure in the glomeruli must be increased, and if the veins are blocked entirely, we may suppose that the capillary pressure is raised to the level of that of the renal arteries. In such experiments, however, the flow of urine is diminished instead of being increased, and indeed may be stopped altogether when the veins are completely blocked. The adherents of the Ludwig theory have attempted to explain this unfavorable result by assuming that the swollen interlobular veins press upon and block the uriniferous tubules.

According to the antagonistic theory of Heidenhain, blocking the veins suppresses the secretory activity of the glomerular epithelium by depriving it of oxygen and the chance for removal of CO_2, and thus producing local asphyxia. The latter explanation seems the simpler of the two, and it is very strongly supported by the opposite experiment of clamping the renal artery. When this is done the blood-flow through the kidney ceases and the secretion of urine also stops as would be expected. But when after a few minutes' closure the artery is unclamped the secretion is not restored with the return of the circulation. On the contrary, a long time (as much as an hour or more) may elapse before the secretion begins. This fact is quite in harmony with the Heidenhain theory, since complete removal of their blood supply might well result in a long-continued injury to the delicate epithelial cells. On the mechanical theory, however, we should expect the contrary. Injury to the cells should be followed by greater permeability and an increased filtration, as is found to be the case with the production of lymph. These two experiments, blocking the renal artery and the renal vein, seem at present to discredit the filtration theory and to support the secretion theory. If we accept this latter theory it may be asked how it agrees with the experiments mentioned above upon the variations in capillary pressure brought about otherwise than by obstructing the venous outflow. Heidenhain has emphasized the fact that all of these experiments involve not only a variation in capillary pressure, but also in the blood flow, and that it is open to us to suppose that the effect upon the secretion of urine is dependent upon the rate of flow rather than upon the capillary pressure. If we adopt this explanation we are led again to the secretion hypothesis, since mere rate of flow should not influence filtration, but should affect secretion, since it would alter the composition of the blood flowing through the glomeruli and also the supply of oxygen and carbon dioxide. An important fact, which seems at first sight to show the influence of pressure, is that when general arterial pressure falls below a certain point, about 40 mm. of mercury, the secretion of urine ceases altogether. Such a condition may be brought about by surgical shock, by hemorrhage, or by section of the spinal cord in the cervical or thoracic region. But here again the great vascular dilatation causing this fall of pressure is associated with a feeble circulation, and the effect upon the kidney secretion may well be due to this latter factor.

In addition to varying the factor P in the formula given above, it is possible also to increase the factor p. Normally the pressure of the urine in the capsule must be very low owing to the fact that the secretion drains away as rapidly as it is formed. If the ureter is occluded, however, the pressure of the urine will increase, and the filtration pressure $P - p$ will diminish. When this experiment is performed and the pressure in the ureter is measured by a manometer, it is found to rise to 50 or 60 mm. of mercury and then to remain stationary. This fact might be explained by supposing that when $p = P$ the secretion stops on account of the failure of the filtration pressure. Little weight, however, can be given to this argument, since it is quite possible that under these conditions the urine may still continue to form, but is reabsorbed under the high tension reached. The experiment simply serves to show the secretion pressure of the urine, and the fact that this pressure rises as high as 50 to 60 mm. mercury, while the fact that the capillary pressure is probably somewhat lower would rather serve as an argument against the filtration theory. Exact figures, however, regarding the capillary pressure in the kidney cannot be obtained, so that the experiment on the whole gives us no satisfactory information regarding the theory of secretion. Dreser has used a different argument to prove that the production of the water involves the performance of work on the part of the epithelial cells. He points out that in some conditions, *e.g.*, after drinking beer, the urine may be very dilute, as shown by the fact that its freezing point may be only 0.18° C. or 0.16° C. below that of pure water, that is, $\Delta = -0.18°$ C. or $-0.16°$ C. Since blood serum has $\Delta = -0.56°$ C. the difference in concentration between the blood and the urine in such a case of extreme dilution shows an osmotic pressure in favor of the blood equivalent to $\Delta = -0.4°$ C. Measured in mechanical units this would indicate an osmotic pressure of 49.08 metres of water tending to drive the water from the uriniferous tubules into the blood, whereas the filtration pressure driving the water in the other direction could not at a maximum exceed 2.72 metres of water. Evidently if this argument is just, the elimination of the water takes place against a strong opposing osmotic pressure, and the energy necessary for its secretion can be referred only to the activity of the epithelial cells.

Function of the Convoluted Tubules.—By convoluted tubule is meant that portion of the uriniferous tubule which extends from the capsule to the straight or collecting tubes. Its epithelium varies, but is distinguished in general from the flat, thin epithelium of the capsule by a larger amount of granular protoplasm. According to the Ludwig theory, this portion of the tubule functions as an absorption membrane and serves thus to concentrate the dilute urine filtered through the glomerulus. The fact that the urine is often more concentrated than the blood proves that this absorption, if it occurs, is not due to simple hydro-diffusion, and later adherents of this theory have been obliged to abandon the simple physical theory proposed by Ludwig and to suppose that the absorption effected by these cells is a physiological process dependent upon their living structure and properties. The Bowman-Heidenhain theory, on the contrary, assumes that these cells are secretory in function and serve for the excretion of the urea, uric acid, etc. With regard to the absorption theory it may be said that positive evidence is lacking, and it is difficult to present briefly the facts that are quoted from time to time in its favor. On the other hand, there is much probable evidence that the secretory hypothesis is nearer to the truth. This evidence may be summarized briefly as follows: 1. It is stated that if the ureters are ligated in birds the urates will be found deposited in the uriniferous tubules, but never at the capsular end. 2. Heidenhain has given proof that the convoluted tubules are capable of excreting indigo-carmine after this substance is injected into the blood. His experiment consisted essentially in injecting the material into the blood after dividing the cord so as to reduce the rapidity of secretion. After a certain interval the kidney was removed and irrigated with alcohol to precipitate the indigo-carmine *in situ* in the organ. Microscopic examination showed that after this treatment the granules of the indigo-carmine are found in the convoluted tubules, but not in the capsules round the glomeruli. 3. Several observers (Van der Stricht, Disse, Trambasti, Gurwitsch) have described microscopic appearances in the cells lining the tubules indicative of an active secretion. They picture the formation of vesicles in the cells and appearances which indicate the discharge of these vesicles into the cavity of the tubules. 4. Nussbaum made use of the fact that in the frog the glomeruli are supplied by branches of the renal artery, while the rest of the tubes are supplied by the renal portal vein. He stated that if the renal artery is ligated the glomeruli are deprived completely of blood, and that as a result the flow of urine ceases. If under these conditions urea is injected into the circulation it is excreted together with some water, thus proving the secretory activity of the tubules with regard to urea. Later experiments by Adami and by Beddard have thrown doubt upon this otherwise crucial experiment. Adami claims that ligature of the renal arteries does not shut off completely the glomerular circulation, while Beddard, although he corroborates Nussbaum in the point that complete occlusion of the renal arteries suspends entirely the secretion of urine, finds that under these conditions injection of urea into the circulation is not followed by a secretion. 5. Dreser has shown that the acidity of the urine is due to an action of the epithelium of the tubules. If an acid indicator, such as acid fuchsin, is injected into the dorsal lymph sac of a frog, and an hour or so later the kidneys are examined, it will be found that the convoluted tubules are colored red, while the capsular end is colorless, indicating that the secretion at that point has an alkaline reaction. The experiment shows that the acid phosphate of the urine is produced in the convoluted tubules. The simplest explanation is that it is formed by a secretory activity of the epithelial cells, although one may adopt the less probable view that the cells produce the acid phosphates by a selective absorption of alkaline salts. On the whole it must be admitted that the weight of evidence is in favor of the Bowman-Heidenhain theory of secretion, and it remains for future investigations to explain more definitely what is meant by the obscure term, secretory activity.

Under pathological conditions it has been shown satisfactorily that albumin and sugar which may be present in the urine are secreted or eliminated at the glomerular end of the tubule.

Influence of the Nervous System on the Secretion of Urine.—Although Berkley states that terminal fibrils of the nerves distributed to the kidney may be traced to the epithelial cells of the convoluted tubules, the physiological evidence at present is opposed to the existence of secretory nerve fibres. The kidney receives a rich nervous supply by way of the sympathetic, but experiments indicate that these fibres are vaso-motor in function. Both vaso-constrictor and vaso-dilator fibres have been described, and inasmuch as the secretion of urine varies directly with the rapidity and volume of the blood flow, it follows that these vaso-motor fibres must exercise normally an important regulatory influence upon the amount of secretion.

Action of Diuretics.—An important side of the theories of secretion of urine is their application to the action of diuretics. Water, various soluble substances, such as salts, urea, and dextrose, and certain special drugs, such as caffein or digitalis, exert a diuretic action on the kidneys. Much experimental work has been done to ascertain whether the action of these substances can be explained mechanically by their influence on the blood flow or the blood pressure in the kidney capillaries, or whether it is necessary to fall back upon a specific stimulating effect exerted by them upon the epithelial cells of the tubules. Adherents of the original Ludwig theory are forced to explain their action by the effect they produce upon the pressure in the kidney capillaries, and indeed it has been shown with reference to the saline diuretics that their effect upon the secretion is in proportion to the osmotic pressure they exert. It has been suggested, therefore, that the action of these diuretics lies in the fact that they attract water from the tissues into the blood and thus cause a condition of hydræmic plethora. But whether the elimination of this excess of water is due to filtration or to an active secretion by the glomerular epithelium simply revives the discussion that has been presented briefly above. Most observers find that the vascular changes in the kidney, particularly after the administration of caffein and digitalis, do not explain satisfactorily the phenomenon of diuresis, and although it is necessary to admit that the diuretics, or some of them, act in part by the changes which they cause in the circulation in the kidney, those who adopt the Bowman-Heidenhain theory assume usually that these substances exert also a direct stimulating action on the secretory cells.

Secretion of the Sebaceous Glands.—Practically nothing is known of the mechanism of secretion of these glands beyond the results furnished by histological examination. It is believed that the secretion is formed not by a liquid discharge from the cells, but by the casting off of the cells themselves. The cells upon the basement membrane multiply, and the daughter cells are displaced toward the lumen of the gland. Gradually these latter cells disintegrate, and their débris forms the thick, oily secretion.

Secretion of the Sweat Glands.—The secretion of sweat is important, partly because it helps to regulate the water contents of the body, but mainly because it is an effective means of controlling the body temperature. In accordance with these regulative functions we find that the formation of sweat is governed by the central nervous system, by means of which a reflex adaptation of the process to the needs of the body is made possible. Definite experimental proof of the existence of sweat nerves was obtained first by Goltz. He showed that electrical stimulation of the peripheral end of the divided sciatic in dogs or cats causes the formation of visible drops of sweat on the balls of the feet. This result has since been confirmed for other parts of the body, and it has been shown that the sweat nerve fibres take much the same course anatomically as the vaso-motor fibres. They take origin in the cord or the medulla, pass over to the sympathetic ganglia where they end round the sympathetic nerve cells. Thence their course is continued by a sympathetic neurone, so that they reach their destination probably as non-medullated fibres. Their course for different regions of the body is known with a fair degree of exactness. All the evidence that we have indicates that the sweat glands, like the salivary glands, do not secrete normally except under the influence of these secretory fibres. Ordinary profuse sweating due to a high external temperature must be explained as a reflex act. The high temperature stimulates sensory nerves in the skin, and the impulses thus generated are transmitted to the cord and returned to the sweat glands by the efferent sweat fibres. Attempts have been made to ascertain whether the general activity of these sweat fibres is controlled like that of the vaso-constrictors by a medullary nerve centre. The work done is not conclusive, but it seems to indicate that the reflex centres for the system are found in different regions of the brain and cord. In all probability the nuclei of origin of the sweat fibres for each skin area constitute the sweat centre for that region. These nuclei or centres may be stimulated reflexly by incoming impulses from the skin or from the higher nerve centres, or they may be acted upon by changes in the composition of the blood as is shown by the effect of dyspnœa and certain drugs. Atropin and pilocarpin exert their well-known antagonistic influence in the sweat secretion, the latter causing a flow of sweat and the former inhibiting it. As in the case of other glands, the action of these drugs is supposed to be peripheral, pilocarpin stimulating the endings of the sweat fibres, and atropin paralyzing them. Nicotin also in proper doses suspends the secretion of sweat, and it is probable that this alkaloid acts upon the connection between the spinal or pre-ganglionic neurone and the sympathetic or post-ganglionic neurone.

SECRETION OF THE MAMMARY GLANDS.—The development of these glands in connection with the processes of gestation and their functional activity for a variable period after the act of parturition, are the points of greatest physiological interest. It seems evident that the causal connection between the changes in the uterus and in the mammary gland must be established either through the central nervous system or through the blood. During the development of the fœtus sensory stimuli may be developed in the reproductive organs of the mother which act reflexly upon the mammary gland and stimulate its growth and secretion; or, on the other hand, the changes in the reproductive organs may result in the formation of an internal secretion, which being discharged into the blood, acts upon the tissue of the gland either directly or through the nervous system. The crucial experiment of destroying the nerve supply of the gland in a pregnant animal has given somewhat unsatisfactory results, but it seems to show that the development and functional activity of the gland proceed as under normal conditions, although the quantity of milk produced is less. As far as it goes this evidence indicates that the bond of connection is furnished by the blood rather than by the nervous system, and we may adopt provisionally the hypothesis of an internal secretion. Assuming that this hypothesis is correct, it still remains possible, of course, that the activity of the gland in lactation may be regulated by extrinsic nerves. Many facts speak for this possibility. It is known, for instance, that in women during lactation the flow of milk is influenced by emotional conditions, and, on the other hand, histologists have described nerve terminations round the gland cells which look like secretory nerve fibres. The physiological evidence for secretory fibres is, however, quite meagre. Mironow in experiments upon goats has stated that stimulation of sensory nerves causes a diminution in the secretion, but that when the nervous connections of the gland are destroyed this reflex cannot be obtained. Röhrig finds that section of the inferior branch of the external spermatic increases the secretion, while stimulation of the same nerve causes a diminished secretion. These experiments might be regarded as proving the existence of inhibitory fibres to the gland, but it is equally, or indeed more probable, that the fibres in question are vaso-constrictors. The known influence of the central nervous system on the secretion of milk may therefore consist only in the control of the circulation in the gland by means of vaso motor fibres as in the case of the secretion of urine.

INTERNAL SECRETIONS.

The term internal secretion seems to have been employed first by Claude Bernard, but the essential idea conveyed by it, namely, a secretion discharged into the blood or lymph, had long been entertained in connection with the so-called ductless glands, such as the thyroid. About 1889 the term and the idea implied by it were emphasized by Brown-Séquard in connection with work upon testicular extracts. This author suggested that not only the glands but all tissues may have internal secretions of greater or less importance in the general nutrition of the body. This extension of the original conception was not justified by subsequent experiments and to-day we must limit the use of the term to the distinctly glandular bodies. Experience has shown, however, that not only the ductless glands but some at least of the typical glands with well-defined ducts may produce internal secretions. There is no *a priori* way of determining whether or not a glandular structure produces an internal secretion. The matter must be decided by experiment and observation.

Internal Secretion of the Thyroid Tissues.—Under the term thyroid tissue we may include the thyroid bodies, the accessory thyroids which have a similar, indeed identical structure, and the parathyroids whose structure is peculiar, but whose function seems to be closely related to that of the thyroids. The history of the discovery of the functions of the thyroids, so far as we know them, is most interesting and illustrates admirably how experimental physiology may co-operate with experimental and clinical work in medicine and surgery. The early work indicated that removal of the thyroids is followed quickly by marked symptoms of disturbed metabolism, cachexia, muscular tremors and spasms which soon end in death. Later work has shown that a rapidly fatal result is obtained only when the operation removes all of the thyroid tissues, and that the characteristic symptoms and their duration before a fatal termination depend somewhat upon the species of animal used and its age. In human beings it is known that atrophy or loss of function in the thyroids leads to cretinism and myxœdema, and that these distressing conditions may be removed completely by feeding thyroid tissue to the patient. In the lower animals the precise results of removal of the thyroids proper and of the parathyroids are not yet clearly known. Upon many animals, dogs, cats, rabbits, rats, operations that remove both the thyroids and the parathyroids result in the rapid death of the animal with the symptoms of cachexia and muscular convulsions mentioned above. In the higher mammals (the monkeys, for instance), the symptoms are said to develop more slowly and to resemble more nearly the myxœdema of man. One observer claims that in those animals, such as dogs, in which the fatal result of thyroidectomy is most prompt, a distinction may be made between removal of the thyroids and removal of the parathyroids. Removal of the former causes a slowly developing malnutrition, a progressive cachexia whose fatal termination may be long deferred. Removal of the parathyroids, on the contrary, occasions more acute symptoms including muscular convulsions and a rapidly fatal result. This distinction needs, however, further confirmation before it can be accepted. It is stated also that the fatal outcome of complete thyroidectomy may be deferred or obviated completely by grafting a portion of the gland under the skin. These results upon man and the lower animals are usually explained upon the assumption that the thyroid tissues furnish an internal secretion which plays an important and indeed essential part in the metabolism of the body, particularly perhaps of the nervous system. There is histological evidence to show that the colloid material contained in the vesicles of the glands is emptied into the lymphatics and thence reaches the blood. On the other hand, it has been proved that the beneficial material in extracts of the glands is obtained from this same colloidal material. We may therefore regard this substance as a secretion which is discharged into the blood by way of the lymphatics. Bauman has succeeded in obtaining from the gland a peculiar organic compound containing iodine to the amount of nine per cent. of the dry weight. He designated this substance as iodothyrin and showed that in the gland it exists in combination with proteid. Inasmuch as the iodothyrin, when used upon animals or patients, has much the same beneficial effect as the crude thyroid extract, we must believe that it represents one at least of the essential constituents of the internal secretion. How it or other substances affect normally the metabolism of the body is not yet explained. We know only that complete loss of this substance is followed by a perverted metabolism and finally by death. There is much evidence to show that feeding thyroid extracts to normal individuals leads to an increase in physiological oxidations, hence its use in cases of obesity. This fact is a further indication of the influence of its secretion on normal metabolism, but the means by which it influences the nutrition of the cells cannot be determined without further work.

The Adrenal Bodies.—Brown-Séquard was the first to show that removal of these bodies in dogs is followed by the death of the animal within a day or two. Subsequent observers have confirmed this fundamental fact, and have shown that the symptoms preceding death are great muscular weakness, a loss of vascular tone, and a feeble heart beat. On the clinical side these results agree well with the observation that in Addison's disease, which is accompanied by a lesion of the adrenals, there is also marked asthenia with feeble heart beat and loss pressure seems to be due to a direct action on the musculature of the small arteries and veins, causing a contraction and therefore an increase in peripheral resistance. This effect is only temporary; in a few moments the press-

The time of the injection and the duration are represented by the white space on line *D*; the effect on blood pressure and pulse rate is represented by line *C*; the effect on the contractions of the ventricle and the auricle are represented respectively by lines *A* and *B*; *E* gives the time in half-seconds. (Schaefer.)

of vascular tone. As in the case of the thyroids physiological investigations of recent years tend to show that the adrenals produce an internal secretion of importance in metabolism, particularly the metabolism of the muscular tissues. Extracts of the medulla of the gland injected into the circulation of a normal animal cause a marked slowing and strengthening of the heart beat and a rise of blood pressure. The heart effect, so far at least as the slowing of the beat is concerned, is due to an action of the extract on the inhibitory centre of the vagus, since ure returns to normal, showing that the active substance is quickly neutralized or destroyed within the body. This active substance in the medulla of the glands is normally secreted into the adrenal veins, since blood collected from these veins and injected into a normal animal gives the effects described above. There is some evidence that the secretion of this substance is under the control of secretory nerve fibres. A number of investigators have attempted to isolate the active substance. Abel has succeeded in preparing from the extracts a basic

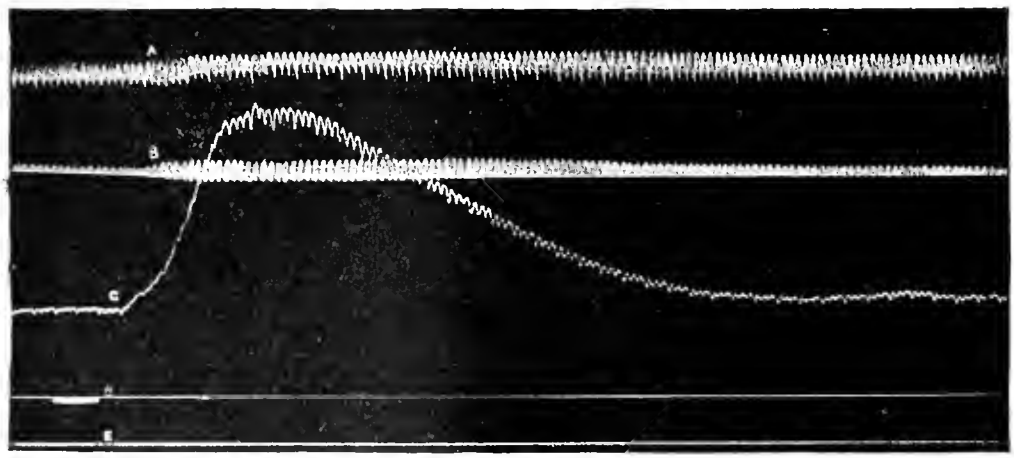

Fig. 4172. Curve to show the Effect of Intravenous Injections of Extract of the Adrenals when both Vagi are Cut. The designation of the curves is the same as in the preceding figure. (Schaefer.)

it disappears on section of these nerves or after the administration of atropin. After section of the vagi injection of the extracts causes a quickening of the heart rate and a great rise of blood pressure. The effect on blood substance to which he gives the name of epinephrin and to which he assigns the formula $C_{10}H_{11}NO_3$. The salts of this substance, when injected even in minute doses, give the characteristic effect upon the heart and blood-vessels. Other crystalline products—adrenalin and suprarenalin—have been prepared from the extracts of the glands and used upon a commercial scale. They show very active physiological properties, but their exact composition and their relations to epinephrin are at present not fully determined. The conclusion commonly drawn from the above facts is that the adrenals secrete continually into the blood a substance that is normally necessary to the proper metabolism of the muscular tissues. When it is completely absent, as in removal or disease of the adrenals, a perverted metabolism ensues, and this expresses itself in a marked loss of muscular tone. The fatal result may possibly be attributed directly to the effect on the circulation, the feeble heart beat, and the loss of vascular tone, giving a condition analogous to that caused by vascular shock. It should be added that some physiologists give a different interpretation to these facts. They hold that the normal function of the adrenals is to produce an antitoxic secretion capable of neutralizing or destroying certain poisonous products of body metabolism, particularly the metabolism of muscular tissue. According to this view the fatal result of removal of the adrenals is due not to the absence of the normal stimulating or regulating action of their secretion, but to the accumulation of toxic products. This theory is designated sometimes as the auto-intoxication theory, but no convincing proof has yet been produced to show that in animals deprived of their adrenals there is present any toxic substance in the blood or the tissues. Attempts to use adrenal extracts therapeutically in cases of Addison's disease, that is, to substitute injections of the extracts in place of the normal secretion, have given negative or uncertain results. This failure may be due to the fact mentioned above, namely, that the effect of injections is quite transient. According to Battelli, continuous injections of adrenal extracts fail to prolong life to any noticeable extent in animals whose adrenals have been removed experimentally, and Christiani reports that grafts of the adrenals under the skin or in the peritoneal cavity fail to ward off the rapidly fatal results of extirpation. The explanation of this last result, however, seems to lie in the fact that when the organ is grafted the medullary portion undergoes a retrogressive change, although the graft as a whole may seem successful. The marked effect of adrenal extracts in causing vascular constriction has been utilized practically in producing local blanching of vascular membranes in the case of the eye, nose, throat, etc.

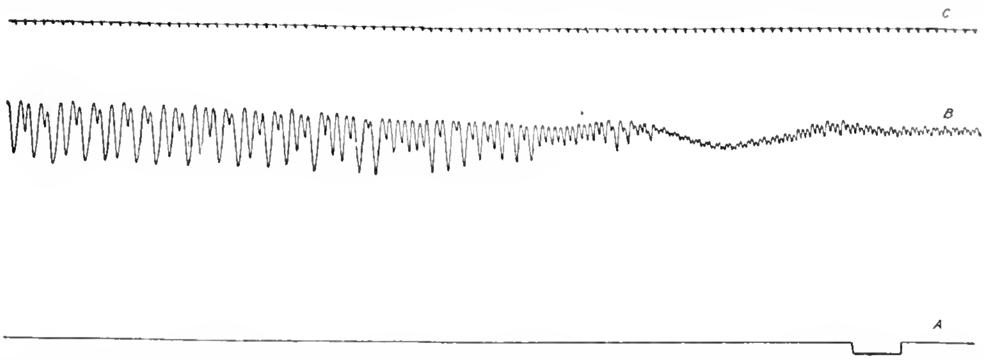

FIG. 4173.—Curve showing the Effect upon Blood Pressure and Heart Beat of an Injection of an Extract of the Infundibular Body when the Vagi are Intact. The point of injection is shown upon line *A*; *B* is the blood-pressure record and *C* the time record in seconds. (Howell.)

The Pituitary Body.—The pituitary body so called consists in reality of two quite distinct structures that possibly have different functions. The anterior lobe or the hypophysis cerebri is a glandular structure that develops in the embryo from the epithelium of the mouth cavity. The posterior lobe or the infundibular body is a mixed structure of nerve cells and glandular cells which develops from the infundibular process of the brain. It is very difficult to experiment upon these structures owing to their position. Vassale and Sacchi state that removal of the entire pituitary body is followed soon by a group of symptoms resembling those caused by thyroidectomy, namely, muscular tremors and

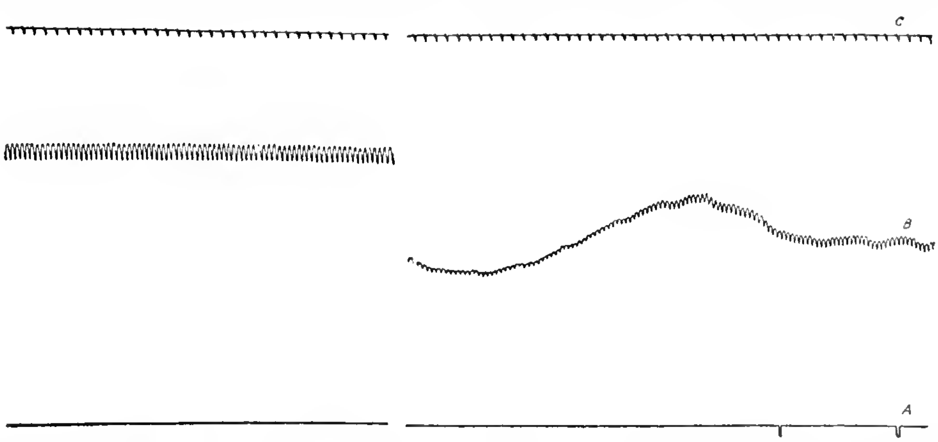

FIG. 4174.—Curve showing the Initial and Final Effect of an Injection of Extract of the Infundibular Body when the Vagi are Cut. The designation of the curves is the same as in the preceding figure. (Howell.)

spasms, apathy and dyspnœa, which soon result in death. It has been suggested, therefore, that the functions of this body may be related to those of the thyroid tissues, but no convincing evidence is at hand to make this view probable. On the clinical side it has been asserted that the peculiar disease known as acromegaly is associated with lesions of the pituitary body, but a causal connection between the two is still very uncertain. Injections of extracts of the body give results that vary with the lobe used. Extracts of the anterior lobe or hypophysis proper give little or no effect when injected into the circulation of a normal animal. Extracts of the infundibular lobe, on the contrary, give a marked effect upon the heart and blood pressure similar in many respects to that caused by extracts of the adrenals. This difference in the effect of the extracts suggests that the two bodies may have different functions in spite of their close anatomical connection. We have no direct evidence that these bodies furnish an internal secretion, but the absence in the adult mammal of a duct would imply that any product formed by them must affect the body by way of the circulation. Cyon, however, contends that the chief function of the pituitary body is to co-operate with the thyroids in regulating the blood flow through the brain. His idea seems to be that the pituitary body fulfils a double function. In the first place it serves as an automatic regulator of intracranial pressure, acting in two ways—mechanically, in that a rise of intracranial pressure stimulates the pituitary body and brings about a slowing and strengthening of the heart beat, and chemically, by secreting substances which act upon the vagus and accelerator centres. In the second place it affects general metabolism also by an action of these last-mentioned substances on the vagi and sympathetic. For the experiments which lead him to this somewhat elaborate theory it will be necessary to consult the original paper, a reference to which is given at the end of this article.

Internal Secretion of the Pancreas.—Few discoveries in physiology have been more interesting and significant than that made by von Mehring and Minkowski regarding the internal secretion of the pancreas. Briefly stated, they found that complete removal of the pancreas brings on a condition of serious glycosuria known now as pancreatic diabetes. Acetone and β-oxybutyric acid are also present in the urine, and, as in the diabetes mellitus of man, the animal shows polyuria and an abnormal thirst and hunger. These symptoms are followed by muscular weakness, emaciation, and in a few weeks by death. If the pancreas is removed incompletely the glycosuria may be serious, or slight and transient, or absent altogether, according to the amount of the gland extirpated. If so little as one fourth or one-fifth of the gland is left in the body the glycosuria may not show itself, and since the portion so left may have no connection with the intestine, this fact as well as others shows that the mere suppression of the pancreatic juice has nothing directly to do with the diabetes that results from complete removal of the gland. In pancreatic diabetes the glycogen disappears from the liver. The blood shows an increase in its sugar contents from 0.15 per cent. to 0.3 or 0.5 per cent., and the urine may continue to contain sugar in quantity when carbohydrate food is withheld completely. On the basis of these and similar results it is believed that the pancreas forms an internal secretion which is given off to the blood. This internal secretion is supposed to play an essential part in the metabolism of the carbohydrates. It has been suggested, for instance, that the internal secretion contains an enzyme of some kind which is necessary for the dissociation or oxidation of the sugar of the body so that in its absence the sugar accumulates in the blood and is lost through the urine. A specific form of this hypothesis has been advanced by Lepine. It has long been known that sugar in the blood disappears on standing, and Lepine has shown that this glycolytic action of the blood is due probably to the presence of a definite enzyme. He assumes that this glycolytic enzyme is formed *intra vitam* from the leucocytes of the blood, but that its formation is a function of the internal secretion of the pancreas. When the internal secretion is prevented the blood loses its glycolytic power, and the sugar escapes oxidation. This hypothesis would seem to demand that in diabetes mellitus the glycolytic power of the blood, when tested out of the body, should be absent or distinctly below the normal. Several observers who have tested this point state, on the contrary, that the glycolytic action of diabetic blood is not less than that of normal blood. Other observers have adopted an entirely different view, holding that the pancreatic secretion normally regulates the output of sugar from the liver and other sugar-producing tissues. In its absence this output is increased and raises the sugar percentage in the blood to such an extent as to cause glycosuria. We must admit at present that the way in which the internal secretion of the pancreas affects the sugar consumption of the body is not known satisfactorily, although there is no doubt that in some way it is absolutely necessary in the process. Considerable experimental and histological evidence has accumulated tending to show that the cells concerned in this important function of the pancreas are not the pancreatic cells proper, but the so-called islands of Langerhans. In man these islands are scattered through the pancreas and form round or oval bodies that may reach a diameter of as much as 1 mm. The cells are polygonal and their protoplasm is pale and finely granular, while the nuclei show a thick chromatin network which stains deeply. In each island there is a capillary network resembling somewhat the glomeruli of the kidney.

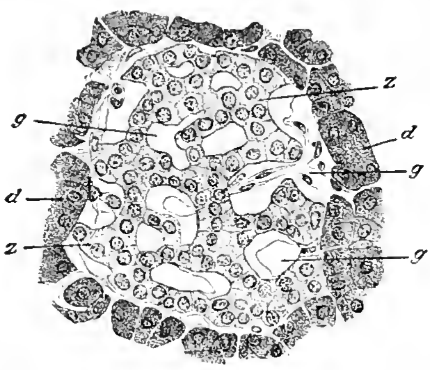

FIG. 4175.—Section Through an Island of Langerhans. *d*, The gland cells of the surrounding pancreatic tissue; *g*, blood capillaries; *z*, the columns of cells composing the island. (Kölliker.)

According to Ssbolew, ligation of the pancreatic duct is followed by a complete atrophy of the pancreatic cells proper, but does not affect to any marked extent the islands of Langerhans. Since under these conditions no glycosuria occurs, while removal of the whole organ including the islands is followed by pancreatic diabetes, the obvious conclusion to be drawn is that it is the removal of the islands that causes the pancreatic diabetes, and that therefore it is these cells that form the normal internal secretion of the pancreas. This conclusion is further corroborated by pathological results upon the lesions of the pancreas in human beings in connection with diabetes mellitus. A number of recent observers (Opie, Ssbolew, Herzog, *et al.*) find that in diabetes mellitus the islands are markedly affected. They show signs either of hyaline degeneration or of atrophy, and indeed may in severe cases be absent altogether.

The Reproductive Glands.—The general interest in the subject of internal secretions in recent years was aroused largely by the work of Brown-Séquard upon the effect of testicular extracts (1889–92). The results of his experiments seemed to indicate that these extracts possess a marked stimulating or dynamogenic action upon the neuro-muscular apparatus. The effect was said to be pronounced not only upon sexual power but upon general muscular and mental vigor. Pohl claims to have obtained from such extracts a definite substance, spermin, to which he assigned the formula $C_5H_{14}N_2$, and which he believes has a general tonic effect upon body metabolism. Similarly Zoth and Pregel report that these extracts increase the power of doing muscular work when measured quantitatively by means of an ergograph. These and other similar experiments give us some reason to believe that the testes may form an internal secretion of importance in regulating and stimulating the metabolisms of the body. If such a secretion is formed, however, its action is not absolutely necessary to normal metabolism as is shown by the fact that castrated animals live in apparently good health. Our natural inference would be that a secretion of this kind might act as a regulator of sexual desire, but it is very uncertain whether such an effect takes place. In the experiments reported the possibility of suggestion playing a part in the results obtained is not excluded entirely, and we must speak therefore of the internal secretion in these glands as a possibility only and not as a demonstrated fact. The evidence is perhaps stronger that an internal secretion is formed by the ovaries. Loewy and Richter have shown that ovariotomy in dogs results eventually in a marked diminution in physiological oxidations as measured by the amount of oxygen consumed. And when an animal is brought into this condition, the administration of ovarian extract is sufficient to bring the consumption of oxygen to its normal figure or to cause an increase beyond normal. Further probable evidence is found in the numerous gynecological cases involving the removal of the ovaries. Quite frequently in such cases disagreeable symptoms ensue, extreme nervousness, vaso-motor flushes, etc., and these results have been sufficiently marked to cause many gynecologists to be cautious in the removal of both ovaries. If one can be left the after-results of the operation seem to be less serious. This general fact, together with the undoubted influence of the ovaries upon menstruation and probably upon lactation, speaks strongly for the existence of an internal secretion; but we lack at present definite scientific proof, such as we have in the case of the thyroids and adrenals. *William H. Howell.*

SEDATIN, para-valeryl-amido-phenetol, para-valeryl-phenetidin, $C_6H_4.OC_2H_5.NH.C_4H_9CO$, is obtained by the action of valeric acid on para-amido-phenetol. It is insoluble in water, sparingly soluble in ether, chloroform, and benzin, and readily soluble in hot alcohol. It is analgesic and antipyretic in dose of 0.2–0.7 gm. (gr. iij.–x.). Sedatin is also an old name for antipyrin. *W. A. Bastedo.*

SEGMENTATION OF THE BODY. Segmentation of the body, or metamerism, is an expression used to convey the idea that the body is composed of a series of segments, also called *metameres*, or *somites*, that are arranged in a series along the principal axis, and in each one of which the principal organs are repeated. Familiar examples of metamerism are furnished by the earthworms and tapeworms. A better example is a typical marine annelid like Polygordius or Nereis, in which each somite, beside the integument, ventral nerve cord, main blood-vessels, and gut, which are continuous through the length of the body, has its own body cavity separated by a partition from its neighbors fore and aft, a pair of limbs (parapodia), a pair of nephridia, a pair of gonads, and several pairs of lateral blood-vessels and nerves, the same arrangement being found in each somite except the terminal ones.

In the vertebrates there is an indication of a similar metamerism. Thus in all vertebrates the vertebræ, the ribs, and the spinal nerves are arranged metamerically, and in the fishes the trunk muscles are divided by transverse tendinous plates into myotomes, which are likewise metamerical in arrangement. This metamerism of the musculature is present to a less degree in the amphibia, but in the higher vertebrates, including man, it has almost disappeared in the adult, as the result, doubtless, of adaptive modifications. But in the embryo metamerism is very evident, even in the highest forms, and has its foundation in the primitive segmentation of the mesoderm, forming the so-called protovertebræ. The divisions of the body being thus outlined at an early stage the spinal nerves, lateral blood-vessels, vertebræ, ribs, and the primitive nephredial tubules are developed in definite relation to them.

The body of a vertebrate may be divided into three main regions—head, trunk (extending from the first cervical vertebra to the anus), and the tail. The segmentation of the trunk and tail is very evident in the embryo, if not in the adult, and the number of segments may be counted. Thus in man there are thirty-seven or thirty-eight originally, of which four or five are caudal segments that disappear during the second month of fœtal life.

The segmentation of the head is not so clear, even in the embryo, and has been a subject for earnest investigation and discussion for a long time. While it is evident that the head is a segmented structure, the actual number of segments and the organs appertaining to each one can be determined only after very minute comparative study of the development of the whole complex of muscles, nerves, ganglia, sense organs, and other structures composing the head, and it is not surprising, therefore, that there should be considerable difference of opinion. Thus Rabl denies that the head contains any segments in front of the ear that can be regarded as homologous with the trunk segments. This opinion is contrary to that of Minot and Hertwig, who regard the whole head as composed of homologous segments. But Hertwig estimates the number as nine, while Minot makes it thirteen.

The segmentation of the body in vertebrates has been held to indicate the descent of this group from the annelids. Comparative anatomy shows, however, that the most primitive known allies of the vertebrates present no likeness to the annelids, but, on the contrary, resemble in some respects the echinoderms, or rather their larvæ; therefore the annelid theory of the origin of the vertebrates seems of very doubtful validity. It is more probable that the metamerism of the body arose independently in the primitive forms of the two groups in adaptation to a similar mode of life.

SEGMENTATION OF THE OVUM.—The segmentation, or cleavage, of the ovum is the first stage in the development of an embryo from an egg. It begins with

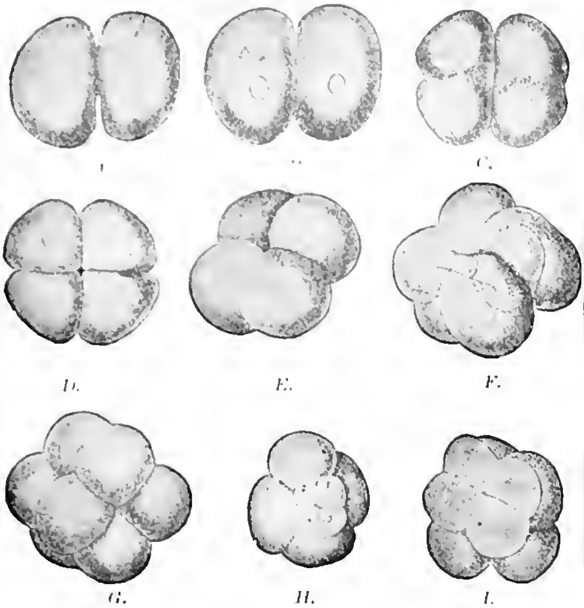

FIG. 4176.—Cleavage of the Egg of an Irregular Sea Urchin, Echinocardium. *A*, First cleavage furrow; *B*, two-cell stage; *C*, beginning of second furrow; *D*, *E*, four-cell stage; *F*, third cleavage, two cells have divided and two are in process of division; *G*, eight-cell stage complete; *H*, sixteen-cell stage, seen from animal pole; *I*, same from vegetative pole. the first cell division after fertilization (or after the last maturation division in case of parthenogenesis, *q. v.*) and ends with the beginning of differentiation of organs (see *Ovum*, *Gastrula*, and *Area embryonalis*).

The course of cleavage differs greatly in different groups of animals. Eggs having comparatively little deuto-

plasm, or yolk, divide completely into two, four, eight, sixteen, . . . etc., cells. The cleavage is then said to be *total*, and the egg is described as *holoblastic*. The cells derived from the division of the ovum are called *blastomeres*. The blastomeres may be very nearly of the same size or some may be much smaller than the others. In the first case the cleavage is said to be *equal*, in the second it is *unequal*. When the blastomeres are not of the same size, the smaller ones are called *micromeres* and the larger ones *macromeres*; and usually they differ in the parts they play in the development of the embryo. Equal cleavage

and molluscs. Unequal cleavage is typical of the annelids, molluscs (Fig. 4180), lampreys, gonoid fishes, and amphibia (Fig. 4179).

Other animals produce eggs that contain a very large proportion of deutoplasm. In such cases only a part of

the egg undergoes segmentation, the rest of the yolk dividing incompletely and being finally absorbed as food by the growing embryo. This form of cleavage is called *partial*, and the egg is described as *meroblastic*.

Meroblastic eggs may be *centrolecithal*, having the yolk chiefly at the centre, or *telolecithal*, having it concentrated toward the vegetative pole (see *Ovum*). Centrolecithal eggs have a *superficial* cleavage, the blastomeres forming a layer of cells, the *blastoderm*, surrounding the unsegmented yolk. This form of cleavage is characteristic of the arthropods. Telolecithal eggs have a *discoidal* cleavage, the blastoderm forming a disc at the animal pole of the egg. This is the form of cleavage to be found in the eggs of cephalopods (Fig. 4181), sharks and rays, bony fishes, reptiles, and birds (Fig. 4182).

The position of the planes of cleavage depends somewhat upon the type of the egg. In centrolecithal eggs the cleavage nucleus takes a position near the centre of the egg previous to division. Then follows a number of nuclear divisions without division of the cytoplasm. The resulting nuclei migrate to the surface of the egg, and the mass of cytoplasm gathered around each nucleus becomes separated from its neighbors by cleavage furrows starting from the exterior.

In alecithal and telolecithal eggs the first two planes of cleavage are always at right angles to one another and cross at the animal pole of the egg (Fig. 4176, *A*, *E*). In the subsequent stages there are developed three types of cleavage—radial, spiral, and bilateral. As examples of the radial type we may take the eggs of sea urchins and of frogs, both holoblastic eggs, the one having equal cleavage, the other unequal. Any one provided with a good microscope can easily observe the cleavage of the eggs of sea urchins or of starfish. The eggs are obtained by cutting up the ovaries of a ripe female. If these are placed in a dish of clean sea water and a small piece of the testis of a ripe male is cut into small pieces and mixed with the eggs, fertilization will take place, and then it requires only a little patient watching of eggs placed from time to time under the microscope for one to observe all

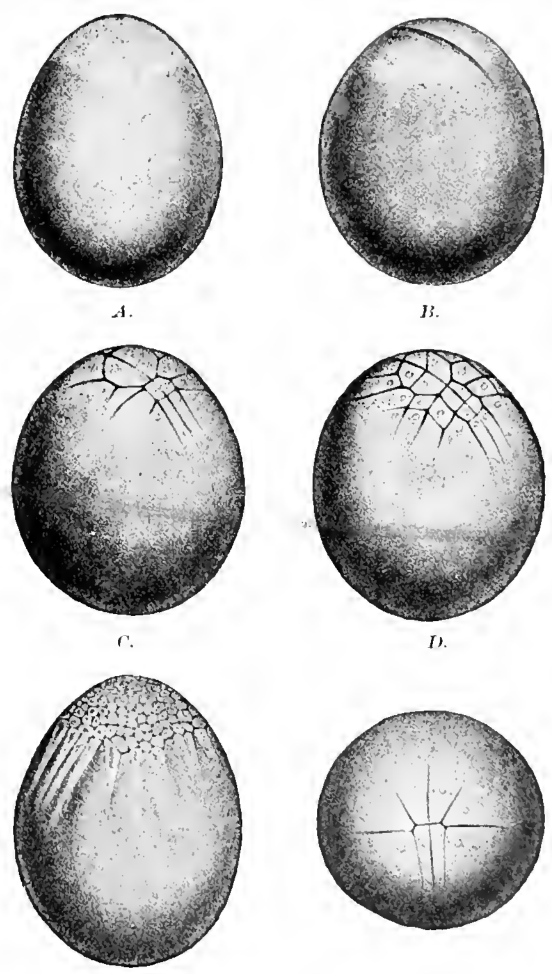

FIG. 4181.—The Discoidal Cleavage of the Egg of a Squid. *A*, Unsegmented egg and polar bodies; *B*, first cleavage furrow; *C, D, E*, later stages; *F*, eight-cell stage viewed from the animal pole and showing the marked bilateral symmetry of the cleavage furrows. × 30. (After Watasé.)

stages up to the formation of the larva. Freshly laid and fertilized frog's eggs may be obtained by careful search of the ponds in early spring. By packing the eggs with ice, development may be delayed until the laboratory is reached. After the eggs have been placed in fresh water at the normal temperature, the cleavage will proceed and may be followed easily with a hand lens or a microscope.

The first indication of cleavage is the appearance of a slight furrow at the animal pole—the position of the polar body in the echinoderm's or the centre of the black half

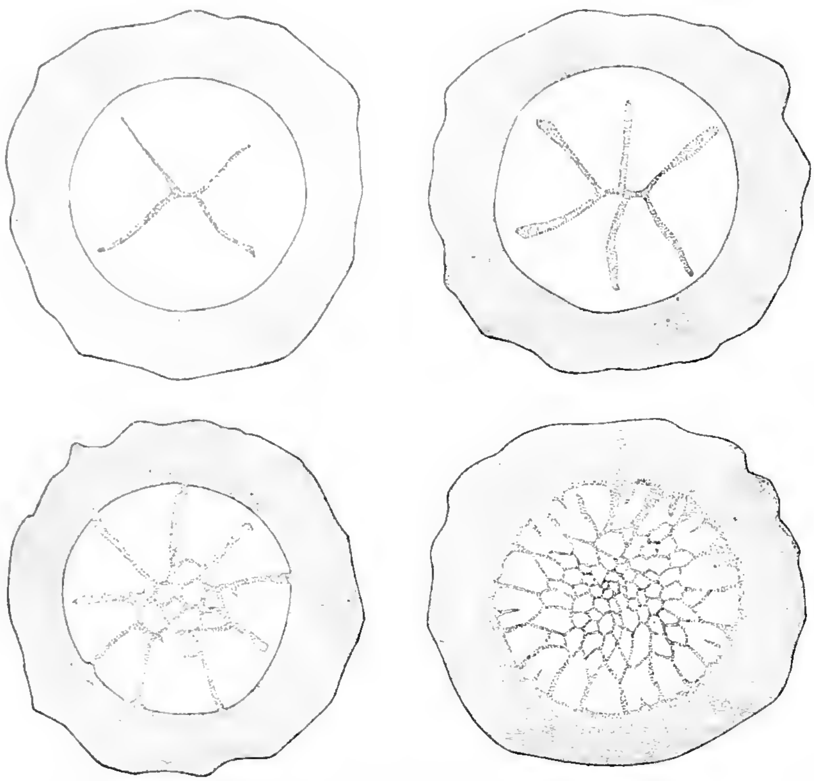

FIG. 4182.—Four Stages of the Segmentation of the Hen's Egg. Only the germinal disc, seen from above, and part of the surrounding yellow yolk are represented. (After Coste.)

in the frog's egg. This occurs in the frog's egg between two and a half and three hours after fertilization. This furrow quickly deepens and extends around the egg to the other side (Fig. 4176, *A* and *B*). Sections of an egg made just before and during this stage show that the nucleus had divided previously by a typical mitosis, and that the plane of cleavage is at right angles to the spindle, so that each blastomere contains one of the daughter nuclei. During the division the blastomeres become more or less rounded. But when it is completed they flatten against one another, so that the line of division becomes indistinct, and the egg rests for a time. At the end of the resting period, about three-quarters of an hour after the appearance of the first furrow in the frog, the blastomeres round up again and the second furrow makes its appearance at right angles to the first at the upper, animal, pole of the egg (Fig. 4176, *C–E*). This furrow extends around the egg like the first, dividing each blastomere into two. The egg is now in the four-cell stage. After another period of rest, the third cleavage furrow appears in a horizontal plane at right angles to both the first and the second. In the echinoderm egg this is very nearly at the equator of the egg, but in the frog it is somewhat above the equator, so that in the eight-cell stage we find four black micromeres and four white macromeres. Compare *F* and *G*, Fig. 4176 with *A*, Fig. 4179. The fourth cleavage in the frog occurs from one-half to three-quarters of an hour later. When this is regular each blastomere is divided into two in a plane at right angles to the preceding one. The planes of division form two great circles bisecting the angles between the first two. But in the frog the eggs are seldom so regular as this and the following cleavages are quite irregular (Fig. 4179).

The spiral form of cleavage is characteristic of the worms and molluscs (Fig. 4180). In these groups the third cleavage plane is not a continuous horizontal circle, but is tilted in each blastomere, to the left usually, looking at the egg from the side. Thus the blastomeres of the two quartets in the eight-cell stage do not lie directly one above the other, but they break joints. The lines of division in the next cleavage are tilted in the opposite direction, and are thus at right angles to the preceding ones. This alternation of spirals may continue for several generations of cells. In these forms the blastomeres are frequently unequal to a marked degree, and the rhythm of cleavage may vary in the blastomeres of different sizes, with the result that there is developed a very complex type of cleavage.

In the bilateral form of cleavage there is but one plane of symmetry, usually coinciding with the first cleavage furrow. The blastomeres are arranged in a bilaterally symmetrical pattern on the two sides of this plane. This form of cleavage is found in both holoblastic and meroblastic eggs, namely, those of tunicates and cephalopods (Fig. 4181).

The cleavage of the hen's egg is not easy to observe, for it takes place before the egg is laid, but it appears to be of an irregular radial type. As in other meroblastic eggs, the earlier cleavage furrows are incomplete, so that the blastomeres are not separated from the undivided yolk. It is only after several radial furrows have formed that concentric ones appear, dividing the blastomeres into a central group of superficially complete ones surrounded

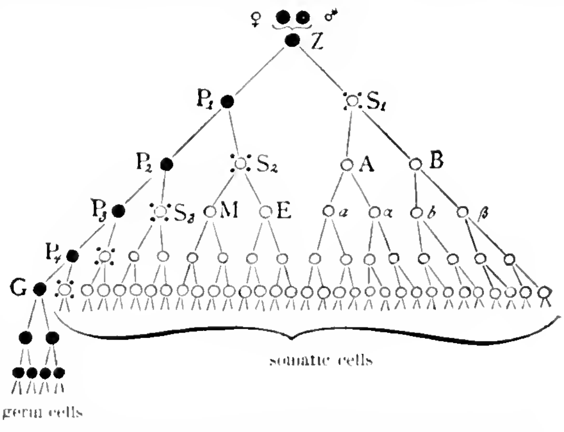

FIG. 4183.—Diagram representing the Determinate Segmentation of the Ovum of Ascaris. *Z*, Fertilized egg; P_1, P_2, etc., protogonocytes; *G*, primordial germ cell (P_5, Fig. 2614, article *Heredity*); S_1, S_2, etc., primary somatic cells; *A* and *B*, primary ectodermal cells; *a*, *b*, daughter cells of the right side; *α*, *β*, of the left side; *E*, primary endodermal cell; *M*, cell which produces mesoderm and part of ectoderm. (Modified from Boveri.)

by a circle of larger blastomeres still connected with the yolk at the surface (Fig. 4182); and it is still later when a horizontal division occurs, separating the central blastomeres from the yolk beneath.

The segmentation of the ovum differs also among the various groups of animals in being either *determinate* or *indeterminate* in character. Typically determinate types of cleavage are found in the eggs of worms (Fig. 4183) and molluscs. In these forms the cleavage is often very complex, and at first glance appears very irregular, but careful study shows that each cell division follows a law that is perfectly definite within the species. Thus the history of each cell may be traced from the first cleavage to the formation of the organs. Conklin, for example, has constructed a remarkable genealogical tree showing the history of each cell in the eggs of Crepidula, the common slipper shell, to the one-hundred-and-nine-cell stage (Fig. 4180), and from the groups of cells present at that stage he was able to observe the development of various important organs.

In the echinoderms and vertebrates, on the other hand, the cleavage soon becomes irregular and no one has succeeded, so far, in tracing the history of the blastomeres. So, for the present, the cleavage of these forms must be regarded as indeterminate. In the frog it has been found that the first cleavage furrow coincides with the principal axis of the body, but this rule is not true for all individuals. So we cannot say that even the first two blastomeres always give rise to certain parts of the body.

SEIGLER'S SPRINGS. — Lake County, California. Hotel.

These springs are located at the foot of Seigler Mountain, at an elevation of 2,372 feet above the sea. They are in the neighborhood of Adams and Bonanza Springs, and lie in Seigler Valley, which is about one mile and a half long by half a mile in width. The surrounding country affords many excellent drives, and magnificent views are encountered on every hand. There are twenty or more springs, which yield approximately three thousand gallons per hour. The "Arsenic" Spring has a temperature of 96° F., and is much used for syphilis, scrofula, and cutaneous disease. The "Soda" Spring is alkaline and carbonated, and forms a delicious drinking-water. It has been much in vogue for Bright's disease, bladder troubles, etc. The "Magnesia" Spring is heavily charged with Epsom salts and carbonic acid gas. A glassful before breakfast insures an easy and painless evacuation of the bowels. The Sulphur Spring is mostly used for bathing and for lung, liver, and rheumatic troubles. There are very good accommodations at the springs.

James K. Crook.

SEMILUNAR GANGLIA, PATHOLOGY OF.—A search through the literature of recent years for the results of work on the pathology of the semilunar ganglia is not very satisfactory. The facts that these organs are such near neighbors of the suprarenal capsules and the pancreas, and that they have such intimate nervous relations, especially with the former, have led to many efforts to establish their pathological association; but these attempts seem to have failed of convincing demonstration, the conclusions reached being largely theoretical. The result is that while the journals contain many articles showing extensive research and experimentation and faithful observation of cases and autopsies, the number of established facts bearing on this subject which can be found in the systematic treatises is small and disappointing.

Romberg was among the earliest to ascribe to the semilunar ganglia definite pathological manifestations. Under the title of NEURALGIA CŒLIACA he describes "a sudden and violent epigastric pain or one preceded by a sense of oppression. It generally extends to the back and there are a sense of fainting, cold extremities, and small intermittent pulse. The region of the stomach is either swelled or sunken and the abdominal parietes are tense. Pulsation at the epigastrium is common. Pressure gives relief. Sympathetic sensations occur often in the thorax, under the sternum, or in the pharyngeal branches of the vagus, but seldom in superficial parts. It lasts for from five minutes to half an hour, and is succeeded by extreme exhaustion. If it breaks off suddenly it is followed by eructations of gas or fluid, by vomiting, gentle perspiration, or copious enuresis. The suppression of accustomed hemorrhages gives rise to it, also it often precedes rheumatism and melæna. Gout predisposes to it, and the development of carcinoma ventriculi is often preceded for years by cœliac neuralgia. The peculiar sense of fainting and annihilation which accompanies it is pathognomonic of this disease, and distinguishes it from such neuralgia of the vagus as is included in the term cardialgia."

Byron Robinson also includes neuralgia cœliaca among the functional disturbances connected with the semilunar ganglia. After remarking that "there may be postmortem findings of lesions of the sympathetic, but these may not have been preceded by records of physical complaints in life, and they may be secondary," he continues:

"Hyperæsthesia or exalted irritability of the sympathetic nerves is liable to manifest pain irregularly, periodically, spasmodically, and yet retain some irritability during the intervals. Anatomically we know little of the characteristic changes in structure in hyperæsthesia. Its etiology also is obscure, although malnutrition is probably a bottom fact. The active hyperæsthesia of the great ganglia of the sympathetic system is characterized by an overpowering sense of prostration, a sense of impending dissolution, as if the centre of life would be destroyed."

These views are quite in line with those of Romberg, and correspond closely with those given by F. A. Hoffmann in discussing the diagnostic significance of subdiaphragmatic pain. He considers radiating pain as characteristic of irritations of the retroperitoneal structures as distinguished from those originating in affections involving the mucous membranes or the parenchyma of organs, the muscular tissue of hollow organs, or the peritoneum. Moreover, he finds that the tendency of pain originating in the aorta, the adrenals, and the solar plexus is to extend downward. He finds that little attention has been paid to a neurosis of this plexus, although it is one comprising very numerous sympathetic filaments, and the neuroses of which must exhibit sensory, motor and vasomotor lesions, suggesting the analogue of migraine.

The characteristic site of the pains which belong to a neurosis of the cœliac plexus is the upper part of the abdomen, and from this point they radiate to the sacral and gluteal regions behind, but not to the genital organs or legs in front. These, with sheeps'-dung fæces and polyuria form a group of symptoms pointing, in the absence of hysteria and tabes, to a diagnosis of a neurosis of the cœliac plexus. He cites three cases in support of his views, two of his own, in which the symptoms mentioned were present, and I would call special attention here to the excessive discharge of urine of low or moderate specific gravity (1.008–1.012) containing neither albumin nor sugar and unaccompanied by great thirst, as one of the pathological features ascribed to the semilunar ganglia.

With reference to the pathological relations said to exist between the semilunar ganglia and the kidneys, as shown in the occurrence of *diabetes insipidus*, the following quotations voice the prevailing opinions: Shapiro says, "that physiologists ascribe an especially weighty influence to the splanchnic nerve in regulating the quantity of urine secreted by the kidneys." He gives the history of a case of diabetes insipidus, the patient having also pulmonary tuberculous disease and becoming greatly emaciated. "The autopsy showed no interstitial inflammation, nor amyloid degeneration of the kidneys, nor pathological changes in the brain or spinal cord, by which the polyuria could be explained, but the microscope revealed noticeable changes in the peripheral nervous elements of the kidneys. The cœliac plexus seemed to be surrounded by a bundle of small lymph glands. The most interesting changes were found on microscopic examination of the cœliac ganglion. There seemed to be thick bundles of connective tissue crossed with many granules. On section, there were seen many enlarged and developed vessels in the neighborhood of which the ganglion cells were distinctly diminished, shrunken, and separated from the capsule. All the cells showed a marked mass of granular pigment. There was also pigment accumulation in the interstitial connective tissue; also fatty degeneration of the axis cylinder of the splanchnic nerve." In this connection it is well to recall the anatomical relations of these nerves and ganglia, viz., that the upper part of each semilunar ganglion is joined by the greater and lesser splanchnic nerves, filaments from them going to the renal plexus and suprarenal gland; also to the inner side of each semilunar ganglion the branches of the solar plexus are connected. The cœliac plexus is a direct continuation of the solar plexus (Gray's "Anatomy"). Futcher quotes from Ralfe as follows: "The sympathetic plays the most important rôle among the peripheral nerves in the etiology of diabetes insipidus. . . . The nerves forming the renal plexus are derived chiefly from the solar plexus. As the right vagus and greater and lesser splanchnics join the solar plexus, it is probable that branches of these nerves enter the kidney by way of the renal plexus. Dickinson reported a case of diabetes insipidus in a patient with *carcinoma of the liver and involvement of the solar plexus;* carcinomatous metastases were found in the retroperitoneal glands which involved branches of the solar plexus. There was marked hyperæmia of the kidneys. . . . Ralfe also refers to tumors pressing on the thoracic and abdominal nerve ganglia, which probably agree in disturbing the vaso-motor governance of the renal vessels."

Pigmentation of the skin, notably that observed as a feature of Addison's disease, has also been ascribed pathologically to the semilunar ganglia. Byron Robinson includes it in his list of the functional disturbances of these organs. Thompson says: "The fact has been confirmed by many observers (Lancereau, Nothnagel, Fleiner, and others) that the pigmentation occurs most prominently in those cases [of Addison's disease] in which the sympathetic nerves are found diseased." Byron Bramwell quotes two French observers, Alezais and Arnaud, as concluding that the essential cause of the pigmentation and other characteristic symptoms of Addison's disease is implication of the pericapsular nervous ganglia, which they describe, by a tuberculous process extending from the adrenals. Marchand, on the other hand, reports *in extenso* a case of disease involving the sympathetic nerves, the suprarenal capsules, and the peripheral nerves, without any bronzing of the skin. Fleiner also reports cases of bronzing of the skin in which there was found no disease of the adrenals, although the cases were ranked as Addison's disease. In fact, until very lately among German writers the pigmentation seems to have been generally regarded as a regular feature of the disease, and the name "bronze Haut" used for it. T. H. Green, however, says that "the cause of the pigmentation in Addison's disease is not satisfactorily explained. Irritation of the abdominal sympathetic is believed to cause increased pigmentation, and the pigmentation in Addison's disease is merely an exaggeration of the normal."

The trend of opinion most recently, however, appears to be that the pigmentation does not belong to Addison's disease as an essential feature, though it may often be noted in connection with it, very probably because of irritation of the sympathetic plexuses and ganglia in the vicinity of the adrenals, which are so often involved in the morbid processes associated with that disease. Neusser says that the formation of pigment in man is controlled by the vaso-motor nerves; in other words, by the sympathetic system acting through the medium of chromatophore cells. Every case of "bronzed skin" does not justify the diagnosis of Addison's disease. Pigmentation is due to a disturbance of innervation in the sympathetic tract.

The pathology of *Addison's disease* has been held to be closely related to the semilunar ganglia since the earliest commentaries were written on the group of symptoms to which that name was given. Thomas Addison's original essay on "The Constitutional and Local Effects of Disease of the Suprarenal Capsules" speaks of an abnormal condition of the semilunar ganglia in but one case, in which they were the seat of fatty degeneration. The writer of the introduction to this essay in the New Sydenham Society's edition remarks that Addison merely noted the correlation as cause and effect of the post-mortem findings of diseased capsules with the group of symptoms he had observed during life, for which he had been able to find no satisfactory explanation. He adds that "true Addison's disease has essential peculiarities of its own, and those not belonging to tuberculous or cancerous capsules." Rolleston quotes Habershon as the first to show that as a result of inflammation spreading from the suprarenal bodies the semilunar ganglia and their branches may become surrounded by dense fibrous tissue. Subsequently to this, and based to a greater or less extent upon the fact noted by Habershon, arose many theories of the pathological relations supposed to exist between the adrenals and the semilunar ganglia, and to account for the various symptoms grouped under the name of Addison's disease. It will be necessary to refer to the more prominent of these, and to some of the cases cited and the arguments adduced for and against them. One of the chief theories was called the "nervous," and Eulenburg and Guttmann say that it "regards Addison's disease as *depending on an affection of the nervous system, especially of the great abdominal plexuses of the sympathetic.* . . . The ganglion semilunare sends a considerable number of twigs to the suprarenal bodies and these form a close network, which is, as Virchow discovered, richly supplied with ganglia. . . . These observations tend to strengthen the theory that Addison's disease is intimately connected with structural changes in the sympathetic. This is not supported, however, by any very good *physiological* reason. . . . Still, *pathological* anatomy has furnished some support for this theory. . . . The results of the examination of the sympathetic still remain, however, antagonistic to each other, at one time negative, at another positive. But even should the positive evidences accumulate in the future, or if it be shown that the changes in the plexuses of the sympathetic are primary and those of the suprarenal capsules secondary phenomena, the question would still be *how* the symptoms of Addison's disease are caused by such changes, a question toward the solution of which we have not advanced one step." This question had to wait some twenty years for an answer.

I quote from Fleiner some account of the pathological findings in two cases of Addison's disease to show in a measure on what this discussion was based. He says: "The facts have been observed that well-marked cases of 'bronzed skin' have post mortem presented no pathological conditions in the adrenals, and, on the other hand, in spite of pathological findings in the adrenals after death the patients presented no symptom of the disease during life."

Fleiner reports two cases of Addison's disease, one slightly and the other much advanced. In the first case on post-mortem examination, tuberculosis of both adrenals was found and noticeable *enlargement* of the semilunar ganglia. In the second case, there was angiosarcoma of the left adrenal, which constituted a metastasis of an extraperitoneal tumor. Here the semilunar ganglia were *diminished* in size. In both cases microscopical examination showed inflammation as well as degeneration of the medullary nerve fibres, not only in the semilunar ganglia but in the whole upper regions of the sympathetic as well as also in the intervertebral ganglia. He also speaks of the degenerative changes in the splanchnic, the cervical ganglia and portions of the posterior columns of the cord, at the entrance points of the posterior roots and in the peripheral nerves. He then expresses the opinion that the principal groups in the symptom complex known as Addison's disease—viz.: (1) The lesions on the part of the digestive organs; (2) the manifestations on the part of the nervous system; (3) the pigmentation—can be satisfactorily explained by the facts he has brought forward in discussing these cases. As a summary he concludes "that for the reasons he has given he feels warranted in regarding as characteristic of Addison's disease a condition of chronic inflammation, which, advancing from the degenerated adrenals, exhibits its highest degree in the semilunar ganglia of the sympathetic and in the intervertebral ganglia, and is appreciable in slighter degrees in the ganglia of the pectoral sympathetic and in the cervical ganglia, and which is emphasized in connection with the alterations in the connective tissue, especially in an intense atrophy of the ganglion cells and in an extensive degeneration of the medullary nerve filaments in the sympathetic and in the splanchnics."

As opposed to these views we find C. Alexander quoting Kahlden to the effect that the assumption that certain symptoms of Addison's disease are referable to the semilunar ganglia is false, that the cœliac ganglion has nothing to do with Addison's disease. He also calls attention to the fact that in various other diseases the semilunar ganglia are involved in pathological changes, as shown by Hale White. That author made microscopical examination of the cervical sympathetic and semilunar ganglia in thirty-three patients dying from various diseases, such as diabetes, cancer of the bladder, aortic disease, sarcoma of the pelvis and breast, chronic Bright's disease, phthisis, tumor of the brain, diphtheria, anthrax, myxœdema, cerebral hemorrhage, etc. "Of the thirty-three semilunars three came from children, and in all of them the ganglion cells were excellent examples of normal nerve cells, some of them showing processes as distinct as those of the cells of the spinal cord. In six only of the remaining thirty were all the nerve cells normal; all the other ganglia showed more or less degeneration of their cells, which in many sections were reduced to minute masses of non-nucleated granular pigment, free in the middle of the capsule. Often there was a large amount of fibrous tissue. In a few instances the section was crowded with leucocytes, but no cause for this could be made out. . . . We may probably conclude that although the semilunar ganglia in the lower mammals and in young human beings are functionally active, in human adults their nerve cells have degenerated and become functionally inactive, but the nerve fibres always retain their structure and function."

So much of the discussion we are tracing out turned upon the question whether the pathological changes in the semilunar ganglia were primary or secondary to those in the suprarenal capsules that I quote the views of Long Fox as follows. He says: "The sympathetic often gives in its coarser lesions evidence that the influence is not that of the sympathetic on disease, but of disease on the sympathetic and its ganglia, and cites such instances as inflammation of the semilunar ganglia associated with headache, increase of their size in case of a tuberculous suprarenal capsule or of cancer of the stomach. Such secondary lesions may in their turn excite certain reflex phenomena, such as flushing, sweating, faintness, palpitation, diuresis. Also the sympathetic, in its character as a connecting link for function between all organs, and subject to various influences, perhaps emotional, perhaps due to altered conditions of the blood, may modify the functional activity of a ganglion or series of them, leaving them even microscopically unchanged. These effects may be motor, sensory, or vaso motor manifestations."

Ziegler also supports the statements of Fleiner and others as follows: "Inflammation of the *sympathetic ganglia and fibres* induces changes in these structures similar to those produced in the spinal nerves. Thus tuberculous caseation of the suprarenal capsules extending to the surrounding tissue sometimes leads to inflammation and proliferation in the solar plexus and semilunar ganglia, resulting in degeneration of the fibres and ganglion cells of the sympathetic. So, too, tuberculous disease of the bones of the vertebral column is apt to extend to the sympathetic nerves and ganglia."

Bramwell distinctly favors the view that the changes in the semilunar ganglia are secondary. He says: "The nerves which pass in such abundance between the capsules and the semilunar ganglia themselves are in a considerable proportion of cases implicated in these inflammatory changes. On naked eye examination they may be seen to be enlarged, thickened, indurated, and sometimes injected and redder than normal. On microscopic examination appearances clearly indicative of inflammatory induration (increase of connective tissue, infiltration with leucocytes, enlargement and engorgement of the blood-vessels) may be present in the fibrous covering of the nerves; in some cases the proper nervous elements (nerve tubes and ganglion cells) are also inflamed, degenerated, or atrophied. These inflammatory changes in the nerve tubes and semilunar ganglia are probably secondary. Sometimes no pathological alterations have been found in the semilunar ganglia or large nerve trunks forming the solar plexus, even when the adrenals have been completely destroyed, and in other cases the solar plexus has appeared quite normal when the adrenals have been completely atrophied, absent, or replaced by fat."

Thompson's study of Addison's disease leads him to the conclusion that the group of symptoms characteristic of the disease, while all pointing to a common origin in a lesion which excites or irritates the sympathetic nervous system, yet are not necessarily referred to the semilunar ganglion alone, but at times to the stomachic, hepatic, or mesenteric plexuses, including irritation of the diseased suprarenal capsules. In a small proportion of cases the adrenals may even remain normal, while the sympathetic nerves and ganglia are alone diseased.

When opinion had reached about the stage represented by authors as quoted above, certain new conceptions and explanations of facts previously observed were brought forward, notably by Rolleston. Attention had been called by Jaboulay to the occurrence of accessory suprarenal glands sometimes to be found upon the semilunar ganglion and in the midst of the solar plexus, and it had been suggested that their presence might explain the absence of the symptoms of Addison's disease in some cases in which the capsules themselves had been found seriously degenerated. Rolleston says "they are often so small as to be found only when carefully looked for, about the size of a grain of corn attached to the main organ by vascular tags and perhaps due to compensatory hypertrophy when the main organ is in a state of caseous degeneration." He quotes Wilks and Greenhow as believing that the *lesion* is primary in the suprarenal capsules and always of the same nature, while the *symptoms* of the disease are due to the secondary effect on the adjacent sympathetic, the solar plexus, and semilunar ganglia. As to the question of the "nervous theory" he concludes that "it is untenable; it does not explain the numerous cases recorded of typical Addison's disease, in which special attention has been paid to the condition of the semilunar ganglia and adjacent sympathetic, and in which they have been found to be normal, since a continued irritation could not last for any time without setting up inflammatory changes *in situ*."

The following quotation from Rolleston indicates the introduction into the discussion of the relations of the semilunar ganglia with Addison's disease, of a new element. It originates in the greater attention paid during recent years to the study of the ductless glands and the results which follow when their secretions are prevented from fulfilling their exact offices in the economy. Rolleston says: "Obstruction to the efferent vessels of the suprarenal capsules is quite a possible cause of Addison's disease." At this point the following of more recent date from Hektoen will show the growth of new views. He says, "Because Addison's disease occurs without any apparent changes in the adrenals, and because the adrenal changes present often involve the abdominal sympathetic, it was attributed to chronic degenerative and inflammatory changes in the semilunar ganglia and abdominal sympathetic" (Wilkes, Jaccoud, Tizzoni, Semmola). This "nervous theory" quite held the field until recently; but the changes described by some in the nerves are frequent in apparently healthy individuals (Hale White, quoted above), and extensive chronic fibrous inflammation in the vicinity of the adrenals might lead to destruction of the efferent vessels, the sequence of events being comparable to Bonnet's experimental ligature of the veins of the adrenals with fatal effects. Addison's disease may occur without any changes in these nerves."

It has been almost impossible amid all these often conflicting theories to disentangle the pathological relations of the semilunar ganglia to the adrenals from those of these latter bodies to degenerative processes in themselves or to the result of pressure upon their efferent vessels by external agencies. It seems justifiable to express the belief, however, that the semilunar ganglia can no longer be regarded as the sole or chief and efficient causes of Addison's disease. Osler, in fact, in 1896 wrote as follows: "Although the view of disturbed innervation consequent upon the involvement of the abdominal sympathetic meets the case theoretically better than any other and is at present widely held, yet there are signs of a return to the old view of Addison."

Most recently, however, we have in Neusser's article such an elaborate and important review of Addison's disease, with independent and theoretical developments also, as cannot be overlooked, although a few brief extracts must suffice. As far as they concern the special topics treated in this article the following embody some of his conclusions and the reasons for them. He quotes from Brauer the opinion that there is no constant relation between Addison's disease and changes in the sympathetic, but reasons out the relations which he regards as intimate though not quite clear between the adrenals and the cœliac ganglion in this way: "Lesions of the sympathetic system have been observed both in connection with and in the absence of disease of the suprarenal capsules. They may affect, first the sympathetic ganglia in the substance of the suprarenal capsules and the pericapsular ganglia occasionally present, then the nerve fibres running from the suprarenal bodies to the cœliac ganglion, the ganglion itself, and the solar plexus, in addition to the sympathetic tracts extending from this point even as far as the cervical ganglion of the ganglionated cord, and finally the splanchnic nerve. . . . Many of these changes are dependent upon tuberculous disease of the suprarenal bodies and the resulting cicatrization. . . . In every case the symptoms of Addison's disease result from impairment or eventually complete suppression of the functions of these capsules brought about by disease of these capsules themselves or of the nerve tracts controlling their function This impairment of function causes most symptoms."

Although this exposition throws the light of modern physiological research upon the question that has occupied us, still it cannot be considered so complete or simple as to be wholly satisfactory, although it does clear away many of the mists of the last half-century. Neusser's article is most careful, comprehensive, and readable, and has the fullest possible bibliography.

SEMINAL INCONTINENCE. See *Sexual Organs, Male, etc.*

SEMINAL STAINS, MEDICO-LEGAL EXAMINATION OF.—This examination is often of great importance in connection with cases of alleged rape or sodomy. The substances which are usually submitted to the expert to be examined for seminal stains are articles of bedding or of underclothing of the supposed victim, but it often happens that other substances are also to be examined. Seminal fluid, after it has become dried, adheres very tenaciously to any substance with which it was in contact when fresh, so that it sometimes happens that specimens of hair or scrapings from the skin require to be submitted for expert examination. In some cases it is also necessary to examine scrapings from the mucous membrane of the supposed victim taken in some cases during life, and in other cases, where a homicide also has been committed, after death. Therefore it often happens that the stain examined is not a simple but a compound one. This stain may consist of pure dried seminal fluid, or it may be an admixture of seminal fluid with blood, pus, or cells from various mucous membranes, or of all combined.

As a general rule, a dried seminal stain upon white cloth does not cause much change in the general appearance of the cloth. It may be slightly tinged, or in rare instances it may be slightly bloody. Upon unstarched cotton or linen cloth it will generally be noticed, however, that the cloth has a stiffer feel than the same cloth in the neighborhood of the stain, and, if it be held up to the light, it will be seen that the meshes of the cloth are filled up to a greater extent than those in the cloth surrounding the stain. If seminal fluid happens to fall on a non-absorbent surface, such as starched cloth, and heavy woollen fabrics as in cases of certain articles of outer clothing, or upon the skin or hair, and dries, the stain forms a nearly white deposit upon the fabric. This white stain would be very readily perceptible upon dark clothing.

Up to within a few years no chemical test was known which could be applied to a seminal stain, but in 1897 Dr. Florence, of Lyons, proposed a new test applicable to human seminal stains, which he considered to be a positive test for human seminal fluid. According to the experience of the writer, it always does produce a positive reaction with human seminal fluid, whether dried or fresh, but it also gives the same reaction with certain other substances. It is, therefore, like the guaiacum test for blood stains, an extremely valuable preliminary test for seminal stains, because, if a negative result is obtained, we know immediately that the stain in question does not contain dried seminal fluid.

The reagent recommended by Dr. Florence is a solution of iodine in iodide of potassium, made as follows: Pure potassium iodide, 1.65 gm.; iodine (previously washed), 2.54 gm.; distilled water, 30 gm.

The test is performed in the following manner: If the stain is on a non-absorbent surface, so that it forms a layer of more or less thickness, a minute fragment can be scraped off with a penknife and transferred to a microscope slide, treated with a drop of water, and then a minute drop of the reagent brought in contact with the edge of the drop of the water containing the fragment of the dried stain. If the stain contains dried seminal fluid, there will be formed a brownish precipitate, which, when covered with a cover-glass and examined with the microscope, will be seen to consist of numerous minute brown crystals, often arranged in groups, somewhat resembling the so-called hæmin or blood crystals. If the stain is upon a piece of unstarched cotton or linen cloth, the same result is obtained if a minute fibre of the cloth is cut out, treated with water in the same manner as above described, and brought in contact with a small drop of the Florence reagent.

Dr. Florence, in his original article ("Du Sperme et des Taches de Sperme en Médecine Légale," Lyons, 1897), states that he has been unable to obtain this reaction with anything but human seminal fluid. He has not obtained it with the seminal fluid of any animal, nor with any other human secretion except seminal fluid, but the writer has obtained the same crystals by the action of this reagent upon a little extract of partly decomposed suprarenal capsule, and also with a minute quantity of lecithin treated with water. It does not give the reaction with any of the ordinary human secretions, so that this reagent is of exceptional value as a preliminary chemical test for seminal stains.

A seminal stain can, however, be detected with absolutely certainty only by the recognition of the characteristic formed elements of seminal fluid, called spermatozoa, by microscopic examination, and generally it is necessary to use the higher powers of the microscope. These are usually found associated with various cellular elements coming from the seminal passages and prostatic ducts. Spermatozoa are usually recognized by their peculiar tadpole shape, having a peculiar conical-shaped head, and a long tail several times longer than the head. The spermatozoa of different animals vary somewhat in their size, and in the proportion of the head and tail. Human spermatozoa when fresh are about $\frac{1}{500}$ to $\frac{1}{550}$ inch in length, the length of the head being about $\frac{1}{3000}$ inch. If seen upon its side, the head of a spermatozoon appears pear-shaped, the anterior one-third of the head being less dense than the posterior two-thirds, so that if a stained spermatozoon be examined it will be seen that the anterior one-third of the head is colored less deeply than the posterior two-thirds. Spermatozoa may be detected in dried seminal stains for many years after the stain was made. The writer has been able to detect them in a dried stain more than four years old. Roussin has detected them after eighteen years (*Annales d'Hygiène*, 1867, i., 152). Unfortunately, however, after spermatozoa become dried, they are very brittle, and the tail is very liable to be broken off from the head by ordinary manipulation of the cloth or by the manipulation necessary in preparing the stain for microscopic examination. It is for this reason that so few perfect spermatozoa are found in the examination of a dried seminal stain.

For the certain recognition of a seminal stain it is, in the opinion of the writer, necessary to find absolutely perfect spermatozoa with head and tail complete, since many other substances, such as certain spores, might be mistaken for the heads of spermatozoa, and many other substances, such as delicate fibrils from the cloth fibres, might be mistaken for the detached tails. Care should always be taken, therefore, not unnecessarily to handle or rub the stain suspected to be a dried seminal stain before submitting it to the expert for microscopic examination.

The recognition of the spermatozoa is comparatively easy in cases in which the stain is a scaly one upon a non-absorbent surface. In that case it is necessary only to scrape off a little of the scaly stain and transfer to a microscopic slide, treat it with a drop of water or some fluid which does not dry readily, such as dilute glycerin, or a solution of potassium acetate, and allow it to soak for several hours. It can then be gently broken up and stained, if desired, by some of the ordinary stains used in pathological work, covered with a cover-glass, and examined with the microscope. Dr. Florence recommends a concentrated aqueous solution of crocein, but the writer has had very satisfactory results by staining with methyl green or eosin. Usually, however, the spermatozoa can be recognized very satisfactorily if they have not been stained. A microscopic power of seven hundred or seven hundred and fifty diameters should be employed for the microscopic examination, and in some cases it will be found advisable to use an oil-immersion lens for the examination.

If the stain is upon unstarched cotton or linen cloth, the recognition of the spermatozoa is much more difficult, because they are much more liable to become broken by preliminary handling, and also because the spermatozoa apparently cling very tightly to the fibres of the cloth when fresh, and are very liable to become broken when the fibrils of any individual fibre are separated. In order to prepare such a stain for examination, care should be taken to select a point near the centre of the stain, because the spermatozoa are more apt to be present in the centre of the stain than near the edges. Then a few threads may be cut from this portion of the stain, so that the individual fibres do not exceed in length one-sixteenth or one-eighth of an inch. Each thread should then be treated separately upon a glass slide or cover-glass with a small drop of water for at least two hours, care being taken to prevent the evaporation of the water. It would perhaps be better if they could be soaked for from twelve to twenty-four hours without being allowed to become dry. These individual threads, after having been digested for several hours, should be very carefully separated into their individual elements or fibrils by means of very sharp-pointed needles. The preparation can then be stained or not, according to the desire of the examiner, be covered with a cover-glass, sealed with paraffin so as to prevent evaporation, and examined with the microscope.

Moist material, such as scrapings from the mucous membrane of the vagina, for instance, can be treated with a drop of water and examined immediately with the microscope with or without being stained.

Edward S. Wood.

SENEGA, U. S. P. (*Senegæ Radix* B. P.).—The dried root of *Polygala Senega* L. (fam. *Polygalaceæ*). The senega plant is a smooth, perennial herb, its habit well displayed in the accompanying illustration. Flowers small, pinkish-white, in terminal spikes; calyx irregular, of three small green, and two (lateral) large, petaloid sepals, the latter concave and enclosing the corolla; corolla consisting of three partly united petals, of which the lower is concave and ornamented with a crest of papillæ; stamens eight, diadelphous (4 + 4); ovary transversely two-celled; style single. Senega has a wide range in the United States, from Western New England and the Middle and Western States southward. It is now mostly collected in Minnesota and Manitoba. The variety *latifolia* is a larger form with broader leaves.

The plant takes its common name, "Seneca snakeroot," from the Seneca Indians, by whom it is reported to have been used as a remedy for snake bites.

The root is mostly 7 to 15 cm. (3 to 6 in.) long and 4 to 8 mm. ($\frac{1}{6}$ to $\frac{1}{3}$ in.) thick, exclusive of the large, knotty, many-headed crown, occasionally reaching several times this size; tortuous, tapering, and bearing several similar horizontal branches, and few rootlets, and for a variable distance below the crown a more or less sharp keel, vary-

FIG. 4184.—Senega, Root and Stem. One-half natural size. (Baillon.)

ing greatly in prominence, and usually taking a spiral direction, often nearly absent; externally yellow-brown to dark-gray-brown, longitudinally wrinkled; fracture rather tough, but short and sharp, the bark thick, yellow or brownish, of a waxy or resinous, faintly fine-radiate appearance, enclosing a yellowish-white wood, from which a larger or smaller radial segment is usually wanting; odor slight, disagreeable; taste sweetish, then acrid.

Various adulterants of senega have been reported, consisting chiefly of the roots of other species of *Polygala* of the Southern United States, but any other than the genuine root is now scarcely seen in commerce.

CONSTITUENTS.—The important constituents of senega are the two saponin like glucosides *senegin* and *polygalic acid*, from one to two per cent. of the former and about five per cent. of the latter. There are also present from six to nine per cent. of fixed oil, some glucose, resin, gum, and very variable amounts of methyl salicylate and methyl valerianate, which latter give to the drug its characteristic odor. Starch is wanting. Senegin resembles in properties and action the saponin of soap-bark, while polygalic acid resembles quillajic acid, but they are weaker, respectively, than these substances.

ACTION AND USE.—Senega possesses in medium degree the characteristic physiological properties of the saponin-containing group of drugs. In the nares it is sternutatory, in the mouth acrid and somewhat sialagogue. In small doses it is stomachic and laxative; in larger ones emetic or purgative. It is a nauseating yet stimulant expectorant, and this constitutes the basis of its principal use. It has been extensively employed in chronic bronchitis and other diseases accompanied by cough. As an ingredient of cough preparations it has probably its most extensive use, but is much less valued than formerly. As an emmenagogue and diuretic it is obsolete.

The dose of senega is about 1 gm. (gr. xv.). The official preparations are the fluid extract and from it the twenty-per-cent. syrup, which also contains one-half per cent. of ammonia water. The compound syrup of squill contains eight per cent. of fluid extract of senega.

Henry H. Rusby.

SENILITY.—(Latin *senilis*, from *senex*, an old man.) Senility is the condition of body and mind resulting from the sum total of degenerative changes characteristic of old age.

The period of old age has its beginning, from the biological point of view, at the time of cessation or decline of the reproductive function. This occurs suddenly in women at the time of the menopause, while in men there is a gradual decline from about the fortieth year. Some animals have no old age, as is the case with those insects that die from exhaustion or shock immediately after completing their reproductive functions. Other animals, notably man, have a considerable period of old age in their lives, unless they are cut short earlier by accident or disease.

During this period, which has been studied chiefly in man, the body undergoes certain degenerative changes which result in the gradual loss of function in the various organs until, if no other cause intervenes, the individual dies, as we say, of old age.

One of the most characteristic features of senility, as was pointed out by Canstatt (1839), is the fact that it does not appear in all the organs of the body at the same time, but it begins sometimes in one organ, sometimes in another, while the remaining organs of the body continue in a normal condition.

Of the various pathological conditions met with in the aged, it is not easy to determine always which should be regarded as strictly senile and which are more characteristic of the period of maturity. But it seems to be the general opinion that the most important and characteristic of the senile changes are those that occur in the walls of the blood-vessels, especially the arteries; and, according to Demange (1886), the impairment of nutrition thus brought about is responsible for all the other strictly senile conditions. In five hundred carefully made autopsies on old people Demange found in every case evidence of endarteritis. The importance of arteriosclerosis as a cause of lesions of the tissues appears to have been recognized first by Gull and Sutton in 1871. In regard to this disease Osler says: "Longevity is a vascular question, and has been well expressed in the axiom that 'a man is only as old as his arteries.' To a majority of men death comes primarily or secondarily through this portal. The onset of what may be called physiological arteriosclerosis depends, in the first place, upon the quality of arterial tissue (vital rubber) which the individual has inherited, and secondarily upon the amount of wear and tear to which he has subjected it. That the former plays the most important rôle is shown in the cases in which arteriosclerosis sets in early in life in individuals in whom none of the recognized etiological factors can be found. Entire families sometimes show this tendency to early arteriosclerosis, a tendency which cannot be explained in any other way than that in the make-up of the machine bad material was used for the tubing."

As causes of wear and tear of the arteries Osler enumerates: (1) Chronic intoxications, as from alcohol, lead, gout, and syphilis; (2) overeating; (3) overwork of the muscles; and (4) renal disease.

It may be too much to say that senility is always associated with or caused by a diseased condition of the arteries, for, according to Schrötter, the literature contains a number of cases of persons who have lived over a hundred years and whose arteries were found to be normal. Unfortunately, these cases have never been gathered together and discussed collectively. So we know practically nothing of senility from which arteriosclerosis is absent. It is interesting to note that according to the statistics of Eppinger, quoted by Schrötter, the period of maximum frequency of this disease is for men between the ages of sixty and seventy years and for women between seventy and eighty years, thus corresponding fairly well with the period of maximum death rate for aged men and women, respectively. (See *Longevity*.)

Councilman (1891) distinguishes three forms of arteriosclerosis: (1) Nodular arteriosclerosis, (2) senile endarteritis; and (3) diffuse arteriosclerosis. While these forms grade into one another more or less, the third form is regarded by Councilman as a definite disease arising during middle life, and is of little interest in connection with the subject of this article. But the other forms are so characteristic of old age and appear to play so important a part in fixing the natural limit to man's life, that they possess a unique biological as well as medical interest. The histological picture of these conditions is described elsewhere (see article *Blood-Vessels, Pathological Anatomy of*), and we will refer here only very briefly to their causation.

The most generally accepted theory is that of Thoma, set forth in a long series of papers, the last of which appeared in 1898. According to this view, the beginning of the process is a "compensatory endarteritis." Thoma's law, as quoted by Peabody (1891), is that "every slowing of the blood current in the arteries and veins of man which is not completely and at once remedied by a proportionate contraction of the media, leads to a new growth of connective tissue in the intima, which narrows the lumen of the affected vessel and thus restores the normal swiftness of the blood current more or less completely." The first cause, according to Thoma, appears to be the slowing of the blood current, which may be due to a stoppage of the flow beyond or to a decrease of pressure. If the muscular coat is not able to contract sufficiently to restore the normal rapidity of current, the slowing of it in some way stimulates the nerve endings, Pacinian bodies, in the arterial wall, and this sets up a reflex hyperæmia of the vasa vasorum, which in turn results in proliferation of connective tissue and an accompanying proliferation of the vasa vasorum themselves into the media, which normally lacks these vessels. According to Councilman, this explanation is extremely hypothetical and without analogy in pathology.

Henri Martin and Huchard have developed an attractive theory of the etiology of arteriosclerosis, starting with a primary lesion in the vasa vasorum. But, then, the lesion in the vasa vasorum is left to be accounted for, and there is the further difficulty, as pointed out by Schrötter, that arteriosclerosis occurs in arteries that have no vasa vasorum.

Sokoloff (1892) has shown experimentally that it is not a lessening but an increase of blood pressure that causes new formation of connective tissue. And this harmonizes with most of Thoma's results, as, for example, thickening of the intima of the aorta between the ductus arteriosus Botalli and the umbilical arteries of children after birth, and the similar process in the arteries of amputated limbs, in both of which cases there is a sudden rise of blood pressure due to the stoppage of the peripheral circulation. It would simplify Thoma's law if we might make it read somewhat as follows: Whenever the intima is unduly stretched the connective tissue tends to increase, giving rise to a compensatory endarteritis. The stretching may be due to increase of blood pressure or to failure of the media under normal pressure. Such a proliferation of connective tissue under strain has its analogy in the reactions of bony tissue to stresses and strains, and might result from the direct stimulation of the cells without the establishment of a reflex arc.

We are indebted to Seidel (1890) and to Councilman (1891) for convenient reviews of the senile changes in the various organs of the body. It will suffice for the present article to give little more than a list of these phases of senility, and the reader is referred for details to the articles on the special topics indicated.

The nodular form of arteriosclerosis, which is found frequently in autopsies on old persons, is confined to the aorta and large arteries. "We find along the course of the vessel, which is otherwise smooth and of normal calibre, elevated plaques, sometimes translucent and cartilaginous in appearance, sometimes calcified or softened. The growth is entirely within the intima, and the media at the point affected is thin and degenerated" (Councilman). This condition frequently involves the orifices into lateral branches and may descend to the valves of the heart, thus giving rise to serious functional disturbances.

In typical cases of senile endarteritis the aorta and all the larger arteries are converted into almost rigid calcareous tubes with walls thinner than normal. Similar conditions may be found less commonly in the veins and even in the capillaries.

The heart is one of the organs most frequently impaired in old people. In cases of senile endarteritis it is frequently small, the condition of brown atrophy being common. On the other hand, in seven out of fourteen autopsies on such cases Councilman found a small degree of hypertrophy. The coronary arteries may become sclerotic, and this is a potent cause of disease of the heart, the walls of which, according to Seidel, may undergo changes analogous to the atheroma of the larger arteries.

All of the organs concerned in respiration are subject to senile changes. The segments of the sternum become ankylosed, the costal cartilages become ossified, the ribs change somewhat in shape, with the result that there is a loss of mobility and capacity of the chest. The chest muscles also atrophy, adhesions form in the pleuræ, and, owing to atrophy of the alveolar walls, the respiratory surface is decreased, producing senile emphysema.

The digestive tract is also subject to important alterations, especially characterized by the atrophy and degeneration of the glands. The muscular fibres of the stomach and intestine lose their tone and allow of dilatation. In connection with disturbances of the circulation, the liver frequently suffers the lesions resulting from engorgement, atheromatous changes, sclerosis of the connective tissue, and reduction in size of the gland cells.

The kidneys are subject to atrophy and sclerosis, and the renal arteries become atheromatous. The result is a diminution in the secretion, and the consequent retardation in the removal of waste products from the body adds another factor to the unfavorable environment of the component cells of the organism in old age.

In the urogenital system the cessation of the reproductive function is accompanied by loss of weight and volume of the ovaries and testicles, with atrophy of the germinal cells and increase in the connective tissue. According to Seidel, the arteries are atheromatous, but Metchnikov calls attention to the fact that degeneration of the ovarian ova and their replacement by connective tissue begins early in life and is completed before arteriosclerosis sets in. Hypertrophy of the prostate occurs in a large number of old men (according to Seidel, in sixteen to twenty-two per cent.), and atrophy of that organ is also common. The muscular coat of the bladder becomes atonous, due to fatty degeneration of the wall with passive distention. The ureters may also become distended, and their muscular coat may undergo fibrous degeneration. The connection of all these troubles with arteriosclerosis was first demonstrated, according to

Seidel, by the Guyon School in Paris (Lannois, 1885; Arthaud, 1885).

The first change in the skin is the appearance of gray hair. The subcutaneous tissue atrophies, producing wrinkles, and the atrophy extends to the cutis. These changes are accompanied by atheromatous arteries and varicose veins.

Even the apparently stable skeleton suffers extensive alterations in old age. There is in general a tendency toward calcification of the cartilages and ankylosis of the joints and sutures, while the spaces within the bones become enlarged and the compact bone becomes more spongy. But arthritis deformans does not belong in the category of senile alterations, as it appears commonly at an earlier period.

Accompanying these changes, there is more or less atrophy of the muscles, sometimes with fatty infiltration. In the central nervous system there is some loss of weight and volume, often with local areas of degeneration; while the meninges become thickened and adherent. The brain is one of the organs in which the connection between the senile changes and an atheromatous condition of the vessels is most evident.

With the changes in the brain substance there appears a decline of its functions. The reflexes become slower and less intense. The organs of special sense become impaired, and there is a decadence of the intellectual and moral attributes.

Recently Mühlmann (1901) has described a deposition of fatty pigmented granules in nerve cells. This begins in the third or fourth year of life, the granules being at first scattered and later collected in a definite place in the cell. With age the number of cells showing this phenomenon gradually increases, and the amount of the inert, pigmented, fatty material becomes larger in each cell until in old age there is but little protoplasm left, for the cells do not increase in size. Mühlmann regards this as a normal process of senile degeneration, finally ending in death.

There are three principal theories as to the biological significance of senility: (1) Senility is the result of the inherent properties of protoplasm; (2) it is not due to the inherent properties of protoplasm, but has been acquired as a normal process by the multicellular animals and plants for the good of the species; (3) it is a pathological condition resulting from the imperfect adaptation of the organism to its surroundings.

Maupas in France and Minot in this country are among the chief advocates of the first theory. They imagine the organism to receive a store of vital energy at the time of fertilization, and this energy is supposed to be dissipated gradually until, if no accident occurs, the organism dies of old age. As evidence Minot cites the results of his investigations on the growth of guinea-pigs, in which it was shown that the rate of growth diminishes from the time of birth. (See *Growth.*) But it would seem that the facts could be accounted for equally well by the familiar physiological principle that with growth the surface for the absorption of food increases in proportion to the square of the stature, while the tissues to be fed increase as the cube. Thus, other things being equal, the larger the organism the slower would be the rate of growth.

The second theory is Weismann's. According to his view, the protozoa never die of old age. But the higher organisms have been endowed with senility and natural death through natural selection, those species which are composed of the greatest proportion of young uninjured individuals being the best fitted to survive the struggle for existence with other species. This involves the idea that senility is a normal condition like growth or hunger, which is denied by the advocates of the third theory.

Metchnikov (1899) has appeared recently among the latter with a remarkable hypothesis of phagocytosis as a cause of senile degeneration. He calls attention to the fact that the loss of the power of cell multiplication is not universal in old age, as one would expect it to be on the theory of senility being a normal process. On the contrary, the connective-tissue elements show a remarkable capacity for growth. He supposes a struggle for existence to be going on continually in the body, in which the megaphagocytes are on one side and all the remaining cells on the other side. These megaphagocytes attempt to attack and devour everything they touch, whether living or dead. Healthy living cells can resist them, but when a cell is weakened by any cause, for example, bacterial poison, the phagocytes are successful, and, after destroying the weakened cells, they take their place and change into connective-tissue corpuscles. Unfortunately for this hypothesis, however, there is very little observational evidence to support it.

On the other hand, there is abundant evidence of the close relation between senility and a diseased condition of the walls of the blood-vessels, and Thoma's main thesis that this condition arises primarily as an adaptive modification to meet unfavorable conditions of life harmonizes well with the facts. The pathologists are agreed that with the beginning of arteriosclerosis a vicious circle is soon established, resulting in the progressive increase of the various troubles associated with that disease. If this group of pathological conditions does not form the sole feature of senility, it certainly forms the most conspicuous one. And in the absence of any knowledge of the unknown conditions, if there be any, we should expect, on the theory of chances, that these unknown conditions would be of the same general character as the known conditions. Spencer has defined life as "the continuous adjustment of internal relations to external relations," and we may define senility as the progressive result of imperfect adjustment of internal relations to external relations. *Robert Payne Bigelow.*

SENNA, U. S. P., B. P. (*Folia Sennæ*, P. G.).—The dried leaflets of *Cassia acutifolia* Delile (*Alexandria Senna*), or of *Cassia angustifolia* Vahl (*India Senna*); fam. *Leguminosæ*.

In the United States, German, and French pharmacopœias, the general title covers both the principal varieties; in the British, the Alexandrian (*Senna Alexandrina*) and Tinnivelly (*Senna Indica*) sennas are distinguished by name; they are always entirely distinct in the market.

1. *C. acutifolia* Delile is a small shrub about a meter (a yard) high. Its pod is broad, flat, coriaceous, slightly curved, rounded, and oblique at the ends, containing about half a dozen seeds. This species has a wide and unknown range in Central Africa, is abundant in Nubia, Kordofan, Sennaar, etc., and is said to be found in Timbuctoo. The leaflets are gathered twice a year by native tribes and carried to Alexandria, where they are very carefully freed from sticks, stems, stones, and other impurities, and the broken and defective leaves separated, the different portions of leaf, even to the siftings, being marketed separately.

2. *C. angustifolia* Vahl, is also a small shrub, a good deal like the preceding, but it has larger flowers and larger, more numerously paired leaflets. Its pod is narrower and straighter than that of *C. acutifolia*, and contains about eight seeds. It is a native of Arabia, and in the wild state supplies an inferior, carelessly collected variety of senna (Arabian). It is also said to be found

in Somaliland. This is the species cultivated in the south of India (where it is not indigenous) as the source of Tinnivelly senna. The leaves, under cultivation, are increased in size and improved in quality.

Although the Alexandrian variety brings a higher price and is generally held in higher esteem, there seem no good grounds for the idea that it is essentially different in its action from the other.

DESCRIPTION.—*Alexandria senna* consists of leaflets with extremely short, stout petioles, about 2.5 cm. (1 in.) long and 1 cm. (⅖ in.) broad, inequilaterally lanceolate or lance-ovate, acutely cuspidate, entire, subcoriaceous, brittle, pale-green or slightly yellowish- or grayish-green, sparsely and obscurely hairy, more so underneath, the hairs appressed; odor peculiar, tea-like; taste mucilaginous, tea-like, bitterish.

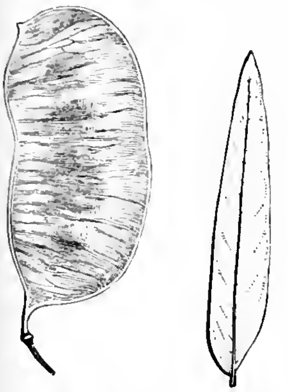

FIG. 4185.—Leaf and Pod of Cassia Angustifolia; about natural size. The leaf is Tinnivelly senna. (Baillon.)

It is frequently contaminated with the one-nerved, thick, wrinkled, glaucous, equilateral Argel leaves.

India senna leaves average nearly twice as long, though but little broader, are more abruptly pointed, usually more yellowish, and the hairiness is even more obscure.

CONSTITUENTS.—As to its active constituents, senna is closely related to rhubarb, cascara sagrada, and some other laxative and cathartic drugs. Like them, its active principles appear to be the anthraquinones emodin, iso-emodin, and chrysophanic acid, all of which have been considered elsewhere, with which exist rhamnetin, a large amount of gum, a little tannin, and ordinary leaf constituents. Cathartic acid, formerly regarded as the active constituent, is apparently a mixed body, and fairly represents the properties of the drug. However, the administration of anything else than the entire drug, or a preparation of it, appears inadvisable.

ACTION AND USE.—This is one of the most satisfactory and generally useful of simple cathartics, usually emptying the bowels thoroughly in ten or twelve hours, with but little depression or other untoward effects, excepting a variable amount of griping; it acts principally upon the small intestine, and the amount of effect produced can generally be pretty accurately regulated, by the dose, from the mildest laxative to a brisk cathartic. It is in universal domestic use, and is the foundation of numerous proprietary laxatives. By combination with salines its activity is considerably augmented; in small doses it does not readily lose its efficiency. It appears to be partially excreted in the milk, when taken by nursing women.

ADMINISTRATION.—A few senna leaves chewed every day are a favorite habitual laxative with many people, who find them to act efficiently, without griping and without producing after-sluggishness of the bowels. One or two dozen leaves usually display some effect. In large doses (6 or 8 gm. [ℨ iss.] or more), as required for thorough action, it is apt to produce colic, unless modified by aromatics or salines. A strong alcoholic extract is inert; a watery extract, made from the residue after exhausting by alcohol, is active and much pleasanter than one made without this previous treatment. Infusion with hot water extracts the active principles and makes a good form for administration, but prolonged boiling destroys it, as do also mineral acids and alkalies. Bitters are said to increase its action.

The official preparations are numerous and good. The Fluid Extract (*Extractum Sennæ Fluidum*, U. S. P.), made with weak alcohol, represents the leaves weight for weight. It is not often given alone, but is eligible for mixture with other medicines. The Compound Infusion, Black Draught (*Infusum Sennæ Compositum*, U. S. P.), consists of: Senna, 6 gm.; manna, 12 gm.; sulphate of magnesium, 12 gm.; fennel, bruised, 2 gm.; boiling water, 800 c.c.

Pour the boiling water upon the senna and fennel, macerate until cold, strain with expression, dissolve in the Epsom salt and manna, again strain, and add enough cold water to make the infusion measure 1,000 c.c. The syrup has a strength of twenty-five per cent. of senna, and contains a little oil of coriander to flavor. The confection contains ten per cent. each of senna and tamarind, sixteen per cent. of cassia fistula, seven per cent. of prune, twelve per cent. of fig, and a little oil of coriander to flavor. It is a blackish extract-like mass of a sweetish taste, and is an appropriate remedy for chronic constipation, being especially useful for children, who take it readily. The compound syrup of sarsaparilla contains 1.5 per cent. of the fluid extract of senna. The compound liquorice powder has already been considered under *Liquorice*.

ALLIED PRODUCTS.—The leaves of a number of other species of the section of *Cassia* to which the official species belong, possess similar properties, though much weaker, and have been at one time or another proposed as substitutes, especially those of *C. obovata* Collad., widely diffused through the tropics of both hemispheres. No others, however, appear in commerce at the present day.

Henry H. Rusby.

SENSATION, DISORDERS OF.—The scope of the present article is the discussion in brief of those abnormalities of sense perception not described under separate headings. General sensibility is the name given to the power of perception possessed by the various body tissues other than those of special sense. It is not, however, homogeneous in kind nor equal in degree, but varies in acuteness, in localizing power, and in other ways. Sensitiveness of the skin and mucous membranes is divided into that to tactile, that to painful, and that to temperature impressions. Muscular sense is an indefinite feeling, by which the weight and size of objects are appreciated or approximated; it is probably composite, the feeling of tension in the muscles being supplemented by tactile impressions from the skin and other tissues. Visceral sensibility has a varying but comparatively slight localizing value. Its appeal is largely to the subconscious psychic stratum; when visceral sensations rise to the level of consciousness, they may consist of visceral pain, local or referred, or be felt as hunger, thirst, fright, nervousness, psychic pain, anger, and so forth. These feelings are more or less indefinite, often not referred to an organ or part of the body, although at times they may be somewhat localized,—as, for instance, hunger and depression as epigastric sensations, thirst as dryness in the mouth and throat.

The general sense of well being on which happiness depends is a form of general sensation known to us mainly by its occasional loss, or rather by a feeling of definite depression, not usually localized, though sometimes felt as a cardiac or epigastric sinking or feeling of heaviness. An allied and in some ways opposite state is nervousness, a much abused term, but one of sufficient importance to deserve careful definition and description.

General sensibility, then, is a function of widely different tissues, much varied in kind, definiteness, and degree. The impact on consciousness due to sensory stimuli may give rise to intellectual or to emotional processes, the first being concepts relating to location, form, size, weight; the latter consisting of either pleasurable or painful feelings.

Disturbances of sensation are classed as anaesthesia,—that is, diminution or loss of sensitiveness, which has been described elsewhere in these volumes; hyperaesthesia,—that is, increased sensitiveness; paraesthesia,—that is, perverted sensitiveness; the different varieties of the latter are usually spoken of as paraesthesiae. Variations in sensitiveness are spoken of as hyperæsthesia or as paræsthesia only when they reach a marked degree and are the result of distinct morbid processes. Normal people vary widely in the acuteness of their perceptive power, both to tactile and to painful impressions; different parts of the body vary widely in sensitiveness, and acuteness of sensibility varies much in any given individual at different times of the day and even more with changing vascularity and varying degrees of heat and cold. Sensation present in consciousness varies almost directly in amount with expectant attention. Even the strongest stimuli may be disregarded and pass unnoticed under excitement or hypnotism.

Although sensation in its restricted sense is a mental impression received from a part of the bodily organism by way of the afferent nerves, and is thus necessarily conscious, the disorders resulting from sensation in the broad sense cannot be so limited. Sensibility is not originally conscious; the earliest and lowest sensory elements subserve the purposes of reflex action; they are evolved from cells capable of motion and possessed of digestive power, and develop their more acute sensory functions gradually. On about the same level are the sensory elements in vaso-motor action. Both these activities are carried on as well without the aid of consciousness, in fact often better, and they are not initiated either volitionally or consciously. Automatic action, as a higher and later manifestation of nerve force than either of the above, is nearer to consciousness. While some automatic acts, especially in the lower animals, are organic and inborn, many of them in man originate in conscious volitional acts and are the result of education.

In order to appreciate the importance of reflex and vaso-motor disturbances from derangement of the sensory mechanism, it is necessary to consider in brief the distribution of the sensory elements in the body. Sensory filaments of some kind are distributed to almost every organ and almost every tissue. Nerve filaments conveying impressions of pain are most abundant and active in the skin and the mucous membranes near the surface. The mucous membranes of the rectum, the tonsils, the stomach, and the intestines may be cut without causing much discomfort to the patient. The same is true of the muscular tissue and the brain. The arteries, on the other hand, are quite sensitive; the peritoneum and other serous surfaces, especially when inflamed, are exquisitely tender.

Tactile sensibility is also much more acute and finely differentiated in the skin and superficial mucous membranes. Touching and wounding the internal organs, the stomach, the bladder, and so on, give only a general idea of the seat of injury. Irritants at the neck of the bladder and in the rectum give the same feelings; pains are not distinguished as between the stomach and pancreas, the liver and gall-bladder, often not even between the appendix and the right kidney. The obvious reason for this fact is to be found in the rarity of opportunities for observing and learning to distinguish between pains in these different organs. How much might be learned if such opportunity existed we do not know. The frequency of referred feelings from visceral irritation, as compared with the rare occurrence of the same phenomena from the skin, points to the low tactile value of visceral sense impressions. Such impressions may be referred from one part of the abdomen to the other, from the teeth to the scalp, and even from the intestinal organs to remote regions of the skin. These referred pains will be described more fully later.

The main use of the sensory elements in the deeper structures is in the determining and controlling of vaso-motor and glandular action and the activity of the unstriped muscles; in other words, in carrying on the vegetative functions of the organism. These may be carried on very well without being brought to consciousness, and often when diseased they may be better performed if removed from consciousness. For instance, the reflex and automatic activity of the bladder is unimpaired in many cases of transverse and other spinal cord lesions, cerebral control alone being lost. The peptic glands probably act largely though not entirely on direct stimulation, but the peristaltic movements of the stomach and automatic control of the pylorus require the intervention of the sensory apparatus, normally apart from consciousness.

The digestive and other visceral functions result in another set of changes which impinge on consciousness only incidentally, but are carried on by the intervention of the sensory system; vaso-motor changes occur in the viscera themselves, and circulatory disturbances often follow in distant organs. It is necessary only to mention as examples the flushing of the face that accompanies the same change in the mucous lining of the stomach on the ingestion of food, the profound vaso-motor changes that often occur at the menstrual period, the faintness amounting to collapse that occurs with many severe abdominal diseases.

In addition to, often in connection with, its activity in reflex, vaso-motor, and automatic acts, the sensory system contributes two elements to consciousness—the one emotional, the other intellectual: the skin and serous membranes furnish almost exclusively intellectual percepts and the single emotion of pain; the viscera and deep mucous membranes furnish almost no intellectual percepts, some pain, and probably all of the emotions.

The emotional results of visceral action are common and familiar. Anger from hunger, irritability from distention of the bladder, depression from constipation, nervousness and motor unrest from thirst are visceral reactions scarcely beyond the bounds of the physiologic.

The emotions are, normally, visceral reactions to psychic stimuli. The psychologic side of the subject has been carefully worked out by William James in his "Psychology." His theory is, in brief, that the psychic cause sets up a physical change in the viscera, and the sensations from these in turn, perceived by the brain, constitute the emotions. For instance, a financial loss or death of a friend causes a change in the heart and vascular system, the stomach, and other viscera. The feeble heart action, loss of appetite, and sense of unrest in the epigastrium are the direct results, not of an emotion following the bad news, but of the news itself. The emotion is the perception of the changed visceral action, and without this the loss would be perceived intellectually but not emotionally. The jaundice of anger, the excitement and accelerated heart action of joy, and the nausea of disgust are similarly explained as the direct result of psychic stimuli, and the emotions are the perception of the altered visceral conditions.

That the physical reaction follows directly on the psychic stimulus is often observed. A man who had never heard a rattlesnake, when walking on the prairie quite quietly, suddenly bounded out of the path, and only a moment after was aware of the rattling noise. In this case the reflex jump and accelerated heart action could have been dependent on no conscious emotion. Similarly men who have run away from battle assert that their legs carry them away before they realize what they are doing. The faster they run the more frightened they become. The contrary attitude of calmness is well known to restore confidence.

James says that when a boy he examined curiously a bucketful of blood at a butchering. He had never heard of fainting at the sight of blood, had no fear or other emotion, and was much surprised when he found himself growing dizzy and fell to the ground. The sight of blood on the next occasion might cause nausea and repugnance from the renewing of the previous experience in memory.

This brief statement of what may be called the visceral theory of the emotions must suffice. To be convincing it should be read *in extenso*. It is necessary to an understanding of the part played in the human economy by the sensory apparatus of both the viscera and the skin.

Increased sensitiveness to stimuli, called hyperæsthesia, is common and is even more important than anæsthesia as an indication of disease. Hyperæsthesia which consists of a heightened power to distinguish variations in temperature or other qualities of objects is rare. Such increase of capability may be regarded as supernormal.

It occurs in some sensitive and gifted individuals, but is usually not the result of disease. On the other hand, a painful reaction to what should be normally felt as touch, pressure, heat, or cold is common as either deep or superficial tenderness. It is one of the most important signs of disease, local or central.

It is important to distinguish between deep and superficial tenderness, as that to deep pressure usually indicates local disease, while tenderness to a light touch with a blunt object like a pinhead, or to pinching up the skin, usually if not invariably in the absence of a superficial and obvious lesion, is tenderness referred from a diseased viscus.

The headache due to brain tumor when associated with scalp soreness, elicited by gently pulling the hair or touching the scalp, is sometimes on the side opposite to the lesion; it has no localizing value, but indicates increased intracranial pressure.

Headaches from visceral disease have been confused with attacks of megrim. The tenderness of megrim, associated with scotomata, hemiopia, and fortification lines,* and sometimes with aphasia, is always to deep pressure. Visceral headaches are not associated with these symptoms; tenderness in them is superficial and confined to areas which depend on the viscera involved and on the tender areas set up by the same disease in other parts of the body.

The headache of hypermetropia comes on at the time of awaking in the morning; it is due to strain from overaction of the ciliary muscle, and is a true visceral pain. It is associated with a superficial area of tenderness over and just above the eyes. The same area, the midorbital, may, however, be tender as the result of disease of the nasal mucous membrane, the stomach, the heart, or the apices of the lungs. Other eye diseases cause pain and tenderness of other regions; glaucoma sets up pain in the temple, which is associated with nausea and vomiting, as are temporal pains from other causes; temporal headache is often associated with gastralgia, and may be due to gastric or thoracic lesions or disease of the bicuspid teeth.

Iritis causes tenderness in the fronto-temporal and maxillary areas. Liver disease causes vertical headache, and ovarian lesions are associated with pain and tenderness in the occipital region, often together with pain over the lower dorsal region of the spine.

The skin of the neck, trunk, and limbs may show hyperæsthetic patches from visceral disease, and there may or may not be with them like patches over the scalp, with headache. They are readily distinguished from the deep tenderness found in affections of the serous membranes, which is always local; for instance, the tenderness due to rheumatic inflammation of the joints, to peritonitis, to meningitis, is found on pressure over the affected structures; the pain of lumbago is similarly elicited; appendicitis sets up local tenderness as well as referred pains in the left side of the abdomen and left lumbar region. Disease of the uterus causes pain referred to the lower part of the back but does not cause headache. Ovarian and rectal diseases may cause pain down the thighs and in the feet, as well as hyperæsthetic areas over the body and head.

The hyperæsthesia of the trunk sometimes seen in tabes dorsalis has the characteristics of the referred variety of pain. The patient, over a greater or less and sometimes a varying area of skin, cannot bear the weight of clothing or the slightest rubbing with a towel. This symptom may persist for years. The lightning pains in the legs are associated with a like soreness, which is, however, much shorter-lived than the trunk anæsthesia, but which corresponds closely in its main features with the headaches referred from disease of the brain, the teeth, and other viscera.

* Gowers (p. 840, second edition) says: "When a luminous spot is the first change and this expands, it may become dim in the centre. Very commonly the outer edge assumes a zigzag shape with prominent and re-entrant angles, like the ground plan of a fortification, and hence called 'fortification spectrum.'" Mills also uses the expression "fortification lines."

The mode of production of referred pains is not known. To suppose them signals from the viscus and apprehended by the receiving stations in the brain as coming from the skin leaves out of account the tenderness, a local phenomenon, as are herpes and sympathetic inflammation. The setting up of such tender spots must be conceived of as a phenomenon analogous to the jaundice, indigestion, suppressed menstrual flow, and local flushings and pallors consequent on psychic shocks and associated with strong emotion. Whatever the explanation, they are important from the therapeutic as well as the diagnostic point of view. The frequency with which so-called osteopathic practitioners find tender spots in the back, and the fact that their removal by treatment usually gives the patient relief in spite of the persistence of organic visceral lesions make the treatment of tender spots, either local or referred, a matter worthy of attention.

The distinguishing marks of local and of referred pains and hyperæsthesia have been given above. A third variety of tenderness is important, viz., that due to inflammation of nerve trunks; such inflammation causes pain along the course of the nerve, with tenderness to deep pressure. This tenderness is due to involvement of the *nervi nervorum* in the nerve sheaths. When the skin supplied by the affected nerve is tender, it is so because the inflammation extends to and involves the terminal filaments and end bulbs. Thus both varieties of tenderness are local, not referred. The pain, however, caused by pressure on sensory nerve fibres anywhere in their course is referred to their terminations in the skin.

Paræsthesiæ are of two kinds: perverted spontaneous feelings other than pain, and perverted transmissions of stimuli to the sensory centres. Of the first of these, itching, ticklings, prickling and burning feelings, numbness, formication, and feelings of heat and cold are common. They may be due to disease in the peripheral nerves, in the cord, in the receiving centres in the brain, or they may be psychic. Of these, the immediate cause will usually be found in the periphery, and any other theory should be accepted with caution and only after careful exclusion of possible change in the nerve endings or small blood-vessels. Vaso-motor changes are prolific sources of paræsthesiæ of various kinds, and are a common accompaniment of central disease. Again, the scleroses, cerebral and spinal, are accompanied not only by vaso-motor and trophic changes, but also by lesions in the peripheral nerve tissues, so that in a large proportion of cases paræsthesiæ occurring in the course of central disease are found due to accompanying peripheral change.

Most of the paræsthesiæ will be found described among the vaso-motor, trophic, and cutaneous disorders. A curious form is the so-called allochiria, or reference of a stimulus to a corresponding spot of skin on the other side of the body. This symptom has been found in some cases of brain tumor, in sclerotic cord lesions, and in hysteria.

Muscular sensibility is the power of feeling in relation with muscular acts. It enables one to appreciate the strength of action of the muscles, the position of the limbs, the extent of objects, and, in the case of the eye muscles, it helps to maintain the equilibrium of the body, and gives information in regard to the size and distance of objects.

Muscular sense is not limited to sensitiveness possessed by the muscles. That the amount of force sent along the motor nerves is directly appreciated or estimated by the sending apparatus is probable, but hardly susceptible of proof. The amount of common sensibility possessed by the muscles themselves is much less than that of the ligaments, tendons, and connective tissues. The impressions conveyed to the brain are the sum of all the sensations set up by strain and pressure in all of these tissues, as well as in the skin, and even in the blood-vessels, their rich sensory nerve supply being affected by pressure of the surrounding parts and the amount of contained blood varied by pressure and change of position.

When an act or series of acts is once carried out as the result of a stimulus, it follows that stimulus the next time with greater ease. Such an impression stored up is a muscle memory. All muscular action not directly reflex is the product of such memories; automatic action is connected with memories which impinge little if at all on consciousness; in fact, much of it is so rapid as to run before consciousness. Volitional acts are dependent on muscle memories combined with or added to memories of sense perception.

The way in which the muscle sense contributes to voluntary acts has been well illustrated by Meynert. A finger is approached to the eye of a new-born child. A memory is stored up of the visual impression on the retina, of the tactile and painful impression when the finger touches the cornea, of the muscular movement which results by reflex. After this has been repeated a number of times, the sight of the approaching finger awakens the memory of the pain and the eye is voluntarily closed by the intervention of muscle memory.

The weight of an object is estimated by comparison of the muscle percept consequent on lifting it, with the muscle memories of other objects similarly lifted. The actions in so testing an object are characteristic.

The position of the limbs is partly gauged by the exertion put forth in maintaining them in that position. The size of objects may be estimated by the position of the grasping hand and fingers, this being made possible by the muscular sense. The amount of eye strain in accommodating and converging for near objects affects one's estimate of their distance and size. As small near objects may subtend the same projection angle on the retina as do large distant ones, it would be impossible to estimate their comparative distance and size if it were not for memories of similar things seen before, with the memories of the effort of the eye muscles in accommodating and converging for them. As distant objects require practically no accommodation and convergence, one's estimate of their size is governed by any opinion which may be formed in regard to the distance and *vice versa*. Very distant objects, like the moon, are apt to be judged in relation with the objects seen at a small angular distance from them—for instance, the objects on the horizon. When the head is moved the eye muscles by their action tend to keep the eyes directed toward the same object. The muscle percepts are in this case changed, and give the impression not of movement of the eyeballs, but of the shifting positions of the head. When body movements are violent, as on a ship or in a swing, muscular sensations may be so acute as to cause nausea and vomiting.

Muscular sensibility is too complex to admit of close localization in the brain. The motor centres and parietal centres for common sensibility are probably the ones chiefly concerned.

Isolated disturbances of muscular sensibility are not so common as would seem likely from the importance of the muscular sense. This is probably due to the fact, just pointed out, that it is complex in action and scattered in various parts of the nervous system. A severe and widespread lesion causes paralysis or general anaesthesia or both, either of which masks the loss of muscular sensibility. Isolated loss of muscle sense usually shows itself in one of two ways: as loss of power to appreciate the position of the limbs, and as astereognosis, or failure to estimate the size, shape, and weight of objects. The former is more marked in the legs and is seen in some cases of locomotor ataxia and multiple sclerosis; the latter is more often found in the arms and is a rare accompaniment of organic brain disease. A curious and rare muscular anaesthesia occurs in the so-called megalopsia and micropsia. These are usually transient symptoms, occurring suddenly in the early stages of tabes dorsalis and other scleroses and in hysteria. Objects seem unusually large or unusually small from a failure of muscular sense in the ocular muscles.

To test the integrity of the muscle sense the limbs should be given various positions, the patient's eyes being closed, and he should be made to guess the degree of their flexion or extension. He should be made to estimate the weight of objects held in the hand; he should name and describe the shape and size of objects held with the eyes closed.

Disorders of visceral sensibility have been less studied and less importance has been attached to them than to those of the skin, probably because of their vagueness and often their slight localizing value. They are, however, from the psychologic and still more from the medical point of view, of much greater importance.

Visceral sensations may be classed, so far as our present knowledge goes, under the heads of local pain; referred pains (already described); more general visceral sensations on the border between pain and emotion, including hunger, thirst, fatigue, sexual desire, nausea, dizziness, and nervousness; emotions, either as direct visceral sensations, or as perceptions of visceral change from psychic causes, including fear, shame, anger, joy, exaltation, and depression or psychic pain.

Local pain in visceral disease is usually dull even when very severe; it is, unlike referred pain, not associated with psychic or emotional change. Tenderness is elicited by deep pressure and may be masked by the referred tenderness of superjacent skin. It may take on varying characters according to its location; when it is abdominal, the patient has a tendency to draw up the knees, with the apparent purpose of diminishing tension in the abdominal cavity.

Hunger is the desire for food, which increases with abstention, but not indefinitely. It is born in large part from the physical state of the stomach, as indicated by the fact of its existence as a dyspeptic symptom. Too free secretion of hydrochloric acid or the presence of an excess of organic acids, either ingested or formed in the stomach by fermentation, may cause craving hunger with consequent over-eating. Spices and alcoholic stimulants have the same effect. The need of the body tissues in general for nourishment causes a feeling of weariness, not of hunger; the appetite is sated before an appreciable amount of ingested food has reached the more distant tissues.

Thirst is a sensation caused by the drying of the tissues. The mucous membranes of the mouth, tongue, and throat are the parts most affected. The feeling may be excited by other irritants.

Hunger and thirst are occasional symptoms of organic brain disease. This fact does not prove the existence of a hunger centre or a thirst centre in the brain any more than running from danger proves the existence of a fear centre. The various mucous membranes have a cortical representation, and excitation of these sensory centres by disease has the same psychic result as that which follows the application of a stimulus to the membranes themselves.

Extreme hunger and, still more, extreme thirst may have an overwhelming effect on the nervous system. Sufferers from thirst in the dry hot air of the desert are maddened by the agony of the drying tissues, and die in delirium within a few hours, practically the victims of shock. Long-continued hunger commonly evokes dreams and hallucinations of banquets.

Fatigue is a toxic symptom. Tired muscles are overcharged with sarcolactic acid, and brain work and other expenditure of nervous energy result in the accumulation of oxidized waste products; in either case the result is a set of sensory signals, consisting of heavy aching pains in the muscles, soreness in the eyeballs, and, in the case of brain fatigue, a tired feeling, not in the brain itself but in the cerebral or cranial blood-vessels, possibly also in the meninges.

Of more interest is the pseudo-fatigue of neurasthenia and of visceral disease. The same tissues are affected by the poisons formed as the result of fatigue and by stomach indigestion and intestinal putrefaction, by defective liver action, and by poisons retained on account of imperfect elimination by diseased kidneys. The result is the same, viz., heaviness in the limbs, aching of the eyes, throbbing and dulness in the head. These may be spontaneous or may ensue on an amount of exertion too slight appreciably to affect a normal person. Such fatigue is spurious and may sometimes be overcome by exercise if the underlying disease is benefited by it.

Great fatigue is the apparent cause of many of the functional and even some organic nervous diseases. Such disorders arise from fatigue in three ways: as the result of the acuteness of the feeling; by the overwhelming of the nervous structures by poisons produced from the overworked tissues; but mainly by the exhaustion of the nerve cells by severe and long-continued action. Of diseases produced in the two last-named ways we are not speaking, but only of those set up by fatigue as a sensation. In the latter sense fatigue is on the same footing with the emotions, and, being ordinarily a weak sensation, it is of not great importance in causing disease.

Of much more import as sensation is sexual desire. It is, even apart from performance, accompanied by vaso-motor changes which, when excessive or perverted, give rise to widespread disturbances of the vascular system. The sexual organs proper are not alone concerned in the sexual act. Desire is influenced by complex considerations in which beauty and even intellectual attractions play a part; the phenomena of blushing, erethism of the lips and breasts, and the mysterious part played by the thyroid gland in sexual life all contribute to involve widely different functions in sensory sexual disorders.

Sexual excitement, especially when accompanied by masturbation about the age of puberty, is likely to be attended with disastrous results. It is not always easy to trace the relationship of cause and effect between sexual excitement and the psychoses. Either may be the cause, or they may intensify each other. They usually coexist with degenerative stigmata. *Dementia præcox*, chorea, habit spasms, exophthalmic goitre, and even epileptiform attacks may follow in the train of sexual excitement in the young apparently as the result of the effect on the sensorium and of the accompanying vasomotor derangement.

Nausea and dizziness are symptoms often associated with each other and with temporal pain. Nausea is not a stomach sensation, but is the sensation or the sensory and motor memory of the act of vomiting, together with that of the flow of saliva and trembling of the lips which precede it. With this there is often the sensation known as dizziness, coming from the semicircular canals, with possibly fulness of the cranial blood-vessels and throbbing in the temples. Some of these phenomena may be absent, according to the cause of the nausea or of the dizziness. Pain in the temples, which so often accompanies nausea, is usually the referred pain of liver or stomach disease, of disease of the cerebrum or cerebellum, or of disease of the eyes or teeth.

One of the most important feelings on the border line between emotion and sensation is nervousness. This term should be dissociated from hysteric and neurasthenic symptoms in general and limited to the pathologic feeling of unrest consequent on physical or psychic stimuli, and leading, or tending to lead, to either purposive or spasmodic movements of the voluntary muscles. The predisposition to nervousness varies much in different people. When not produced by psychic causes it is present in consciousness usually as a distinct feeling from the arms or legs, although it may be occasionally referred to the head, back, or other parts of the body. The lesion may be a local irritant, a suppurating wound, a felon, or compression of a nerve trunk among other alterations, or the abnormal feeling may be referred from a viscus to the limbs or trunk as ordinary pains are referred. This referred nervousness is common and is remarkable at times for its intensity. Patients suffering from an overloaded sigmoid flexure and rectum may suffer torments from nervousness in the legs and feet as do patients suffering from uterine or ovarian disease; intestinal putrefaction sometimes causes a generalized nervous feeling that keeps the patient walking the floor day and night in agony.

Of the causes of nervousness, aside from the predisposition which is always to be reckoned with, it makes little difference whether they are psychic, irritative, or toxic, so far as the symptoms are concerned. Any one of these causes is more effective in the presence of either of the other two, and, as with ordinary pains from whatever cause, the amount of nervousness felt is much modified by diversion and increased by attention. Nervousness is no more under the direct control of the will than is ordinary pain, but like the latter it may be more or less controlled by suggestion or affirmation. While the motor effects of nervousness are in some ways like those of exaltation of acute mania, the underlying emotional content is entirely different, being in the one case disagreeable, in the other pleasant. Nervousness is, in fact, often associated with profound depression, especially when both states of feeling arise from visceral disease.

The sensations which have just been described have an obvious emotional content; they hold a position about midway between feeling and what has been considered pure emotion; they may be set up by purely physical or by purely psychic causes, and there is no peculiarity in the resulting feeling to mark its origin. The fact that impressions of touch and pain may have a purely psychic, and true emotion a purely physical cause, justifies the inclusion of the three kinds of sensation in the one category. The emotions of depression, of exaltation, fear, joy and the like, have the peculiarity in common that they are projected into the psychic environment. The tendency to find an object for a feeling of anger, and to attribute depression to a misfortune great or small, connects these emotions definitely with the realm of thought. That they really consist of the normal individual sensations which come from the viscera but which are not recognized as such, has already been pointed out. This fact puts them among the most important sensory manifestations from the medical point of view.

The study of emotion from visceral disease is attended with certain difficulties. Chief among these is the fact that disease of any one viscus, and even the same disease of a particular organ, so far from always causing the same feeling, may give rise to the most varied play of emotions. Much, however, may be learned by observations of such cases, and reasoning back from psychic symptoms to the disease is often possible even in the absence of definite physical indications.

The lighter grades of emotional change may be called moods. These moods are of frequent occurrence in otherwise normal people, and apparently depend on either autotoxic or meteorologic influences, or both. The referred pains of organic visceral disease are associated with well-defined changes of mood which are coincident in time with a sudden increase in the amount or intensity of the pain. These moods are depression, exaltation, suspicion, irritability, and with them there may be hallucinations of sight, hearing, and smell. The patient assigns no cause for his depression; he has no delusions with his hallucinations; although his suspicions attach themselves to his friends and those about him, they are readily removed by simple denial of their truth. The moods have practically only an emotional content; they come as suddenly as the pains, last for a few minutes or a few hours, and leave equally suddenly. They are, according to Head, singularly little affected by outside circumstances, by cheerful society, music, and so on. Pains below the mid-dorsal segment are likely to be associated with depression; above this, with exaltation.

A more profound and lasting change in the emotional life is wrought by toxins of various kinds. An instance of this kind is the well-known irritability of a masked attack of gout. Depression from auto-intoxication may be so intense as to overshadow all other symptoms. Typical instances are furnished by patients who, following an indiscretion in diet, have a mass of sour material retained in the stomach. They may have with this marked but not intolerable depression, which is promptly relieved on emptying the stomach with a tube or by vomiting. Much more serious is the depression associated with intestinal putrefaction, following acute diarrhœa in patients in whom the poisons have been allowed to accumulate in the intestinal canal, and in putrefaction from other causes. In these patients depression is extreme, often not associated with delusions except possibly the pardonable idea that they are going insane; there may be with the depression a nervousness so great that the patient presents a typical picture of *melancholia agitata*, walking the floor in agony. Such cases are acute. A deficiency of the hydrochloric acid of the gastric juice may cause a mild chronic depression, simple, and easily improved or cured by appropriate treatment.

In all of these cases it is not known where or how the poisons generated in the alimentary tract have their effect. As the emotions are sensations from the viscera, and as the sensory nerve endings of the affected viscera are bathed in the poisons, it is not a remote possibility that their action may be a local one and not due to their being absorbed and in this manner producing an effect on the sensory centre. The prompt action of local remedies, stomach washings, purgation and enemas, favors this view.

The prevailing emotion in consumption is moderate exaltation. This may be heightened by the stimulus of an attack of referred pain, especially that due to disease of the upper pulmonary lobe; disease of the lower lobes is likely to cause referred pain with attacks of depression.

Uterine and ovarian disease is especially prolific of emotions, either simple depression, to which in extreme cases delusions may be added, or exaltation amounting in some cases to mania. The most deceptive forms of these affections are those in which there are no accompanying symptoms, sensory or otherwise, calling the patient's attention to the affected organs. The difficulty is further increased by the fact that digestive disturbances may make their appearance and mask the other symptoms. The difficulty of distinguishing between these cases and cases of insanity with coincident visceral lesions may be considerable, as these patients possess many or all of the symptoms of insanity, and yet it is not very important to make the distinction between the two classes of cases. Organic defects should be remedied, if possible, even in the insane, and in addition it may be fairly doubted whether even in cases of hopeless insanity, organic visceral disease may not often be the determining cause of the mental breakdown.

The pelvic organs sag and pull on their attachments and as a result there are sent out to other parts of the nervous system signals of distress which take not only the form of moods, but of pains in the back and head, vasomotor disturbances, flushing, fainting, palpitation and the like. In the same way sagging abdominal organs set up all these classes of symptoms. In especial a prolapsed kidney is often responsible for attacks of dizziness, headaches, flushings, and faintness which are often attributed to anything but their real cause.

One of the most striking emotional changes from visceral disease is the fear suffered by patients afflicted with angina pectoris. A good deal of anxiety is felt by many patients who suffer from palpitation, over and above what would be warranted by the nature of their complaint. The fear in angina pectoris is inherent and does not proceed from a knowledge of the danger incident to the disease. It is a signal to the brain direct.

Little more has been attempted in the present article than an outline of the subject of sensory disorders, with the idea, especially, of tracing the complex relations which exist between the sensory system of the skin and that of the viscera. Consciousness is not, in this connection, of prime importance. It is a mysterious light that shimmers on a few of the actions and reactions of the nervous system; in considering the part played in disease by the sensory system, it is of especial importance to recognize the fact that sensory phenomena may and often do take place without its intervention.

Henry S. Upson.

SEPTICÆMIA AND PYÆMIA. Historical Memoranda.—A constitutional disturbance accompanying putrefaction in wounds, particularly fractures and injuries of the skull, was described by Hippocrates. In the Middle Ages Ambrose Paré and Paracelsus, both noted metastases following certain injuries in which suppuration occurred. In 1720 Boerhaave first enunciated the doctrine that the condition was due to pus in the blood. His contemporaries, Morgagni and Petit, also tried to prove that metastatic abscesses were brought about by penetration of pus into the blood. In 1774 John Hunter recognized phlebitis as an intermediate factor in producing metastatic abscess, but the exact relation of the two was not clearly defined. In the early part of the nineteenth century (1808–22) Gaspard initiated the experimental method of studying septicæmia by injecting putrefying materials into the veins of animals. Later, the investigations of Virchow, Billroth, O. Weber, Koch, and others formed the basis upon which Gussenbauer built the following definitions: "By *putrid infection or septicæmia* we mean that general disease of the body which results from the introduction into the circulation of the products of decomposition, and which is characterized by definite changes in the blood, a typical succession of inflammatory processes, and a continuous fever together with peculiar nervous symptoms and critical discharges." *Pyæmia* is defined by him as "a general infective disease which arises from the entrance into the blood of the constituents of infected pus, and is distinguished from other septic infective diseases by the development of multiple pus foci in different organs, and an intermittent fever."

Since Gussenbaur formulated these definitions, extensive investigations have been made from both a bacteriological and a pathological standpoint. From the studies of Ogston, Rosenbach, Doyen, von Eiselsberg, and others the conclusion is drawn that the general systemic disease known as septicæmia depends upon the *introduction of pathogenic, especially pyogenic micro-organisms into the general circulation.* Marmorek further limits the definition of septic intoxications, infections (mycoses), and pyæmia to those general systemic diseases caused by the activity of the streptococcus pyogenes and staphylococcus aureus, for, he claims, that these are the only two micro-organisms which can cause all the various phases of septicæmia, from a carbuncle to the most severe pyæmia. He excludes as etiological factors such agents as bacterium coli, pneumococci, etc., which he claims cannot cause furunculosis, lymphangitis, and lymphadenitis. However, this cannot be accepted by the clinician, for not only are his premises and therefore his conclusions incorrect, but in addition there are so many forms of septic intoxication and infection presented to the observer, in which the etiological factor is other than the streptococcus pyogenes and staphylococcus aureus, that it is impossible to limit the disease to those agents alone.

Classification.—Konrad Brunner ("Erfahrungen und Studien über Wundinfektion und Wundbehandlung, III. Theil. Die Begriffe Pyämie und Septhämie im Lichte der bakteriologischen Forschungsergebnisse") classifies the disease from an etiological and symptomatological standpoint. Slightly modified by the present writer, it is as follows:

I. *Septicæmia Not due to Bacterial Activity.*—A general disease brought about through necrotic or putrefactive processes.

II. *Systemic Diseases due to Pyogenic Microbes; Pyæmia, Acute or Chronic.*—General infections in which metastases make their clinical appearance, due generally to staphylo-, strepto-, pneumo-, and gonococci, or to proteus, pyocyaneus, coli, or typhoid bacilli; the fundamental principle being that the signs and symptoms of metastases break in upon the general symptoms.

2. *Ptotoxinæmia, Toxinæmia, Toxæmia.*—A general disease without the clinical signs of metastases, but with the symptoms of a constitutional intoxication, brought about by all kinds of bacteria.

III. *Pyosepticæmia or Septicæmia.*—A general disease in which the products of pyogenic bacterial activity combine with those of decomposition to cause the symptoms. For a fuller discussion of the subject of classification the reader is referred to the above work by Brunner.

Etiology.—So far as the classification is concerned, the bacteria, in all but the first form of the disease, play the chief rôle. There is *no specific micro-organism*, but a whole series of them as etiological factors. The same micro-organism acts differently under different conditions. There are many factors which tend to change or govern the result of their activity. The point of infection, the character of the media into which they penetrate, the personal factor, the microbic association, the varying virulence of the micro-organisms themselves, the lowered vitality of the parts—all these influence the course of the infection.

The *mode of entrance of bacteria* into the system has been the subject of much investigation. In some cases they are, through the medium of a seemingly slight wound, introduced rapidly into the circulation, presumably being taken up by the capillaries. In the great majority of the cases, however, the bacteria first gain access to the lymph spaces and are carried through the lymph channels to the blood. Starting from a localized pus focus the bacterium first has to pass the barrier of *granulation tissue*, which has been thrown up by the tissue as a bulwark against the bacterial invasion. That healthy granulation tissue does act as a successful barrier has been conclusively demonstrated by Noetzel in his experiments on sheep. When these granulations, however, are not sufficiently developed, the micro-organisms pass through them and enter the lymph spaces. By the lymph they are carried to the lymph nodes, which present the next barrier against their invasion. In their course to the nodes varying degrees of *lymphangitis* may be set up. The nodes increase in size and in some way, as yet not definitely known, they retard the growth of the bacteria and in many cases limit their further growth. Dr. Mallory, of the Harvard Medical School, has lately demonstrated that in the periphery of the node there sometimes occurs a proliferation of the endothelial cells lining the trabeculæ which traverse the lymph spaces. These take upon themselves phagocytic properties and enclose not only the bacteria but also leucocytes themselves, which may already have ingested some bacteria and in addition large numbers of red blood cells. In the nodes the pyogenic bacteria often bring about suppurative processes and, destroying these organs, pass on and are emptied into the blood stream. More often the resistance of the nodes is overcome without producing suppuration. Upon reaching the blood the bacteria are again attacked. Through the production of so-called *sozins* and *alexins* (the mode of origin of which is unknown) the growth of the bacteria is again hindered; in fact, these sozins and alexins, aided by the leucocytes acting as phagocytes (Metschnikoff), may destroy the bacteria. Canon believes that the chief difference between septicæmia (pyotoxinæmia) and pyæmia depends upon the phenomena, that in septicæmia the bacteria increase and produce their toxins in the blood, whereas in pyæmia the bacteria are introduced into the blood but do not increase there. Brunner holds that there never occurs any marked growth of bacteria in human blood, and he thinks that this is one reason why bacterial blood tests sometimes fail. An acute mycosis is met with in no human infection. He further holds that the micro-organisms are especially prone to collect in the parenchymatous organs, and in the acute cases they set up metastatic processes, which, however, remain microscopically small, the duration of the disease being too short to develop macroscopic foci or to be clinically evident.

The bacteria carried by the blood may be deposited in the various tissues and organs of the body and there continue their activity and bring about local inflammatory or suppurative processes. They may, on the other hand, be destroyed in the tissues and be excreted. The relation of thrombophlebitis to the blood will be discussed later.

All authors hold that *in the majority of the cases the ordinary pyogenic cocci, i.e., the pyogenic staphylococci and streptococci, alone or associated together, constitute the cause of the disease.*

The streptococci have long been looked upon as liable to bring about more virulent infections than the staphylococci. But no absolute line can be drawn. We may have an acute or a chronic streptococcus infection with or without metastases. The same is true of the staphylococci. However, many other bacteria play an important part, etiologically, in this disease. The *pneumococcus* may cause a metastatic-pyæmia, or a pneumococcus-toxæmia, in which the bacteria are found in the blood. Metastatic foci occur most frequently in the meninges and the joints. The *B. coli communis* generally invades the system from the intestinal tract. Cholecystitis, abscess of the liver, peritonitis are often sequelæ. Cystitis is set up, the bacillus being carried by the lymph vessels or the blood. Meningitis, pneumonia, strumitis, etc., have followed its escape into the blood. It has also been isolated in local phlegmon and lymphangitis. The *gonococcus* is frequently met with in pyæmic conditions. *B. typhosus, B. pyocyaneus, B. Friedländer, Proteus vulgaris, Micrococcus tetragenus*, and many others are capable of bringing about the disease.

The infection may be a mixed one, a *double infection* taking place at the same time, or a *secondary infection* taking place in a focus alr ady the seat of microbic activity. It often happens that only one of the bacteria can be demonstrated in the blood, and when streptococci and staphylococci are associated, the streptococcus is generally the one to bring about the general infection.

Pathology.—In the mildest form of the disease, *septicæmia without bacterial activity*, or, as it is more commonly termed, "*sapræmia*," the pathological changes are limited to the site of the necrosing or putrefying focus. In the *pyosepticæmic* form of the disease we have locally the combined phenomena of pus formation and putrefying, decomposing, or necrosing tissue. It may exist in the form of a moist gangrene. Often, in the case of wounds which seem at first insignificant, but in which cases there ensues a malignant and rapidly fatal toxæmia, the pathological findings are very slight. More often we have the local changes of a pyogenic disturbance, presenting all of the characteristics of local inflammation and abscess formation. The primary focus may be a carbuncle, an infected wound, an otitis media, an osteomyelitis, a gastro-enteritis, a pneumonia, etc. From the seat of infection the inflammation spreads, the *lymphangitis* is set up, the nodes are attacked, and *lymphadenitis* follows. The bacteria reach the blood and here many changes occur. *Sozins* and *alexins* are produced, and *antitoxins* are elaborated. Ewing holds that the bacteria are present in the circulating blood only for short periods and at infrequent intervals, and that a few hours before death various bacteria, some of which may not be active in the original process, make their way into the circulation. There is a rapid development of severe anæmia. The red blood cells are diminished in number, and in the more severe cases a slight poikilocytosis and degeneration of the cells occur. Sometimes normoblasts appear. Grawitz reports a case of acute septic infection, in which after two days the red blood cells were reduced to 300,000 per cubic millimetre. The blood plaques are increased. Leucocytosis is marked, except in the very mild and very severe cases. Changes in the blood vessels occur mostly in relation to the local pus foci, but often by means of mural inplantation the endocardium is attacked and ulcerative or malignant endocarditis ensues. When a vein in the neighborhood of an abscess is attacked the adventitia is the first to be affected. The ordinary phenomena of inflammation follow, and the other coats of the vein become involved. The intima becomes swollen and inflamed and fibrin is deposited on it, which becomes the nucleus of a coagulum. This increases until the lumen of the vein is occluded and a thrombophlebitis established. Sometimes the thrombus extends for a considerable distance along the vein. As the infective process advances from the primary focus, the microbes invade the thrombus and there bring about purulent softening of the mass. Before this occurs small particles of the thrombus may be broken off, and, entering the general circulation as emboli, find lodgment in the various organs. In this way infarcts are produced, and these in turn may become infected by the bacteria in the circulating blood, thus giving rise to metastatic pus foci. In the original thrombus the process of purulent softening goes on, and if not checked by local forces or by treatment the whole mass breaks down and the particles laden with micro-organisms follow the course of the embolus and lodge in the portion of the vascular system where the size of the vessel retards its progress.

Post-Mortem Findings.—In *pyotoxinæmia* and *pyosepticæmia* putrefaction develops rapidly. In the subacute and chronic cases the original wound is found to be foul and unhealthy in appearance. The lungs may show congestion and œdema; small pleural and pericardial effusions are frequently seen. There is a marked degree of gastro enteritis, the inflammation affecting especially the lower bowel; generally cloudy swelling of the spleen, liver, and kidneys is present; the nervous system is not much affected; bacteria may be demonstrated in the connective tissues; the lymph nodes are enlarged. In the rapidly fatal *peritoneal pyotoxinæmias* the gut is found greatly distended with gas; the peritoneum is grayish and lustreless, and shows a fine network of congested vessels.

In *pyæmia* the wound looks gangrenous. The adjacent veins are thrombosed. Metastatic abscesses are seen, most often in the lungs, liver, spleen, and kidney. The intestinal tract is not so often affected. The brain may show a passive hyperæmia but metastatic foci are rare. In the joints there may be either serous or purulent effusions. Heart lesions are not frequent, but they do occur.

When recovery takes place, there is a gradual regeneration, the bacteria disappearing from the blood and the local conditions subsiding.

Signs and Symptoms.—The complex of objective signs and subjective symptoms of the disease in its various forms vary to such an extent that no hard-and-fast lines can be drawn. And still there are groups of symptoms which are most frequently observed in certain manifestations of the disease.

Under the division of *septicæmia without bacterial activity* are included all those conditions in which from a specific focus of necrosis or putrefaction or decomposition the toxic elements elaborated by these processes are absorbed into the general circulation and thereby bring about a general poisoning of the system. The primary focus may become infected, and so, through the addition of the bacterial element, we have a pyosepticæmia, to be described later. Septicæmia without bacterial activity—or, as it is more commonly termed, "sapræmia"—is most strikingly exemplified in the so-called ptomaïn poisoning, which originates in the gastro-intestinal tract, and in the cases of retained secundines, in which the putrefactive changes take place in the placental tissues and without bacterial activity bring about a general poisoning. The tyrotoxicon discovered by Vaughan, of the University of Michigan, is accepted as the etiological factor in the poisoning from cheese, and is supposed to be the active principle in some of the other forms of ptomaïn poisoning.

Large masses of gangrenous or sloughing tissues which are confined within the body may bring about the disease. The symptoms which develop are those of a poison which is gradually progressive, acting as a depressant on the nervous system, and bringing about a considerable febrile movement. The disease affects more especially the gastro-intestinal tract. There is no chill to mark its onset. The patient has a persistent headache, general malaise, anorexia. At first there is only a slight rise of temperature; the pulse frequency is increased; there is some nausea. If the cause is not removed the headache becomes more intense, the temperature rises, vomiting takes place, and diarrhœa is the rule. The blood shows degenerative changes, diminution in the number of the red blood cells, decrease in the hæmoglobin index, and some leucocytosis. These changes vary with the intensity of the poison. In the fatal cases the temperature is continuously high, the pulse rapid and feeble, delirium follows restlessness, coma develops, and death occurs. In the cases which originate in the intestines the most marked symptom is the violent vomiting and purging, which may even simulate cholera. Most of this class of cases of septicæmia react well to treatment, and when the cause is removed there is a rapid return to normal conditions.

In *pyotoxinæmia* attention is first called to the local conditions. It may be a suppurating wound which is draining poorly, an unopened abscess, or some deeply seated inflammation. In the *cryptogenic form* (*i.e.*, that form in which the original focus of infection cannot be found) there may be a history of some old trouble which is supposed to have subsided. A gastro-enteritis, a pneumonia, a cystitis, or a perityphlitis may be the starting-point. The patient at first does not appear to be very ill; there is some prostration; he complains of a slight headache which does not yield to treatment; the appetite is poor; no interest is taken in surroundings; the symptoms of lymphangitis and lymphadenitis may be present; the temperature shoots up, especially in the evening, with only slight morning remissions; the pulse becomes rapid; the patient feels "feverish"; there may be some pain in the wound. Often an examination of the local condition will demonstrate the cause of the symptoms, and prompt surgical treatment may cut short the further course of the disease, the condition returning rapidly to normal upon removal of the local cause. If the disease goes on, gastro-enteritis appears, with vomiting and diarrhœa. The tongue, at first thickly coated, becomes dry and hard. The heart's action becomes weaker and increasingly rapid, often out of proportion to the temperature; the arterial tension is lowered, and in the severe cases cyanosis appears. The liver and spleen are often enlarged. The urine shows albumin and casts. The skin may show a slight yellow tinge, but icterus is not so marked here as in pyæmia, and is probably due to destructive processes in the blood rather than to hepatic disease. At first dry and hot, the surface of the body later is bathed in perspiration, the skin feeling cold and cadaveric. The prostration increases, the expression is listless, the face being drawn and colorless, the eyes are sunken, and the alæ nasi dilated; no complaints are heard. If the disease reacts to treatment, a general improvement of the sensorium is first noted; the pulse becomes a little stronger although still rapid; the temperature gradually subsides, often showing at first marked morning remissions, until finally the evening rise disappears; the desire for food gradually returns; the heart is the last entirely to recover its normal condition. The disease may run a chronic course, lasting for from three to twelve weeks. The temperature in these cases is not generally high, but is often quite irregular. The spleen is frequently palpably enlarged, this being simply a phase of the general lymphatic enlargement. If, however, recovery does not occur, the condition may rapidly become worse, the temperature continuing high and the heart rapidly failing. Finally, violent purging, anuria, delirium and coma, are likely to precede the patient's death. In the malignant cases the course may be very rapid, presenting possibly only a slight lymphangitis, an increasingly high temperature, rapid cardiac failure, rapid overwhelming of the nervous system, and death. This last form is occasionally seen in cases of wounds received at the post-mortem table, cases in which, from a seemingly slight wound, the most intense and rapidly fatal toxæmia develops.

In typical cases of *pyæmia*, in which multiple abscesses are produced as a result of infected emboli, the clinical picture is somewhat different. The conditions at the primary focus may be the same as in pyotoxæmia. Severe local injuries, wounds of the joints, compound fractures, injuries of the veins, fracture of the skull, associated with pyogenic processes, are the most frequent among the primary lesions in pyæmia. The local condition may not appear to be especially active, but is markedly persistent. The wound looks bad and exudes a semi-serous, foul-smelling pus; and the surrounding tissues become œdematous and deeply inflamed. The temperature is not very high, with moderate morning remissions, and the pulse is rapid. This may continue for about a week, during which time the induration does not lessen, but extends more deeply into the tissues. Suddenly, on the tenth or twelfth day, the patient has a severe chill, following which there are a burning fever and then a profuse perspiration. Again, the wound may have been doing very nicely, and the evidence of infection may have been slight, when suddenly a chill appears and pyæmia is ushered in. Such chills are generally a reliable index of the lodgment of an embolus in some portion of the vascular system. The chill may, however, be very slight, and in those forms of pyæmia in which the secondary foci are caused through direct infection by the bacteria circulating in the blood, and not by infected emboli, often no chill at all appears. In *pyotoxinæmia* and *pyosepticæmia* a chill rarely is noted. Chilly sensations sometimes occur, but a sudden, violent chill is the exception. Following the sweating there is marked exhaustion. The temperature immediately preceding or during the chill is likely to shoot up to the highest point of the curve only to drop in a few hours, but not to normal. The chill may be repeated the same day or on the next day. The temperature runs apace, and describes a very irregular tracing, varying from hour to hour. The sensorium is perfectly clear, and the patient exhibits none of those somnolescent features which are seen in an acute toxæmia or pyosepticæmia, but he is keenly sensible to his suffering. The local symptoms of the new foci soon make their appearance. Pain is felt in the chest or under the border of the ribs, and upon examination an abscess of the liver, a pleurisy, or a pneumonia is found. The joints may be swollen and tender. Icterus is generally seen, slight at first but often marked in the later stages of the disease when the emaciation is far advanced. There is not so much gastro-enteritis as in toxæmia, and, in fact, in the earlier stages the constitutional symptoms are very little in evidence. The temperature continues as before, possibly not so high, exhibiting, however, the same marked irregularity. The tongue, at first thickly coated, becomes later dry and hard and looks dirty. The patients are often hyperæsthetic and suffer much from local pain. They often complain of pain first in one place and then in another, and sometimes there is a general sensitiveness all over the body. The cause may possibly be referred to localization of bacteria in the tissues, where they set up inflammatory processes and, in many cases, purulent collections. Later, the patients lose all sensation of discomfort. Erythematous and sometimes pustular eruptions appear on the skin. The pulse, which at first was fairly strong but rapid, later becomes weak and rapid. At any time the local symptom of some new metastatic focus may be ushered in. Prostration is very marked, the emaciation is severe. Gradually the patient becomes unconscious and dies in a comatose condition.

In *puerperal pyæmia* the course is very similar. In the chronic form of pyæmia chills are much less frequent and recovery may occur.

Von Leube ("Specielle Diagnose der inneren Krankheiten") states that from a scientific standpoint it is not always possible at the bedside to differentiate between the two conditions septicæmia (meaning toxæmia, pyosepticæmia, etc.) and pyæmia, or, better, strictly to draw the lines between these forms. The one leads into the other, and many cases of pyotoxinæmia would develop into pyæmia were it not for the short duration of the disease. Therefore he holds that in most cases it is proper to speak of a *septicopyæmia*. This is the form, he maintains, which is most likely to occur in the cryptogenic type of the disease. The patient, sometimes in fine health, sometimes suffering from a slight illness, begins to have pain in the legs, loss of appetite, eventually headache, vomiting, then a severe fever, and is very ill. The fever, often like a fluctuating typhoid, may be, however, continuously high, with slight remissions. The tendency is markedly to an up-and down course, with irregularly intercurrent chills. The pulse in the severe cases is very rapid, varying from 120 to 150, soft, dicrotic, and sometimes irregular, especially so in cases in which, on post-mortem examination, the heart walls are found to be the seat of metastatic abscesses. The heart is dilated, and endocarditis very frequently occurs. At times the endocarditis is the only objective sign of the disease at first (a loud systolic or systolic-diastolic murmur, increased second pulmonic sound, etc.). This cardiac condition governs very markedly the course of the disease. Embolic processes in the spleen and kidney follow, and abscesses form. This is the condition commonly termed "malignant endocarditis," but von Leube believes that the so-called malignant endocarditis is really a cryptogenic septicopyæmia, in which the septic poisons become localized in their action on the endocardium and remain circumscribed for a long time here. In the majority of cases, however, the endocarditis is only a link in the great chain of multiple inflammatory foci.

Next in diagnostic importance comes the inflammation of the joints, which may occur as an involvement of a single joint, or many joints may be affected at the same time. In such cases the disease will very closely resemble acute articular rheumatism. The process concentrates itself most often in one joint, which becomes greatly swollen. In connection with this we often have bone involvement, which, however, may take place independently of the joint inflammation. The long bones are especially susceptible. The foci may be circumscribed or be extensive in their involvement of the bone tissues, and they may present the ordinary symptoms of osteomyelitis. Changes in the skin are almost constant. Roseola, erythema-like urticaria, purpuric spots, hemorrhagic pemphigus, blisters, pustules, herpes, etc., are among the most frequent of its manifestations. As the disease advances these cutaneous inflammations may extend into the underlying tissues and large areas of inflammation and œdema, or hæmato-purulent infiltrations, may be found.

These affections, especially the hemorrhagic forms, are met with in three-fourths of the cases of "cryptogenic septicopyæmia," and are therefore important signs from the standpoint of differential diagnosis. Symptoms referable to the nervous system are quite constant: headache, vertigo, sleeplessness, delirium, convulsions, and temporary paralysis are chief among these. When metastases develop, purulent meningitis, abscesses of the brain with their various symptoms, are among the possibilities. Retinal hemorrhages are occasionally seen. Through localization of the septic processes on the pericardium, pleura, and peritoneum there ensue at times small areas of inflammation, or serous or purulent exudations, with their symptoms. In the lungs miliary abscesses are found, or in other cases large infarcts, abscesses, lobular pneumonia; especially frequent is a diffuse bronchitis. Cyanosis and increased respiratory movements are brought about by the heart weakness and pulmonary complications.

The spleen is no more enlarged in this form than in the others. But metastatic abscesses in the spleen and liver may increase the size of these organs very markedly. The symptoms referable to the digestive tract are neither constant nor characteristic. Icterus is only occasionally seen. The kidney functions are almost always affected. Albumin in the urine is the rule, and is caused by the septic irritation of the renal parenchyma. Acute nephritis, with its characteristic symptoms, often follows. Large abscesses may be formed, but as a rule there exist multiple miliary, sanguino-purulent collections in the kidney tissue.

Résumé.—Here we have, then, a form of the disease, put down by von Leube under the name of "cryptogenic septicopyæmia," characterized by the following symptoms: A very pronounced, irregular fever with a disproportionately high pulse frequence, great emaciation, more or less marked nervous disorders, enlargement of spleen, and special symptoms referable to the various organs in which the septic poisons become localized. In brief, then, the disease is one in which a peculiar form of exanthema develops, and in which the inflammation of the joints, the muscle and bone tenderness, the endocarditis, the embolic processes in the spleen, liver, lungs, and brain, the nephritis, the inflammation of the serous membranes, the petechial hemorrhages, all play a part in making up the complex of symptoms.

Grawitz ("Klinische Pathologie des Blutes," 1902), in discussing this form of septic poisoning, states that in most cases of "cryptogenic septicopyaemia" pyogenic bacteria are present in the blood, and that in many uncertain cases a positive diagnosis may be established by a blood examination. A negative result, however, does not exclude the disease. He further maintains that in cases of ulcerative or malignant endocarditis repeated failure to isolate the micro-organisms from the blood speaks most strongly against the disease being present, and *vice versa*.

In the cases of *pyosepticæmia* the symptoms vary somewhat, and are very largely governed by the pathological conditions which give rise to the disease. In gangrene of the lung, in tuberculous coxitis which has become secondarily infected, in chronic myelitis and myelitis transversa, in which decubitus, necroses, etc., are associated with poly-infections, we have striking examples of a pyosepticæmia. These processes, when examined bacteriologically, are found most often to harbor many different varieties of micro-organisms acting together. The streptococci, bacillus coli communis, proteus vulgaris, and bacillus pyocyaneus are frequently found associated in such a process. The symptoms then are those of the local condition and the general poisoning of the system. The fever is marked and the pulse rate is high and, as in the other forms of septic poisoning, the spleen is enlarged. The temperature is very irregular and of the remittent type. The nervous system is markedly involved, more so than in the pyotoxinæmic forms. The blood itself does not show such marked changes, and frequently micro-organisms cannot be demonstrated in the general circulation. We have then in these cases to deal with a condition of poisoning, due chiefly to the absorption of the toxic products from a localized process, rather than with disease resulting from a bacterial invasion of the whole system.

The symptoms in cases of septic intoxications and infections, as given above, are only composite pictures of the various forms of the disease. In many of the actual cases the disease manifests itself differently, and the course of these cases can be best demonstrated by giving examples of actual cases. The following cases, unless otherwise designated, have been taken from the records of the Methodist Episcopal Hospital of Brooklyn, New York.

Case I. Pyotoxinæmia Following Infection of Knee-Joint.—On June 20th, 1888, an operation was done on the knee-joint to remove a foreign body. The next day there were considerable pain in the joint and tenderness. Temperature rose to 100.6° F., pulse 110, respirations 25. Second day after operation pain continued, the temperature jumped to 104° F., pulse 118, and patient felt listless. Third day: Patient began to vomit, at first at intervals of two or three hours and later in the day almost continuously, temperature remaining high and pulse becoming irregular and rapid. Some diarrhœa. Fourth day: Vomiting not so marked; bowels moving involuntarily; patient very restless. Temperature continuously above 102° F., pulse averaged 138, respirations 28. Fifth day: Joint re-opened and small amount of sero-sanguineous fluid was evacuated. Irrigated with antiseptic solutions and thoroughly drained; no change in general condition. Sixth day: Patient delirious, the bowels still moving frequently, temperature and pulse continuously high. Eighth day: Still delirious; much diarrhœa. Patient lies in a sort of stupor, twitching of muscles of the left shoulder and fingers of right hand; marked flushing of left side of face. Slight paralysis of the left facial muscles. Picking at bedclothes. Temperature had fallen to 100° F., pulse 120. Perspired freely. Under treatment, by thorough drainage and irrigation with antiseptic solutions, these symptoms gradually abated with the exception that the temperature remained continuously above 100° F., and the pulse about 100. On the thirtieth day the joint was again opened and some dead bone removed, after which the wound healed, the temperature becoming normal and the pulse dropping to 90. The patient had entirely recovered after an illness lasting over two and one-half months. In the accompanying chart are shown the temperature and pulse curves for the first sixteen days of the disease.

CLINICAL CHART.

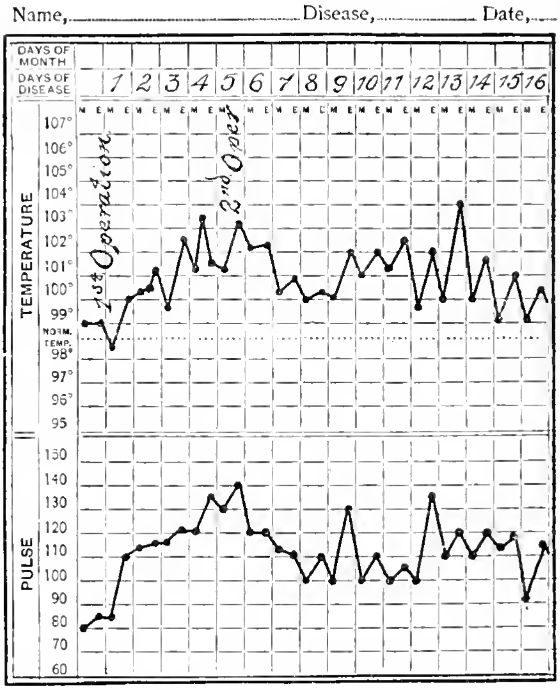

FIG. 4186.

This is an example of a case of pyotoxinæmia arising from an infection in the knee-joint. Infection of this joint is an event always to be dreaded by the surgeon, for in almost all such cases a rapid and often fatal toxæmia, and frequently a pyæmia, occurs. The synovial membranes of the joints offer very little resistance to the inroads of bacteria, and when once affected are easily destroyed and the process attacks the underlying tissues. It has been shown that streptococci may be introduced under the skin of an animal and there set up only a localized abscess, but the same organism when injected into the synovia of the knee-joint will bring about a virulent and rapidly fatal intoxication. In the present case, no bacterial examination was made. The infection evidently took place during the operation, and although the condition was soon discovered and thorough drainage established, still the process persisted for over two months. During the course of the disease the temperature and pulse were continuously high, with intercurrent remissions. The point of special interest in this case is the peculiar involvement of the nervous system, which showed itself in the unilateral paralysis of the facial muscles, the twitching of certain sets of muscles, and the flushing of one side of the face.

Case II. Cryptogenic Pyotoxinæmia.—Patient had been in poor health for about a year. Two weeks previous to admission had a severe chill, followed by fever and sweating. Chills occurred on successive days thereafter. In a few days patient began to complain of great pain in gluteal region, and then in knee and ankle. At end of eight days there were marked swelling, pain, and tenderness of the left knee and ankle. This continued, and on admission to hospital the temperature was 103° F., pulse 120. Under local treatment inflamed condition of ankle subsided, but knee remained swollen and tender. May 19th: Knee-joint was opened and considerable pus evacuated. Drained. During the ten days following the operation the temperature abated somewhat, but the pulse remained continuously high. Patient in a semi-stupor. June 1st: Patient passed into a "typhoid state," temperature becoming irregular again. June 3d: A necrotic spot appeared on left buttock. Wound looks more healthy. June 6th: Severe chill, following which temperature reached 103° F. and pulse 140. Necrotic spot on buttock broken down and surface granulating slowly. During next six days temperature at no time high, but irregular. Pulse vacillating between 120 and 170, very weak and irregular. Frequent diarrhœal movements. June 12th: Death.

Autopsy showed only inflammatory condition in and around knee-joint; cloudy swelling of kidneys; fatty degeneration of liver. Spleen was soft and normal in size.

The question arises in this case as to how the bacteria gained entrance to the joints. The autopsy does not help us in deciding this. There were no other foci of inflammation and no history of any wound as a starting-point. It therefore comes under the head of cryptogenic pyotoxinæmia, the main point of suppuration being, as in the previous case, in the knee-joint. There evidently was also an inflammatory process in the gluteal region and in the ankle, but these were controlled. There had been no pneumonitis, otitis media, enteritis, or urethritis to attract our attention. The initial symptoms, repeated chills, and high temperature, followed later by pain in the gluteal region, knee, and ankle, would suggest embolic pyæmia. But this we cannot have without some initial lesion. The origin then remains a mystery, cryptogenic. In this case there was no enlargement of the spleen.

Case III. Staphylococcus Pyotoxinæmia with Transition to Pyæmia.—February 19th, 1888: Patient fell downstairs, sustaining an injury to left ankle. No external wound. February 28th entered hospital complaining of pain in and around ankle-joint, which was somewhat swollen, tender, and red over a circumscribed area. No fracture could be demonstrated under chloroform. Pain increased in spite of local applications, and on March 2d patient had a temperature of 103° F. There were slight remissions of the continuously high temperature. Patient's general condition poor, pulse 110 to 120 per minute. March 5th: Very restless and during night slightly delirious. Area of redness extended slowly. March 6th: Fluctuation appeared at ankle. Incision was made and considerable pus was evacuated. Bone not involved. Following the operation there was a slight fall in the temperature, which, however, rose again the next day to above 103° F. March 7th: Temperature still high, respirations very rapid and superficial, but examination of the lungs was negative. Over the cardiac region, most distinctly over the aortic area, were heard a distinct friction sound and a blowing murmur, where previously there had been none. In the evening this friction sound disappeared. During the night the patient became very restless, and toward morning began to vomit at long intervals. Temperature reached 104.5° F., pulse increasingly rapid, 130 to 160. There was marked emaciation. Vomiting became more frequent, bowels moving involuntarily. Gradually the patient became comatose, pulse imperceptible. Death.

Autopsy: Pericardium injected and the sac distended with pale, greenish-yellow fluid and flocculi of fibrin. No fluid in either pleural cavity. Lungs in places adherent. Heart is covered with a layer of fibrin, thicker in some places than in others; fibrin also seen on the pericardium. Left lung: Scattered through the lung are areas of congestion surrounding infiltrated patches with whitish centres; none of these areas is larger than a pea. Right lung: On surface, especially on anterior border, are a number of small circumscribed white spots, cone-shaped upon section. On posterior surface are a number of small punctate spots of hemorrhage. The lung is somewhat œdematous and congested; bronchi are normal. Heart muscle is very pale. Spleen enlarged and soft. Right kidney: Just beneath the capsule is a single small abscess.

Microscopical examination: The nodules described in the lungs and kidney proved to be small infarcts, the blood-vessels leading to them being occluded by firm thrombi. They consist of masses of inflammatory tissue with small pus collections.

Bacteriological Examination: Original wound, infarctions of kidney and lungs, showed pure culture of staphylococcus pyogenes aureus.

Diagnosis: Acute pericarditis, multiple infarctions of both lungs, abscess of kidney. Staphylococcus pyotoxinæmia passing into pyæmia.

Remarks: We have here the history of an injury to the ankle-joint without any external wound being present. The staphylococci may have gained entrance through the skin which was evidently bruised, although no actual open wound occurred. Again, the micro-organisms may have been conveyed to the joint by the blood from some other undiscovered focus. The only clinical evidence of pyæmia was noticed on March 7th, when a pericardial friction sound was heard. There were no chills, but there were marked gastro-intestinal symptoms, a continuous remittent fever, and a weak but rapid heart's action—in fact, all the clinical symptoms of a pyotoxinæmia, which at autopsy proved to be an embolic pyæmia.

Case IV. Pyosepticæmia.—November 8th: Patient on admission to hospital presented an area, over right eye, about three inches in diameter, bright red in color, with a well-defined margin, slightly œdematous and gangrenous in places. It was covered with small suppurating points. Upper eyelid enormously swollen. Temperature 106° F., pulse 120, respirations 35. Operation: Curetting of necrotic tissue, free incisions. November 9th: Temperature dropped to 95.6° F., pulse 75, respirations 25. Patient delirious, tinnitus aurium. Extensive reddish, papular eruption on chest. Skin cold and clammy. Later in day, temperature rose to 104° F., pulse 110; vomiting. November 10th: Diseased area shows the characteristics of a sloughing phagedæna. November 11th: Restlessness and delirium alternating with stupor. Great prostration. Temperature continuously high. The phagedæna spread rapidly and involved a large portion of the head. Patient died in coma.

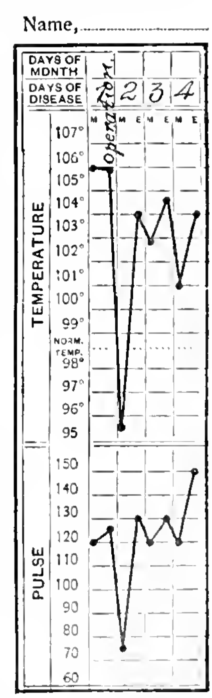

FIG. 4187.

A glance at the accompanying chart (Fig. 4187) will show the remarkable deviation in the temperature and pulse curves. The disease, originating in an inflammatory condition of the face, developed into a virulent phagedæna, combining a suppurative and a putrefactive process, which resulted in a rapidly fatal intoxication and infection of the entire system. It therefore falls into the class of *pyosepticæmia*. However, most cases which may be classified as pyosepticæmia run a more subacute or chronic course. The following case reported by Brunner (*loc. cit.*, p. 101) is an excellent example of this, and his analysis of the same is of interest:

Diagnosis: Chronic myelitis; decubitus sacralis. Putrid abscess of thigh. Polyinfection by streptococci, bacillus pyocyaneus, bacterium coli, proteus vulgaris. Death. Pyosepticæmia.

History: Patient well until three years ago. First signs of disease appeared as feeling of fatigue in the feet, chilly sensations and formication. The symptoms were steadily progressive. Disturbance in the function of the bladder and rectum appeared, and finally loss of control of same. In December complete loss of use of the legs; later, decubitus sacralis. Admitted to hospital January 25th, 1898.

Status præsens (at time of admission): Both legs useless. Hardly any sensation in them. Beginning involvement of upper extremities. Involuntary micturition and defecation. Decubitus spots, about size of silver quarter of a dollar, on each heel. Over the sacrum a deep decubitus about the size of the palm of the hand; sacrum exposed, a further defect over the lumbar vertebræ and over the trochanters. High temperature. Urine cloudy, strongly ammoniacal.

Course: February 13th: The decubitus slowly enlarging. Application of vinum camphoratum. In the region of the left trochanter a collection of foul-smelling pus, undermining the skin. February 19th: Always high temperature with morning remissions (see accompanying chart, Fig. 4188). On right thigh a large fluctuating abscess has formed. Incision and drainage. A large amount of filthy, bad-smelling material and gas evacuated. During the night *exitus lethalis.*

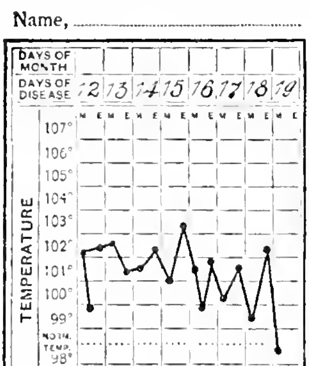

FIG. 4188.

Autopsy: Ten hours after death. Extract from the protocol. On back, over the sacrum and over the trochanters, the above-described decubitus defects. The abscess cavity on the right thigh reaches from the patella to the middle of thigh; its periphery presents masses of bad-smelling necrotic tissue, with threads of fascia running through it. A sound can be passed from this abscess cavity up to gluteal region. Spleen very much enlarged and soft. Both kidneys contain small abscesses, the size of a pea.

Bacteriological Examination.—I. During life: 1. Examination of urine: bacterium coli. 2 Examination of blood. February 19th: Blood aspirated from vein of arm, under aseptic conditions. Cultures made on glycerin-agar and in gelatin. *Result negative.* 3. Examination of pus evacuated from abscess cavity at time of incision. Smear examination; streptococci in short chains, numerous small rod shaped bacteria. In the glycerin agar and gelatin cultures, copious growth of pure culture of proteus vulgaris. Pathogenesis: Injection of 1 c.c. of original culture into ear vein of rabbit, evening of February 24th, caused death during night of February 25th. Guinea-pig: Injection of 1 c.c. of the same culture subcutaneously into wall of abdomen on February 24th, 4 P.M. February 27th, local infection. February 28th, fluctuation. March 1st, incision and thick yellow pus evacuated! Culture on agar showed proteus in pure culture. Injection of 1 c.c. of the same growth into abdominal cavity of guinea-pig. Animal lived.

II. At the autopsy: 1. From the deepest portion of the decubitus; proteus vulgaris greatly predominating; Bacterium coli and bacillus pyocyaneus also present. 2. Thigh abscess: proteus vulgaris. 3. Heart blood: pure culture of proteus vulgaris. 4. Liver: proteus vulgaris. 5. Spleen: negative. 6. Kidney abscess—could not be properly examined owing to use of non-sterilized knife in making the section.

Analysis of the case by Dr. Brunner. Avenue of the infection. On account of the myelitis the trophic changes and anæsthesia of the skin took place, and owing to pressure the mortification of the tissues occurred and pressure-necrosis resulted. Owing to incontinence of urine and fæces the area became easily infected with the proteus vulgaris and bacterium coli, to which later was added the bacillus pyocyaneus. The B. coli caused early a cystitis. Subcutaneously the tissue surrounding the sacral decubitus broke down under the attack of the pyogenic micro-organisms. The process worked down along the thigh and manifested itself there in the formation of a putrid, gas-containing abscess. In this abscess the proteus vulgaris was the most active agent, and was found in pure culture in the remotest portions of the cavity. Streptococci were found only in smear preparations and could not be demonstrated in the cultures. It is probable that they were active during the abscess formation up to the time when the incision was made, but were no longer able to develop or were killed by the proteus in the culture media. From this extensive area of putrefaction with destruction of much tissue, the poisons which were elaborated were doubtless absorbed into the blood. It is also very probable that from time to time various streptococci and proteus rods wandered into the blood stream; they, however, did not develop in the blood; a bacteriæmia—bacterial septicæmia, in the sense of Koch's definition—was not present. That such a condition did not exist at the height of the disease is proven by the negative result in the examination of a relatively large amount (5 c.c.) of the blood. The bacteriæmia post mortem was in itself not proof positive.

Characteristics of the Clinical Picture. If one may ever speak of a "rotten infection" and "putrid intoxication," this case certainly falls into such a class. Putrefaction and malodorous decomposition were brought about through the activity of four dangerous micro-organisms: streptococcus, bacterium coli, proteus vulgaris, and the bacillus pyocyaneus. Together with this disintegration occur the pyogenic phenomena due to these germs. A large gas abscess developed, and this, together with the decubitus, was the chief source of the poison which brought about the general intoxication. High fever, high pulse frequence, dry tongue, enlargement of the spleen, changes referable to the nervous system—these are the symptoms of the intoxication. The temperature curve again shows the zigzag remittent type without special diagnostic significance. An intense invasion of the circulation by the causative agents, or any growth of the same in the blood, did not occur. Bacteriæmia is excluded, and a toxæmia remains. Since we have in this case a combination of pus formation and putrefaction, it falls into the class of pyosepticæmia. The small abscesses in the kidneys are explained as an extension of the B. coli infection from the bladder. In the absence of a bacteriological examination a definite conclusion cannot be arrived at.

The gonococcus starting from an initial lesion in the urethra may act alone or in combination with other micro-organisms to bring about a general infection or pyæmia. Bujwid, in his article, "Gonococcus als die Ursache pyämischer Abscesse" (*Centralblatt für Bakteriologie*, 1895, Bd. xviii., S. 435), presents the following case: Young man, thirty-two years of age, suffering from chronic gonorrhœal urethritis, after passage of a sound had a severe chill which lasted some time. This was repeated the next day and the two or three days following. Later, four abscesses appeared: one in the region of the left shoulder, one in the right popliteal space, one on the inner side of the left leg, and one over the external malleolus of the right leg. These abscesses were all confined to the muscular tissues and did not involve the connective tissue or the joints. Upon incision they contained a small amount of odorless, brownish-red pus, in which the gonococcus in pure culture was found.

Ohmann reports a case in which the complications were multiple arthritis and tendo-vaginitis, epididymitis, and nephritis, and in which case he was able to demonstrate the gonococcus in the blood. Brunner states that in these cases the course may be very acute with all kinds of complications, but that there is very little tendency to destruction of tissue. Finger, from his observations in gonococcus pyæmia, holds that in such inflammations there is always a tendency toward the early formation of granulation tissue and later an increased connective-tissue formation. There occur in the urethra strictures; in the prostate a destruction of the glandular structure; in the epididymis, thickening of its walls; in the joints, ankylosis etc. The micro-organism is less energetic and less destructive in its action than are the other pyogenic agents.

In the cases of puerperal infection, owing to the richness of the blood and lymph supply incident to pregnancy, the disease is often very rapid and fatal. It may follow the type of a pyotoxinæmia, a pyosepticæmia, or lastly a pyæmia. In the rapidly fatal cases pyotoxinæmia is most frequent, while pyæmia is often a complication. In the subacute cases pyosepticæmia is often the form of the disease which is present, the uterus and adnexa being found in a necrotic or gangrenous state associated with pus formation.

Otitis media frequently is the starting-point of a general septic infection, the sigmoid sinus becoming involved and thrombo-phlebitis resulting. Purulent meningitis and abscess of the brain with their characteristic symptoms may cause death, or a typical embolic pyæmia with metastatic foci in the lungs, heart, kidneys, etc., may develop. The course is generally long.

Prognosis.—In septicæmia without bacterial activity the prognosis depends mostly upon the etiological factors and the ability to remove the cause. When the condition is due to retained secundines, the removal of the same is followed by rapid recovery. In the various forms of ptomaïn poisoning, from the ingestion of putrid foods, some prove rapidly fatal, while others recover upon removing the offending material from the intestinal tract. But, in general, the adoption of prompt treatment, as soon as the cause is discovered, is followed by recovery.

In the milder forms of *pyotoxinæmia* and *pyosepticæmia* the disease often is amenable to treatment, but all forms depend upon many factors. The age of the patient, the ability of the tissues to check the inroads of the bacteria, the virulence of the micro-organism, the site of the infection have all been referred to above. Even in the severe cases, the establishment of thorough antiseptic treatment may bring about recovery. In general the prognosis is poor. In the majority of cases of pyosepticæmia the prognosis is bad.

The prognosis in pyæmia is always grave. When metastases develop rapidly and involve important organs the result is usually death. In gonorrhœal pyæmia the prognosis is better. Warren ("Surgical Pathology," p. 378) claims that there is a relatively high percentage of cures in puerperal pyæmia.

Diagnosis.—To distinguish between the different forms of the disease from a clinical standpoint is often impossible. It must be remembered too that one form may merge into an advanced form without any marked symptoms to designate the period of transition. In septicæmia without bacterial activity surgical interference with disappearance of the symptoms will establish the diagnosis. In the cryptogenic or spontaneous forms of the disease a careful examination of the entire body must be made and all of the secretions be carefully tested. The presence of a suppurating focus, lymphangitis, enlarged regional lymph nodes, with a continuously high temperature, very rapid pulse, absence of chills, indifference of the patient, gastro-enteritis, presence of albumin and bacteria in the urine, and bacteriæmia would point most strongly to pyotoxinæmia. Such conditions as a gangrene of the lungs, moist gangrene of the extremities or other portions of the body, extensive decubitus and other necrotic and putrefactive processes in which pyogenic bacteria are present, and accompanied by a markedly irregular temperature, rapid and feeble pulse, pronounced nervous disorders, no marked blood changes, and negative bacterial blood tests, together with the other phenomena of septic intoxication, may be safely diagnosed as pyosepticæmia. If, in the presence of an imperfectly draining wound, cellulitis, lymphangitis, thrombo-phlebitis, ulcerative endocarditis, pyosepticæmia, pyotoxinæmia, or any of the conditions above mentioned, there occurs a sudden sharp chill, accompanied by a marked rise in temperature, and followed by sweating and pain referred to some distant point, pyæmia must be suspected. If, in the subsequent course of the disease, the chills are repeated, the mental faculties remain clear, marked emaciation, hyperæsthesia, diaphoresis, and great prostration are present, and the symptoms of metastatic abscesses make their appearance, the diagnosis of pyæmia is definitely established.

Among the diseases which resemble the various forms of toxæmia, septic intoxications, and septic infections, may be noted acute articular rheumatism, malaria, typhoid fever, acute miliary tuberculosis, severe anæmias, and uræmia. But in each case a careful inspection of the history and a thorough consideration of the signs and symptoms which each disease presents will result in a correct differential diagnosis.

Treatment.—*Prophylactic.*—The state of our knowledge at the present day enables us to operate almost without fear of infection, and a thorough understanding of the aseptic treatment of wounds is presupposed by the writer. It is, however, to be especially emphasized in the preparations for any operation on the knee-joint. Chronic tuberculous processes, wherever they may be, especially those of the joints and bones, are most frequently confined to the points of their primary activity and do not generally give rise to a systemic intoxication; but if, during the course of an operation upon such a process, it becomes secondarily infected the condition becomes much more serious, and any of the forms of intoxication or infection may develop. This must also be borne in mind in the treatment of any infected wound, for a polyinfection is generally more difficult to handle than a monoinfection. In the various nervous diseases in which trophic disturbances are present, much care must be exercised to prevent bedsores. If a decubitus should appear despite the frequent change of position, rubbing with alcohol, etc., they should be treated antiseptically, to prevent if possible any infection. The prophylactic measures in the treatment of compound fractures, extensive lacerated and contused wounds, and burns, should always be carried out most carefully.

Local Treatment.—In the cases of septicæmia without bacterial activity the results of removing the cause are very marked and satisfactory. If the offending substance be contained within the intestines, a course of calomel in divided doses, followed later by a saline purge, may be all that is needed to bring about recovery. In the puerperal cases the removal of the secundines, the fingers being used as a curette and the scraping being followed by a hot saline irrigation, is indicated. The same principle is to be followed in all of its forms, *i.e.*, the cause must be removed under all possible aseptic precautions.

In the other forms of the disease the care of a pus focus must first be considered. If the case presents itself with an abscess already formed, the indication is to evacuate the pus. *Ubi pus, ibi evacua.* If a putrefying area is associated with a purulent focus, as much as possible of the putrid material should be cut away, the surgeon being careful not to expose healthy surfaces. In such a condition it may be proper to swab out the cavity with pure carbolic acid and then immediately after to cleanse it with alcohol. All such abscess cavities should be irrigated with some antiseptic solution and thoroughly drained, at first with iodoform gauze and later by means of rubber-tube drains. In cases in which, following an operation, there develop the symptoms of toxæmia, an early inspection of the wound should be made, and if infection has taken place the sutures should be removed, the wound irrigated with some antiseptic solution, drainage established, and dressings wet with some non-irritating solution, as Thiersch's solution of boracic and salicylic acids, be applied. The wound should be dressed daily or, in the virulent cases, more often. In some cases constant irrigation is indicated. In pyæmia, where possible, the secondary foci should be opened and treated as above.

General Treatment.—The routine treatment always includes as a preliminary procedure the stimulation of all of the excretory organs. The bowels should be freely moved, the kidneys stimulated, and diaphoresis increased. The proper nourishment of the patient should be carefully looked after, easily digested food being given in small amounts, and, when the stomach is unable to retain food, rectal enemata of peptonized milk, peptonized egg, and whiskey should be given every four hours, in amounts not exceeding from four to six ounces. The hygiene of the sick-room is also of importance; every opportunity for fresh air, sunlight, and cheerful surroundings is to be favored. In no condition is careful nursing more necessary. The use of drugs is not very satisfactory. Antipyretics are contraindicated, for they often act as powerful cardiac depressants and mask the symptoms. Alcohol in the form of egg-nogs, whiskey, and brandy, is considered by many to have very beneficial effects. In fact, these patients bear large amounts of alcohol very well, and it should be given freely. The heart's action can be stimulated best by using relatively large doses of the tincture of digitalis. If the diarrhœa is troublesome, it may be controlled by opium, or by bismuth and salicylic acid in their various forms. Paresis of the gastro-intestinal tract may be treated by an hypodermic injection of atropine sulphate gr. $\frac{1}{80}$, and bisulphate of quinine gr. v., to be repeated in five hours if necessary.

The use of intravenous and subcutaneous infusions of normal salt solution acts very beneficially in these cases. It helps to maintain the circulation, protects the nervous centres, dilutes the poisons, and assists very materially in the elimination of both the micro-organisms and their toxins. The infusions may be given daily in relatively large amounts, 1,000–1,800 c.c. being given intravenously. An objection has been raised to this, the statement being made that such a regular dilution of the blood would cease, after the first day or two, to have any beneficial effect; but this is not true, for in the course of twenty-four hours the excess of the solution may be entirely excreted from the body and a new infusion be called for. With this as a basis, many experiments have been made by adding antiseptics to the solution with the hope of bringing about a direct antiseptic influence upon the micro-organisms in the circulation and tissues.

Intravascular Antisepsis.—Experiments were carried out by Maguire, of London, to ascertain the effects of introducing a solution of formaldehyde gas directly into the circulation. His experiments were carried out upon animals and upon himself, and he concluded that 50 c.c. of a 1 to 2,000 solution of formaldehyde gas, or 50 c.c. of a 1 to 800 solution of formalin, could be safely introduced into the circulation without bringing about any serious blood changes. After injecting 100 c.c. of a 1 to 2,000 solution of formaldehyde into his own circulation, the only change that was noted was the appearance of albumin in the urine. Later, he injected 263 c.c. of a 1 to 2,000 formaldehyde solution. There followed considerable cramp-like pain in the arm, where the solution was injected, and peculiar cardiac distress. Many red blood corpuscles and blood-coloring matter were noted in the urine. This disappeared the next day. A solution of 1 to 1,000 formaldehyde, of which 63 c.c. was injected, caused severe pain in the arm and faintness. Maguire's conclusions were that 50 c.c. of a 1 to 2,000 solution of formaldehyde (1 to 800 solution of formalin) was the maximum dose to be safely injected in man. That is to say, if the total quantity of blood in an adult be estimated at 5,000 c.c., the solution of formaldehyde in the blood would be 1 to 200,000, which is a very efficient germicide. Barrows, of New York, applied this principle in the successful treatment of an advanced case of puerperal sepsis, as reported in the New York *Medical Journal*, January 31st, 1903. In his case he gave an intravenous infusion of 500 c.c. of a 1 to 5,000 aqueous solution of formalin, and on the third day following a second infusion of 750 c.c. of the same solution was given. There followed a rapid, marked, and permanent improvement which resulted in recovery. As a result of his experiments and those of others he concludes that the procedure depends on its being correctly and scientifically applied. He warns the profession against its indiscriminate use where proper blood cultures have not been made. It is also suggested that normal salt solution be used in making the formalin solution, as it has been found that no change takes place in the formaldehyde in this solution. Although no harm has been done to the blood cells by the infusion of formalin in distilled water, theoretically the normal salt solution is to be preferred.

Fortesque-Brickdale, as a result of his experiments upon rabbits, published in the *Lancet*, January 10th, 1903, does not favor the use of intravascular antisepsis. He states: "That rabbits injected daily with non-toxic doses of oxycyanide of mercury, formic aldehyde, chinosol, protargol, or taurocholate of sodium are not thereby protected from the usual effects of a previous inoculation of virulent anthrax; and that chinosol and formic aldehyde in large doses (toxic) so depress rabbits infected with the pneumococcus that they die sooner than an untreated animal."

Credé has applied the theory of intravascular antisepsis in the use of colloidal silver or collargol. This he claims to be a non-irritating, strongly bactericidal agent which may be employed as an inunction or as an intravenous infusion without any detrimental effects, and which is followed by marked improvement and often by recovery from the most severe forms of septic infection. He recommends it especially in cases of general sepsis, puerperal fever, pyæmia, and septic osteomyelitis. In the less severe cases, especially where the infection is localized, he uses a fifteen-per-cent. ointment of colloidal silver, rubbing two or three grams into the skin, after mildly irritating the same and causing local hyperæmia. In the more severe cases he recommends an intravenous injection of from 5 to 20 c.c. of a one-half to one-per-cent. solution, repeated daily or every week as required. Of his more recently perfected collargol solution he uses from 2 to 10 c.c. of a two-per-cent. solution. His technique is as follows: The syringe should be cleansed, the silver solution, and no other chemical, being used for this purpose. The syringe is then partially filled with collargol solution, and the detached needle is inserted, either through the skin or, if necessary, but only after a carefully made preliminary dissection, into the vein. The syringe having been attached to the needle, some blood is withdrawn into the syringe in order to remove from it any bubbles that may be present. Finally, the fluid is slowly injected. Subcutaneous injections are not effective. Viett used the intravenous method in a series of twenty cases of sepsis, and recommends it strongly.

The experiments of Grindes and Balardzsheff, however, do not bear out the conclusions of Credé, for they reported that a one-per-cent. solution of collargol had no effect on anthrax, staphylococcus, and streptococcus infections. They report that unless the injection is given at the point of the inoculation of the micro-organisms, no effect followed. They claim that the simple injection of collargol intravenously causes death sometimes. Baginski, Naltenius, and Kunzl-Krause report no beneficial results. However, other experimenters have met with decided success in its use, and the failures of others may be due to faulty technique.

Unguentum Credé, an ointment of metallic silver, has been used by some in the treatment of these cases. Forty-five grains are rubbed into the skin very gradually.

Antistreptococcus serum of Marmorek is limited in its usefulness to certain kinds of cases, but in these it has met with marked success. The favorable cases are those which are caused by streptococci alone, and when the infection is a mixed one, the serum acts upon the streptococcus infection alone. In many of the cases reported the disease was already far advanced, and consequently they can scarcely be considered satisfactory test cases of the usefulness of the procedure. Packard and Wilson (*American Journal of the Medical Sciences*, December, 1902, p. 1033) have collected 117 cases treated during the past two years with antistreptococcus serum, and in 114 of these cases there followed either temporary improvement or prompt recovery. After citing many other cases they make the following statement: "All of these reports tend to convince us of the fact that antistreptococcus serum will at least do no harm, and that in cases in which the streptococcus is alone involved it will eliminate that micro-organism and control the symptoms caused by its toxin unless used too late for any remedy to be of avail. When the streptococcus infection is found in combination with those of other micro-organisms we have learned that the serum has no influence except in so far as it controls the streptococcus symptomatology. Undoubtedly the attempt to obtain a polyvalent serum is one in the right direction, and, as in typhoid fever, it presents a key to new accomplishments in the line of special serum therapy."

Special forms of treatment are indicated in infections of different regions of the body. In extensive processes involving the extremities amputation may save life, but even after such a drastic measure it may be found that the infected thrombus has extended too far to be checked, or the systemic disease may be developed to such an extent that amputation is contraindicated. Klebs first suggested the idea of ligating and removing the veins in which thrombi had formed before the infected emboli should become broken off and pyæmia set up. This procedure is especially considered in involvement of the lateral and sigmoid sinuses following suppuration in the middle ear. Here thrombo-phlebitis is very likely to occur, and the internal jugular vein is also frequently involved. The first step of the operation should be in most cases the ligation of the internal jugular below the point of involvement. Then the sinus may be exposed and the purulent material scooped out or gently washed out. Sometimes an excision of a portion of the vein is indicated.

In cases in which the pyogenic focus is in the pelvis, or in which a general suppurative peritonitis exists, the entire abdominal cavity may be flushed out with hot salt solution. The head of the patient's bed may be raised, which, as Fowler suggested, will favor gravitation of the purulent material into the pelvis, from which it may be aspirated every few hours.

The question of the treatment of puerperal sepsis occupied the attention of the Fourth International Congress of Obstetrics and Gynæcology in Rome, September, 1902, and formed one of its chief topics for discussion. The following extracts are taken from the report by Dr. H. N. Vineberg ("American Gynæcology," January, 1903). The conclusions of H. Treub (Amsterdam) were as follows: The usual methods of treatment (curettage, intra-uterine irrigations, ice bags, cold baths, turpentine injections, antistreptococcus serum, alcohol) for puerperal sepsis localized in the uterus are in most cases followed by cure. In a few exceptional cases hysterectomy will be indicated. Tuffier (Paris) said that in a given case of *septicæmia*, post partum, or post abortum, when there is no cause for the fever to be found either in the external genitals or in other organs, when the usual methods of treatment are of no avail and when the peritoneum and adnexa are intact, and the uterus is large, flabby, and is discharging fetid lochia, and if the patient's general condition warrants it, total extirpation of the uterus should be done, whether there be placental retention, a sloughing myoma, or the so-called "metritis desiccans." A. Pinard (Paris) recognized only the following indications for hysterectomy: retained putrid placental remains, sloughing myoma, and perforation of the uterus.

The *convalescent stage* calls more for careful nursing and attention to general hygienic principles than for drugs. Nourishing food, fresh air, and cheerful surroundings are the essentials. *Paul Monroe Pilcher.*

SERUM DIAGNOSIS AND SERUM THERAPY.—I. SERUM DIAGNOSIS.—Serum diagnosis and serum treatment rest upon the same fundamental principles. When a group of foreign cells enters an animal body, whether in the form of disease or of experimental infection, there results a group of changes both in the foreign cells and in one or more cell groups of the body which they invade. These changes are peculiar and specific in relation both to the invader and to the territory invaded. The blood, as the representative of all organs, undergoes specific changes which are at the basis both of serum diagnosis and of serum therapy. A few examples will make this clearer. When a human body is invaded by a group of cells of that peculiar species known as typhoid bacilli, the blood acquires a number of new and specific properties, specific in the sense of manifesting their action only in relation to the typhoid bacillus. Upon one of these new properties serum diagnosis is based. The ability to agglutinate any specimen of the race typhoid bacilli is possessed to a feeble degree by the blood of many healthy human beings. But when a person is or lately has been suffering from typhoid fever, the agglutinating power of the blood over typhoid bacilli becomes greatly increased, and the resulting reaction, first brought into clinical use by Widal in 1896, is that ordinarily known as the "Widal reaction." This reaction, like all the agglutinative reactions, is specific in a double sense. The bacilli are thus agglutinated only by the serum of patients recently or formerly infected with typhoid. On the other hand, no bacillus, except the typhoid bacillus, is clumped in high dilutions by typhoid serum. The reaction has therefore a double use. Given a group of bacilli clearly identified as typhoid, we can use them for testing the serum for diagnosis in doubtful febrile cases. Or, given some serum or blood from a case known to be typhoid, we can use this liquid either fresh or dried on blotting-paper as a means of identifying doubtful cultures of bacteria.

The agglutinative reaction has now been shown to be of use, in both the ways just exemplified, as a means of identifying a considerable variety of diseases on the one hand, and of bacterial species on the other. The diseases in which it has been found of value thus far are, first and foremost, typhoid in which its use has been firmly established since 1898. Probably the number of tests performed in this disease exceeds those performed in all of the diseases put together. Next to typhoid, Malta fever and epidemic dysentery of the type due to Shiga's bacillus are the diseases in which the agglutinative reaction between the patient's blood and the specific bacillus of the disease is most frequently performed. The reaction has also been found to be of value in the diagnosis of the bubonic plague, and it is apparently our only reliable means of diagnosis in cases of infection by the so called paratyphoid bacillus, an organism closely allied to, but not identical with, the bacillus of Eberth.

A certain amount of agglutination has also been demonstrated in infections due to the tubercle bacillus, the pneumococcus, the pathogenic streptococci, and various others, but the reaction is not distinct enough to be clinically available. An agglutinative reaction may also be obtained with the serum of cases of glanders, whether in animals or in human beings, but the usefulness of mallein has thus far prevented any widespread application of the agglutination test in glanders.

Technique of Serum Diagnosis in Typhoid Fever.—First of all we must have a culture of the typhoid bacillus identified as such by all known tests. Bacilli that have recently been obtained from a human body are usually preferable. From such a well-identified stock culture, which is best grown on agar-agar, a loopful is transferred to a test tube containing about an inch of sterile bouillon. At the end of twelve hours at room temperature the bouillon will be slightly cloudy owing to the presence of very actively motile bacilli. Such a culture remains fit for use for from twenty-four to thirty-six hours, at the end of which time a loopful of the bouillon culture should be transferred to another tube of sterile bouillon and so on, a new culture being started every twenty-four hours and all being kept at room temperature, not in the thermostat. In order to be fit for use the bacteria must be very actively motile and show no tendency to spontaneous agglutination, such as often occurs in cultures more than thirty-six hours old. Since such spontaneous clumping occasionally occurs even in cultures frequently transplanted, it should be an invariable rule to examine, between slide and cover glass, a drop of the culture to be used, before adding any of the suspected blood. Spontaneous clumping is the most frequent source of error in performing the Widal test, for if we have added the blood of a suspected case without previously examining the culture, and if agglutination is then found, we have no means of knowing whether it was produced by the action of the blood or had previously taken place in the culture.

It should never be forgotten that the reaction is a quantitative one and not a qualitative one. If enough *normal* serum is added to a culture of typhoid bacilli and they be left in contact an hour or two, some agglutination often occurs. The Widal reaction is the occurrence of agglutination in a particular dilution and within a specified time. The dilution recommended by Professor Welch of Johns Hopkins is one part of blood to fifty parts of bouillon culture of typhoid bacilli. Any agglutination which takes place in such a mixture, if accompanied by a cessation of motion within one hour, is considered a positive reaction. In my own work I prefer a dilution of 1 to 10 with a time limit of fifteen minutes. With a longer time limit this dilution often gives rise to mistakes, but among many thousands tests I have known not more than one per cent. of mistakes, provided the short time limit (fifteen minutes) is rigidly enforced.

Either the whole blood or the serum may be used, in fluid condition or dried on glass or glazed paper. The chief obstacle to using dried blood is the difficulty of securing accurate dilution. A full drop of blood should be allowed to fall upon a glass slide and dried. (In this condition it may be preserved for weeks without losing any of its properties, or may be sent by mail in case no laboratory is at hand.) To make the test the dried blood is simply scraped off into a test tube containing ten drops of a bouillon culture of typhoid bacilli. It is difficult to measure the size of the drops accurately, but in a vast majority of cases this degree of accuracy is unnecessary.

The reaction is present in about ninety eight per cent. of all cases of typhoid fever, but in a small proportion of these the reaction does not appear until so late a period of the disease that we cannot use it for diagnosis. In about two-thirds of all cases the reaction is present by the time the patient feels sick enough to consult a physician, that is, somewhere about the end of the first week of the disease. After defervescence the reaction persists in many cases for three or four months, occasionally for years. In a case of this latter type, if the patient is seen for the first time with some febrile affection and without knowledge of his previous history, the agglutinative reaction to typhoid still persisting in the blood may give rise to an error in diagnosis. As a matter of fact, however, I have very rarely known this difficulty to arise.

Technique of Serum Diagnosis on Other Diseases.—*Plague.* Since the bacillus pestis clumps spontaneously in bouillon it has been found necessary (Klein, *Lancet*, June 8th, 1901) to make an emulsion of a small fragment of solid culture in 0.75-per-cent. solution. Cairns (*Lancet*, June 22d, 1901) has made three hundred tests in twenty-four cases by this method, and finds that in all but the mildest and the most rapidly fatal cases an agglutinative reaction appears by the end of the first week in dilution of 1 to 10. This increases until by the eighth week a dilution of 1 to 75 is often insufficient to prevent agglutination. The time limit is fifteen minutes. In hanging-drop preparations agglutination within two hours often occurs in dilutions as high as 1 to 200.

Malta Fever. The test is performed exactly as in typhoid. Agglutination is often found in dilutions of 1 to 100 or more with a one-hour time limit.

Dysentery. The serum of cases studied by Vedder and Duval (*Jour. of Exp. Med.*, February 5th, 1902) agglutinated several strains of dysentery bacillus in dilution varying from 1 to 30 up to 1 to 500 within one hour. Controls with B. coli and B. typhosus were always negative. The reaction does not always appear simultaneously with the symptoms and may disappear in convalescence with great rapidity. The clumps are usually like those in the Widal reaction. Rarely, long loose skeins of bacteria are formed.

II. Serum Therapy.—As already intimated, serum therapy depends upon the fundamental fact that a group of body cells—for example, those of the central nervous system—have a way of rising to the emergency when compelled to defend themselves against a group of foreign cells (*e.g.*, tetanus bacilli) and of producing in excess substances antagonistic to such foreign cells or to their products. Such an antagonism is known as immunity. To be immune against a given cell is to possess the power of poisoning or dissolving that cell. This is known as antibacterial immunity. When the body is attacked, not by cell groups but by cellular products, such as toxins, another type of immunity is produced by virtue of which the blood of the immunized individual is able to neutralize and render inert the toxin molecules.

Either of these forms of immunity may be "natural" or "acquired," that is to say, the blood of many individuals contains substances similar in their action to antibacterial or antitoxic substances, even when the individual has never, so far as we know, been obliged to repel the attack of foreign cells, or, in simpler language, has never had the disease against which he is thus immune. Thus negroes seem to be, for the most part, congenitally immune to malaria, in much the same way as many species of animals are immune to the typhoid bacillus.

Acquired immunity is the result (*a*) of the disease, (*b*) of inoculation with the bacterial cells or the non-cellular toxins which cause the disease, or (*c*) of the inoculation of the body with the serum of persons convalescent from the disease in question or of some animal which has previously been rendered immune to the disease. Immunity acquired as the result of infection, whether accidental or experimental, is known as "*active immunity*." That acquired as a result of the injection of serum from a convalescent or immune animal is called "*passive immunity*."

In the great majority of instances practical serum therapy consists in causing a patient to acquire a *passive immunity* by the means just described, but there are a few examples of serum therapy by which we endeavor to give the individual's blood antibacterial rather than antitoxic power.

The diseases in which serum therapy has been used may be divided for convenience into those in which its utility has been definitely established, those still in the experimental stage, and those in which experiment seems to have demonstrated that by our present methods immunity cannot be conferred. In the first class we may group the following diseases in which it may be considered that serum therapy has come to stay: 1. Diphtheria. 2. Tetanus. 3. Snake-bite. 4. Rabies.

I will subdivide the next class into those diseases in which the outlook for serum therapy is very promising, and those in which it is distinctly less hopeful. Very promising have been the experiments with serum therapy in: (1) Bubonic plague; (2) acute epidemic dysentery; (3) typhoid.

Less promising, but still hopeful, is the outlook in: (1) Cholera; (2) anthrax; (3) scarlet fever.

Unpromising has been the result of our work so far in: (1) Tuberculosis; (2) pneumococcus infections; (3) streptococcus infections.

A few experiments have also been made with sera in Graves' disease (milk of thyroidless goats), epilepsy (serum of epileptics between paroxysms), syphilis, and various other diseases with results thus far inconclusive.

Diphtheria. Antidiphtheritic serum (into the details of its production I cannot here enter) is the serum of horses rendered immune to diphtheria toxin by increasing doses of the toxin administered subcutaneously. Its uses are two: (1) Prophylactic and (2) curative.

Its *prophylactic* value in communities exposed to infection (schools, hospitals, etc.) is very great. The immunity begins about twenty-four hours after the injection and lasts for from three to four weeks. For a young child two hundred and fifty units is a proper dose. For adults a proportionately larger dose is required.

Its curative properties are now established beyond reasonable doubt. By its use the mortality in large contagious hospitals has been reduced from an average of forty-five per cent. to an average of sixteen per cent. (this last figure is based on an analysis of over 200,000 cases by Bayeaux). The mortality is less the earlier the serum is given in the course of the disease. In mild cases 4,000–6,000 units are sufficient. In severe cases 80,000–100,000 units may be needed to save life. The single dose for adults is 4,000–8,000; for children 2,000–4,000, and the dose is to be repeated every four to six hours unless marked improvement shows itself after the first dose.

Urticaria occasionally results from the use of antitoxin in diphtheria and may be very troublesome, but there is no evidence that nephritis, neuritis, or any other severe complication is ever produced by the serum.

Tetanus. Less brilliant than those of antidiphtheritic serum, the results of antitetanic serum are still such as place it far ahead of all other known remedies for tetanus. The great difficulty is to get it into the system sufficiently early in the disease.

Two sera are used: (*a*) that of Behring and Roux; (*b*) that of Tizzoni. The latter has been the more successful, but there is reason to believe that the type of disease is milder in Italy. Pfeiffer* has recently collected the cases treated with Behring's serum and finds a mortality of 52.7 per cent.; in 88 cases treated with Tizzoni serum the mortality was 36.3 per cent.

The Behring serum is used in doses of 20 c.c. every five to ten hours. Of Tizzoni's product (solid) 2.25 gm. are used for the first dose and 0.6 gm. for subsequent doses.

Recently cases have been treated by subarachnoid injections of the antitoxin by means of lumbar puncture, and there is some evidence that this method is preferable. Intracerebral injections have also been employed, but without any evident advantage.

Preventive inoculations with tetanus antitoxin in cases of injury in a community in which tetanus has been prevalent, have resulted in a marked lessening of the number of tetanus cases developing.

Snake Poisoning. Calmette's antivenene, 10–20 c.c., frequently repeated, is a most useful remedy especially for the bites of cobras and colubrine serpents, less so for bites of vipers or rattlesnakes.

Antivenene appears in the serum of horses treated with increasing doses of cobra venom slightly modified by heat. Injected in patients suffering from a cobra bite it neutralizes one of the two poisons present in cobra venom —the nervous poison—and "enables the individual to devote all his vitality to overcoming the local injury" done by the other poison (the irritant) present in the venom. Since the nervous poison is the chief death dealing agent in venoms antivenene is of great value and should be carried by all travellers likely to be exposed to snake-bite.

Rabies. Although the specific poison is as yet unknown, much has been accomplished in the prevention of rabies by injections of what is probably a toxic serum (in all essentials) obtained from the spinal cord of mad dogs. Cords preserved in dry air gradually lose their virulence, and in the treatment of mad-dog bite in the human subject injections are begun as soon as possible after the bite, first with material from cords nearly devoid of virulence and later with material of gradually increasing virulence.

The figures of the Pasteur Institute from 1886 to 1894 include 13,817 persons supposed to have been bitten by rabid animals. The mortality is 0.5 per cent. Allowing for many mistakes in diagnosis we can hardly doubt that these inoculations have been effective, since the mortality of the disease is usually estimated at from sixty to eighty per cent.

Plague. Three sera are in use: 1. The Haffkine prophylactic vaccine. 2. The Yersin "antipest" serum. 3. The Lustig "antipest" serum.

1. According to Haffkine's own reports, the difference in mortality between those inoculated and those uninoculated is from eighty to ninety per cent. As sample results he reports (Proc. Roy. Soc., vol. lxv., No. 418) an epidemic in the Umerkadi Jail: 127 uninoculated; 10 cases, 6 deaths; 147 inoculated; 3 cases, *no* deaths.

The vaccine has no effect on cases in which the disease is incubating at the time of inoculation. The dose is 2.5 c.c. The duration of immunity is not well determined.

In a Russian village Tchistowitch (*Annales de l'Institut Pasteur*, March, 1900) succeeded in stamping out an alarming epidemic by the prophylactic use of Haffkine's vaccine. Its effects are very unpleasant, far more so than those of—

2. *Yersin's serum*, which is used as a curative in cases of plague actually under way. Daily injections of 20–40 c.c. subcutaneously or intravenously have reduced the mortality from thirty-three to thirteen per cent. in Calmette's hands. The serum also conveys a brief prophylactic immunity (twenty-five to thirty days).

Lignière has used 40–60 c.c. at a dose (*Annales de l'Institut Pasteur*, October, 1901) with ninety per cent. of recoveries in cases in which the serum was employed early.

Dysentery. Since Shiga's discovery of the bacillus of acute dysentery in the tropics, Flexner's identification of the same organism in the acute dysenteries of this country, and the discovery of the same organism in the summer diarrhœa of infancy by Vedder and Duval, work upon an antidysenteric serum has been pushed with eagerness. So far, the most definite results are those obtained in Japan and in Manila with Japanese serum from Kitasato's laboratory, but enough work has been done in this country to make it evident that the outlook is not at all unpromising.

Typhoid. The serum used in the vast majority of cases has been an antibacterial rather than an antitoxic serum, and has been administered as a prophylactic, not as a cure.

Wright (*Brit. Med. Jour.*, 1901, No. 2105) reports that among 2,669 uninoculated and 720 inoculated soldiers (Cyprus and Egypt, 1900) 68 of the former and only 1 of the latter contracted typhoid. Birt (*Brit. Med Jour.*, January 11th, 1902) noted at Harrismith (1900–01) the following data: Among 947 cases of typhoid in those not previously inoculated the mortality was 11.25 per cent. Among 203 cases of typhoid in men inoculated six to eighteen months before, the mortality was 6.8 per cent. and the type of disease milder.

Sterilized cultures of typhoid bacilli are the material used for inoculation.

Anthrax. Sclavo (*Berl. klin. Woch.*, 1901, pp. 480, 520) succeeded in obtaining from sheep, subjected to progressive inoculation of anthrax bacilli, a serum efficient

* Pfeiffer: Zeit. f. Heilkunde, xxiii., 2, 1902.

against the disease in sheep and apparently also in human beings. He refers to about twenty cases of human anthrax treated with this serum in various parts of Italy, and states that most of the patients recover.

Cholera. Working in the epidemic of 1891 at Calcutta, Haffkine inoculated with an emulsion of living cholera vibrios some 40,000 of the inhabitants. In one town, of 340 uninoculated, 45 got cholera and 39 died; of 181 inoculated, 4 got cholera and 4 died. Among 18 people living in one house, 11 were inoculated and no cholera occurred in any of them. Seven were not inoculated, 4 of them took the cholera, and 3 died. The inoculations cause a rise of 1° to 2° C., lasting with some constitutional symptoms for twenty-four hours.

Scarlet Fever. That the serum of patients convalescent from scarlet fever seems to exercise a favorable influence on the course of active cases has been noted by many observers (*e.g.*, Huber and Blumenthal, *Berl. klin. Woch.*, 1897, No. 31, and Leyden, *Munch. med. Woch.*, January 18th, 1902).

More recently sera prepared from streptococci isolated from the organs of scarlet fever cases have been used especially by Baginsky (using Aronson's serum) and by Moser, using a serum of his own manufacture. Each reports good results. *Richard C. Cabot.*

SEVEN SPRINGS.—Washington County, Virginia. These springs are located two miles from the Glade Springs. Depôt, on the Norfolk and Western Railroad. They have been known for many years, but no accommodations have as yet been provided for visitors. The waters are used commercially in the form of Seven Springs Iron and Alum Mass, an evaporated residue. An analysis of this mass by Prof. J. W. Mallet, of the University of Virginia, showed the presence of a large proportion of aluminum, sulphate and iron persulphate, besides a considerable quantity of magnesium and calcium sulphate, and numerous other ingredients in smaller proportion. This substance is highly recommended as a general tonic and reconstructive, and is said to possess special merits in such affections as cholera morbus and dysentery, and in various hepatic and intestinal disorders.
James K. Crook.

SEWERAGE AND SEWAGE DISPOSAL.—A system of sewerage is the network of pipes, conduits, etc., constructed for the purpose of collecting and carrying away from a city, town or village, the wastes of human life other than that portion of the wastes which are known collectively under the term garbage. The wastes entering the sewers may come from houses, stores, stables, factories, etc., and, if the sewerage system is constructed upon the so-called combined plan, the sewers will also carry street wash. If the system is constructed upon the so-called separate plan, street wash will be excluded, to be cared for by means of drains built for that purpose. The volume of sewage flowing in the sewers of a town or city of a given population depends mainly upon three things: (1) The consumption of water; (2) the tightness of the sewers, that is, their ability to prevent the entrance of ground water; and (3) whether the sewers are on the so-called separate or on the combined system. In England and upon the Continent, where the consumption of water does not average much more than thirty gallons per capita per day, the average volume of sewage produced by a given population must necessarily be less than in America, where the consumption of water in our largest cities and towns varies from seventy-five to two hundred and fifty gallons per capita per day. Upon the tightness of the joints of the pipes of the sewer system rests a great deal of responsibility in regard to the volume of liquid entering these sewers. By careful construction of the sewers and in some soils the ground water may be almost entirely excluded, but faulty construction in porous soils will often allow the entrance of a volume of ground water sometimes fully as great or greater than the volume of true sewage. In the combined system of sewage the volume of sewage flowing in the sewers is very much augmented at times of storm by the addition of street wash.

After collection in sewers some satisfactory method for the disposal of sewage is necessary. Formerly it was considered sufficient to empty this sewage into some body of water or flowing stream, which would either dilute it sufficiently to prevent visible nuisance, or carry it away from the vicinity of the town or city producing it. This method can still be carried out without offence by fortunately located cities and in sparsely settled countries with large rivers, lakes, and streams. As a country becomes more thickly settled, however, it is not sufficient simply to pass the sewage from its source to a point where it will not cause a nuisance to those producing it, but it must also be cared for in such a way as to prevent it from becoming a nuisance or a source of danger to other communities. On this account and coincidently with the great increase of urban life in civilized countries during the past twenty-five years, the question of sewage disposal has become a most pressing one. So general had the nuisance caused by sewage entering streams become in England as early as 1876, that the Rivers Pollution Prevention Act was passed—a law providing that no rivers or streams should be polluted because of the admission of crude sewage. In the twenty-seven years elapsing since that time there has been a constant agitation in England upon the subject, with an idea to bettering the condition of the rivers and streams, but even now the Act is very imperfectly carried out.

Practically the first agitation of this question in America was in the State of Massachusetts. The report of the State Board of Health for 1876 contained an article by the then secretary of the board, in regard to sewage disposal systems in England and on the Continent, and the same volume contained a report by an engineer of an examination in regard to the condition, on account of sewage pollution, of certain rivers and streams of Massachusetts. Since that date more important investigations upon sewage disposal and purification have been accomplished than during any previous period. An outline of this work, however, with descriptions of the most important methods, is all that can be given here. It is also well to state at this place that in this article little mention can be made of methods of dry disposal of wastes. These methods do not properly come under the head of sewage disposal, but they are methods in vogue in towns, dwellings, public buildings, etc., by means of which the wastes are collected in such manner as to render them more or less valuable for fertilizing purposes; that is, either without having been diluted or mixed with water, or only to a very slight extent. Besides the common middens, privies, etc., many patent processes for the accomplishment of the same result are in vogue in different places, and many processes by which by some means the solid matter of these wastes is, even when mixed with water, separated more or less efficiently from it before the main body of liquid enters the sewers.

The demands made upon modern engineering in complex and difficult sewerage construction are very great, and as a result methods of construction are constantly improving. Sewerage works are increasing enormously, in number, in the area covered by a single system, and in the volume of sewage collected at a single point. The volume of sewage thus collected for disposal by a single city or metropolitan district now often reaches into the hundreds of millions of gallons daily.

Direct Disposal into Bodies of Water, or Disposal by Dilution.—Fortunately located cities and towns can satisfactorily discharge their sewage unpurified into large bodies of water. Where such communities are in close proximity to the seacoast or upon a very large river, the discharge of unpurified sewage into tidal waters or swift currents is still resorted to successfully. The method is practically without expense after the sewerage system is once complete, other than that, in some instances, of pumping. It is efficient if the tidal or other currents are strong and the sewage is prevented in this manner from reaching adjoining shores, and if the volume of water into which the sewage is discharged is large compared with the volume of entering sewage. In some instances, however, even in such locations, some attempt at partial purification is made by collecting the sewage in basins and allowing sedimentation to occur before the discharge of the supernatant liquid; this sedimentation often being aided by the use of chemical precipitants.

Beginning in 1852 the straggling sewers of the city of London were given more definite form, and the sewage of this city was collected and carried by means of sewers to Barking Creek and Crossness, twelve miles below London Bridge. This enormous work was made necessary by the polluted condition of the Thames River. Before this date the sewage was discharged through many sewers directly into the Thames, as the river passed through the city. The greater part of the new works emptying at Barking Creek were completed in 1864, and in 1865 works on the opposite side of the river at Crossness were also completed. Ten years after the opening of these works it became necessary, on account of sewage carried up the river from these outfalls, to build large settling tanks in which the sewage was collected and chemicals were added for the purpose of precipitating the solid matter before discharging the clarified sewage into the tidal estuary. The solid matter resulting from this precipitation is taken out to sea in sludge boats, and the sewage is discharged between high and the middle of ebb tide. During 1901 and 1902 the average volume of sewage discharged daily amounted to 234,508,000 gallons and 47,673 tons of sludge were carried to sea each week. Twenty-two thousand tons of protosulphate of iron and five thousand tons of lime were used during the year.

Boston, Mass., together with the cities and towns surrounding it and composing a metropolitan district, with a population of 1,200,000 and having an area of 187 square miles, collects its sewage into three main systems, all of which discharge into strong tidal currents in the outer parts of Boston harbor. With two of these systems the discharge is continuous, while in the other the sewage is collected in large storage tanks and allowed to pass out on the ebb tide. Two of these points of discharge have been in operation for many years, and, notwithstanding the volume of the sewage, amounting at the present time to about 120,000,000 gallons daily, so efficient is the disposal because of dilution, sedimentation, and the rapid carrying away by swift tidal currents, that well-patronized summer resorts exist within short distances of the points of discharge.

The sewage of Greater New York all empties into New York harbor by means of many sewers, and is so diluted and dissipated by the swift and deep tidal currents that it is well cared for and practically unnoticeable. The sewage of Buffalo enters the Niagara River between Lakes Erie and Ontario. The sewage of St. Louis enters the Mississippi River, as does now the main portion of the sewage of Chicago through the Chicago drainage canal and the Illinois River, and in each instance, on account of the large volume of water flowing in the river, the disposal from some points of view is adequate.

Sewage Farms.—Berlin, Germany, passes its sewage to immense sewage farms, which have been in operation for many years, and are eleven thousand acres in extent; Paris, a portion of its sewage to farms at Gennevilliers and other places, where it is adequately cared for. Many other cities and towns, both in Great Britain and upon the Continent, follow the same method of disposal satisfactorily. This method can be carried out successfully, however, and at a profit to the farm only where the sewage is comparatively rich in organic matter, that is, where the volume of water is small compared with the population producing the sewage. It is with considerable difficulty even then that these farms can be made to return a profit above the cost of operation. It goes without saying that American sewage cannot be disposed of satisfactorily in this manner, being altogether too dilute; and any attempt so to utilize it means generally the use of only that portion valuable for irrigation, with the direct discharge of the remainder, unpurified by filtration through the soil, into the most convenient body of water. Sewage irrigation or farming, however, was the first attempt properly to purify sewage upon land, but having, sometimes at least, for its main object the utilization of the sewage rather than its purification; a profit from the farm being deemed of more importance than purification.

Continual agitation upon the subject of the prevention of the pollution of streams by sewage making a wide-felt demand for a thorough understanding of proper and efficient purification, scientific studies upon this subject were begun practically about eighteen years ago. It had been observed that the passage of sewage through soil not only caused the removal of the suspended matters, but that the matters in solution were also changed or destroyed, that is, they did not appear in the effluent unless in an unrecognized form. The knowledge of germ life and the science of bacteriology having practically its beginning at about this period, it was believed that these changes occurring in sewage were caused by bacterial life in the soil. These first investigations were made by Schloessing and Muntz in France, and Warrington and Frankland in England. Their experiments were upon a laboratory scale and, without attempting to show that bacterial life was present by means of observation, they did demonstrate that, if germicides were added to the filter or to the sewage, purification in the filter did not occur. They also observed that th ir small tube filters, containing the earth, marbles, and other media experimented with, not only purified the sewage, but the filters themselves remained fairly clean, and organic matter accumulated very slowly within them. These investigations were very meagre and not long continued.

Toward the end of 1887, however, the State Board of Health of Massachusetts established an experiment station for investigations upon the subject of sewage purification, and accomplished and published the results of the most important scientific studies that had ever been made upon this subject. This experiment station is still continued. During the past eight or ten years much work along the same lines, but upon a larger scale, has been done in England, practically all of this work being based upon the Lawrence data, with such additions in construction of filters and methods of application of sewage as local needs have suggested. Many of these English studies have been largely carried on by cities and towns with the intention of applying the results directly to their own problem of sewage disposal, and thus have a practical and in some cases limited bearing only, and are without such thorough investigation of the science of the subject as has been aimed at in the long-continued Massachusetts experiments.

Sewage farming having caused the recognition of the fact that it could not be successful except with comparatively small volumes of strong sewage and where land was plentiful and cheap, nearly all the scientific investigations at the Lawrence experiment station have centred upon evolving processes of sewage purification by means of which the largest possible volume of sewage can be efficiently purified upon the smallest possible area and at a minimum cost. These studies have nearly all been upon bacterial methods of purification, that is, the oxidation or purification of the organic matter in sewage by means of the bacteria which establish themselves sooner or later in sewage filters of all kinds. With these studies others have been made in regard to methods for the treatment of sewage preliminary to filtration, which would result in allowing larger volumes to be efficiently purified upon given areas than is possible with untreated sewage.

Theory of the Bacterial Purification of Sewage.—In the purification of sewage by the action of bacteria the process is about as follows: The bacteria in the sewage, in the presence of oxygen, first attack the carbonaceous matters, carbonic acid being formed, nitrogen and hydrogen are set free and unite to form ammonia, this in turn uniting with the carbonic acid, forming ammonium carbonate, which goes into solution. The next step is the oxidation of the nitrogen of the free ammonia, first to nitrous acid and then to nitric acid, by the nitrifying bacteria working in the presence of oxygen. The nitric acid then unites with a base, such as sodium or potassium, present in the sewage or the filter, and sodium or potassium nitrates are formed. These are, in the small amount present, innocuous mineral salts, and appear in solution in the effluent. In this work of the bacteria much of the organic matter is also changed to gaseous forms, and many gases are set free. If filtration through properly prepared filter beds is carried on slowly enough, all the organic matter in the sewage applied to these beds can be changed either to gaseous forms, such as carbonic acid, ammonia, free nitrogen and hydrogen, which escape into the air, or to mineralized bodies, which appear in solution in the effluents of the filters. Such thorough purification as this, however, is not generally necessary, nor is it practicable in many instances, except where the volumes of sewage to be dealt with are comparatively small and where land is cheap.

Intermittent Filtration.—Next to sewage irrigation or farming, in which mere driblets of sewage are generally applied to each acre under cultivation—at Berlin the volume is from five hundred to five thousand gallons—the best results and the best purification can be obtained by filtration through properly prepared filter beds of sand or similar material. In order that good work may be done in such beds they must be constructed of sand coarse enough to allow sewage to enter easily, and the sewage must be applied in such a manner, at such intervals and in such volumes, that it will pass through the entire area of the filter in a fairly uniform manner, and meet an abundance of oxygen within the filter.

Physical Characteristics of Sand Used for Filtration.—At the Lawrence experiment station a method for determining the efficiency of sands in sewage filtration was elaborated from practical experience. By this method the sand is sifted through sieves, these sieves being so calibrated that the approximate size of the sand grains passing through can be easily determined. It was found that the quantitative and qualitative efficiency of sands used in filtration depends to a considerable extent upon the finer particles present. Owing to this, a certain arbitrary standard was adopted, called the "effective size"; this being the diameter in millimetres of the finest ten per cent. by weight of the sand grains. Following this standard, if a sand is stated to have an effective size of 0.25 mm., the meaning is that ten per cent. by weight of the sand consists of grains with an average diameter less than this figure. The determination of the volume of water which a certain depth of sand of a known grade, well underdrained, will hold by capillarity is easily made. The knowledge of these two facts gives adequate data to enable one to foretell the volume of sewage which can be held by a well-underdrained sand filter of a given depth, or, in other words, its time of passage through such a filter when successive applications are made; this having a direct bearing upon the volume that can be purified satisfactorily and successfully upon a given area.

An average sand has about thirty-five per cent. of open space; that is, when this sand is dried and packed as closely as natural, the space between the grains filled with air amounts to about thirty-five per cent. of the total volume of the sand. This percentage of open space differs but little with coarse and fine sand. When a coarse sand, well underdrained, has water applied to it for a considerable period, it will hold but a small portion of this water by capillarity, while each finer grade will hold more and more, until a grade is reached that will hold itself practically saturated to within a few inches of its surface; that is, the open or air space present when the sand is dry will be filled with water.

Rate of Filtration Through Sand Filters.—A sand as fine as this last grade, which will in fact resemble clay, is practically useless in sand filtration of sewage. Any sand, ten per cent. by weight of the grains of which have a smaller diameter than 0.05 mm., is of small value for sand filtration, especially in a cold climate where freezing occurs in winter, although areas constructed of a grade of sand as fine as this can be used if trenched with coarse sand, and if the sewage is applied to these trenches. All grades of coarse sand are valuable for filtration purposes, none being too coarse to effect good results, if the underdrains of the area are placed at sufficient depths and a proper distance apart. A rate of filtration equal to 100,000 gallons per acre per day can easily be maintained upon coarse sand filters with sewage of average strength. On two filters of the same grade of coarse sand the rate that can be maintained depends very largely upon the strength of the sewage; that is, upon the amount of organic matter present in each unit volume of water going to make up the volume of sewage. Many weak sewages from towns having a considerable length of pipes laid but with comparatively few connections, or systems into which ground water enters in considerable volume, can be filtered through sand with satisfactory purification results at rates at least three times as high as the figure given above—that is, if the filters are properly cared for.

Care of Sand Filters.—The care of sand filters is, of course, one of the main points in maintaining permanency of operation. In order that the surface of the beds may not become clogged, much of the matter reaching them in suspension in the sewage either has to be raked up and removed from time to time, or else ploughed under. With a fresh sewage—that is, a sewage where the mixture of filth and organic matter of all kinds with the waste water of the town has just occurred and little time has been given for mechanical, chemical, and bacterial actions to take place in the sewers—we have a liquid containing organic matter in quite a different form from the same matter in the sewage when opportunity has been given for these various actions to take place. A fresh sewage generally contains free oxygen, nitrogen in the form of nitrates and nitrites, the proportion of organic matters in suspension to those in solution is comparatively large, and the matters in suspension are in comparatively coarse particles. When sewage reaches a filter area in this condition, the matters in suspension are easily strained or filtered out upon the surface of the bed and can be removed by raking. If then they are mixed with loam or sand—that is, composted—they cause little or no offense, and even when placed in a heap without mixture with soil or loam, the organic matter generally decomposes so slowly that little, if any, nuisance occurs. As fresh sewage flows along in the sewers and mechanical, chemical, and bacterial forces have a chance to act upon it, the organic matter present undergoes a decided change. The chemical and bacterial change is practically the breaking up of the organic matter into simpler forms, and the mechanical change is the disintegration of the matters in suspension into finer particles. Sewage in this condition—that is, with much of its suspended organic matter either changed to soluble forms or finely disintegrated—is designated as stale sewage, and, when it flows upon a filter bed, much more of the organic matter present in it is carried into the pores of the filter than when the sewage reaches the bed in a fresh state. Upon the surface of beds receiving such sewage, little matter accumulates that can be removed by raking, but the disappearance of this matter by bacterial oxidation can be very much aided if the surface of the bed is loosened from time to time by raking, harrowing, or ploughing.

Method of Operation of Sand Filters.—In order to purify sewage satisfactorily while passing it through sand filters, an abundance of air in the pores of the filter is a necessity. To assure the presence of this air, the application of sewage must be intermittent—that is, it must be applied from time to time and in limited volumes. If we should apply sewage continuously to a sand filter, keeping the surface of the sand covered with sewage, the entire open space in the filter would become filled with liquid, air would be excluded, and those organisms which oxidize the organic matter by working in the presence of air would be either destroyed or rendered unable to work successfully. This fact has often been proved, and is what occurs when attempts are made to purify sewage by passing it in any but very limited amounts through soil or clay—materials useless in sewage purification. Instead of oxidation in such beds, if they are overworked, we have reducing actions occurring, oxygen is taken from the oxides in the soil or clay or sand, and the base of these oxides passes into solution. Putrefaction of the organic matter of the sewage also occurs, with the production of odors, and an effluent often less pure than the applied sewage is the result. In order to prevent this the volume of sewage applied to any intermittent sand filter must be such that under no conditions will the sewage entering the filter exhaust the air present, or keep the surface of the filter covered for too long a period. The volume of sewage which can be applied to filters of coarse or fairly fine sand with good results varies comparatively little, but the method of application should vary considerably if good results are to be obtained. That is to say, with a filter of fine sand the sewage should be applied in large doses as it enters the filter slowly, and when once it has passed below the surface of the sand a considerable period should elapse before another application is made, in order that air may enter the upper portion of the filter. With a filter of coarse sand, into which the sewage enters readily, more frequent applications of a smaller volume of sewage is the preferable manner of operation, in order that the sewage may not pass through the filter too quickly. Much air may be made to enter the filter by this manner of flooding, as the sewage disappears quickly from the surface of the coarse sand. This difference of action of different sands can be modified very much, however, by different distribution of the underdrains. By such equalization as can be obtained in this way a filter of coarse sand may be worked practically in the same manner as a filter of finer sand, and vice versa.

The following table shows first the average results for one year obtained when filtering sewage through two different experimental filters that had been in operation for ten years at the Lawrence experiment station when these results were obtained. One of these filters (A) is constructed of coarse mortar sand and the other (B) of fine river silt trenched with a coarser sand, the coarse filter being operated at a rate three times as great as the fine filter, or approximately 60,000 and 20,000 gallons per acre daily respectively. In the same table are given the results from a third filter (C) of coarse sand, operated at a rate of 300,000 gallons per acre daily, the sewage applied to this filter being of such strength, however, that 300,000 gallons contained no more organic matter than the 60,000 gallons applied to Filter A:

TABLE I.—PARTS PER 100,000.

	Sewage (A and B).	Filter A.	Filter B.	Filter C.
Ammonia—				
Free	3.8200	0.5502	0.0660	0.0404
Albuminoid				
Total	.8000	.0697	.0166	.0306
In solution	.3800	....	....	....
In suspension	.4200	....	....	....
Chlorine	8.4800	8.3600	7.8900	2.8200
Nitrogen as—				
Nitrates	.0000	2.7100	2.9300	1.2500
Nitrites	.0000	.0118	.0009	.0014
Oxygen consumed	3.9000	.4500	.1100	.3400
Bacteria per cubic centimetre	4,760,000	28,800	58	15,800

In calculating the percentage of purification obtained by filtration the common method is to show the removal

PERCENTAGE PURIFICATION.

	Albuminoid ammonia.	Bacteria per cubic centimetre.
Filter A	91.3	99.4
Filter B	97.9	99.9
Filter C	96.2	99.7

or oxidation of organic matter as shown by the determinations of albuminoid ammonia in the sewage applied to and the effluents from the filters, and this is given in this instance in the table below. True purification in sand filtration is by nitrification, and it will be noticed that the nitrogen appearing as nitrates in the effluents of Filters A and B in the accompanying table, accounts for a large part of that present in the sewage as free and albuminoid ammonia.

Sand Filter Areas.—Massachusetts has more sand filter areas for the purification of the sewage of cities and towns than any other State in the country at the present time. These filters are in successful operation, and undoubtedly produce better results in the New England climate than could be obtained the year round by any other method of filtration yet known. At the end of the year 1902 there were fifteen cities and towns in the State, besides many large institutions, disposing of and purifying their sewage upon sand areas. It is well to describe one or two of these areas, with the results which are being obtained from them.

Sewage Disposal System of Brockton.—The city of Brockton has a population of approximately 40,000. The sewerage system was first put into operation in the year 1894, the sewage being conveyed through main sewers to a pumping station on the outskirts of the city. At this pumping station the sewage is received into a covered masonry reservoir, from which it is pumped to the filtration area. In designing this system it was planned to take house sewage only, and to exclude all surface water and as far as practicable all ground water from the sewers. There are several main lines of brick sewers, but the principal part of the system is constructed of pipe sewers. The main sewer, which is brick, is laid in the valley of a river and considerably below the level of the water in that river. On this account at times of high water in the river the surface of the ground in the vicinity of the sewer is flooded. When the main sewer was completed and before any connections had been made, the amount of leakage into this sewer was measured at a time when the water in the stream was low, and the results were as follows: In a section of the sewer about 2,000 feet long the leakage of ground water was found to be about 17,000 gallons per day, or about 45,000 gallons per day per mile of sewer. The entire amount of leakage in the main sewer amounted to about 61,000 gallons per day per mile of sewer, and this has increased, when the meadows along the river are flooded, to about 178,000 gallons per day per mile of sewer; these figures being given to illustrate the amount of ground water which may in some locations enter a well-constructed sewer. The measurements were made in a section of brick sewer of a maximum size, at the lower end, of 23 by 48 inches, underdrains were built beneath the sewers to take care of the ground water, if possible, and particular care was taken in construction to make the sewer tight.

From the masonry reservoir already mentioned, which has a capacity of 619,000 gallons, the sewage passes through screens consisting of iron slats with an open space between them of three-quarters of an inch, and then to the pumps. It is necessary to clean the screens several times each day while the pumps are being operated, and the material removed is burned beneath the boilers in the pumping station. The solid matter which accumulates in the reservoir is stirred up from time to time and pumped to the filter beds, this stirring being done by means of an agitator, consisting of perforated pipes laid on the bottom of the reservoir and connected with the force main through which sewage can be discharged under a head. The force main from the pumping station to the filtration area is a cast iron pipe 24 inches in diameter and 17,500 feet in length. The filtration area comprises approximately thirty-nine acres, on which twenty-three filter beds have been constructed, each having an area of about an acre. The beds were prepared for receiving sewage by the removal of the loam from the surface, and from twelve beds the subsoil was also removed. The sewage is distributed on the beds by means of wooden carriers which are laid across the bed from the centre of one side, so arranged as to discharge the sewage at several points. The grade of sand and soil in these beds differs very widely in different beds and in different portions of the same bed. The subsoil has an effective size of about 0.07 mm., and the effective size of the various grades of sand found varies from 0.07 to 0.75 mm. The underdrains in the filters are laid about sixty feet apart and discharge into two main underdrains. The heavy sewage which accumulates in the bottom of the reservoir is, when pumped to the beds, generally discharged upon a special sludge bed. The average volume of sewage reaching these beds amounts to about 900,000 gallons per day. The average analysis of the sewage and effluent during a certain period is shown in the following table:

TABLE II. PARTS PER 100,000.

	Sewage.	Effluent.
Residue on evaporation		
Total	72.0200	48.3000
Loss on ignition	34.9200	......
Ammonia		
Free	4.7383	.1633
Albuminoid		
Total	0.9058	.0163
In solution	.4983	......
In suspension	.4075	......
Chlorine	10.9100	10.4200
Nitrogen as		
Nitrates	.....	3.1667
Nitrites	.....	.0056
Oxygen consumed	13.0300	.1700

The percentage purification obtained by these beds is about ninety-eight per cent., as shown by the organic matter determined as albuminoid ammonia.

Sewerage and Sewage Filtration at Marlborough, Mass.—Marlborough is a Massachusetts city of about 17,000 people. The sewerage system was constructed in 1891, and was designed to take house sewage only. All the sewage is collected in a system of pipe sewers and conveyed by gravity through a main pipe sewer to settling tanks and filter beds about three and one-half miles away from the city. In constructing the sewers considerable ground water was encountered, and a large amount of this water leaks into these sewers. In this city, in distinction from Brockton, no underdrains were laid beneath the sewers to care for the ground water. The average amount of sewage reaching the beds daily is about 1,500,000 gallons, the amount varying very much at different times of the year. Accurate measurements have shown that the volume during wet months, such as in the early spring, is four or five times that flowing in the dry months of the late summer and early fall. The sewage at the filtration area enters settling tanks, two in number and with a combined capacity of 16,000 gallons. When the average volume of sewage is reaching these tanks, it is about twenty minutes in passing through them, this time being very much decreased as the volume of sewage increases, and of course increased when the volume of sewage decreases. The material which accumulates in these tanks is usually removed about once each fortnight and is discharged upon special sludge beds, where it is allowed to dry, and is then raked up and carried away, this material being used by the farmers in the vicinity as a fertilizer. The sewage in the tanks passes upward through horizontal screens having a one-inch mesh, before its discharge into the carriers leading to the filter beds. There are twenty-six of these beds having a combined area of about eleven acres. In preparing them nearly all the loam was removed, but the subsoil was allowed to remain in place. The beds were originally underdrained by lines of pipe about fifty feet apart, with a depth of from five to eight feet beneath the surface. On account of these drains receiving a large amount of ground water, it was found that their capacity was insufficient to remove both ground water and effluent, and additional underdrains were put into place.

The material in the beds is quite uniform in grade, and has an effective size of about 0.14 mm. The sewage is discharged upon these beds near the corners, and the

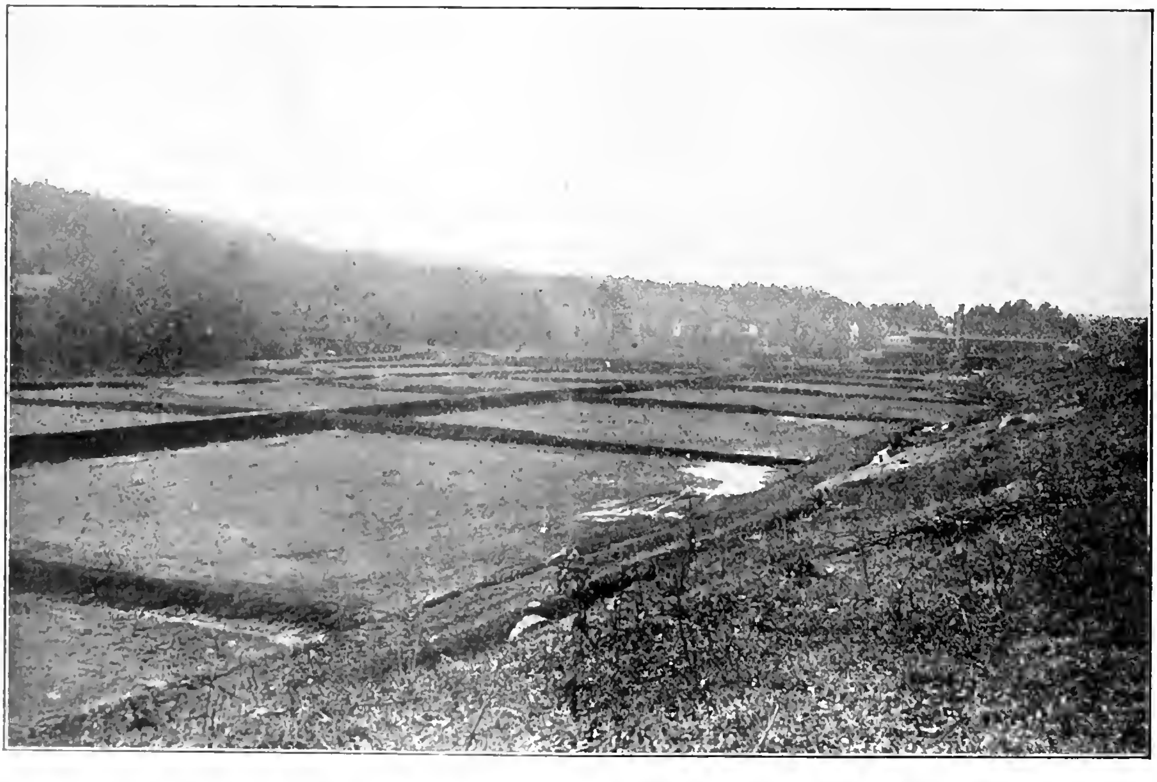

FIG. 4189.—A Massachusetts Filtration Area.

FIG. 4290.—A Massachusetts Filtration Area.

general method has been to turn all the sewage on to one, two, or three beds, according to the quantity flowing, and allowing it to flow upon these beds for twenty-four hours. In wet weather, of course, the flow has to be more widely distributed over the entire area. The sewage is applied to the beds in rotation, and once in about five weeks the surface of each of the beds is raked to remove the surface deposit, and then harrowed and allowed to remain out of operation for a short time; the solid matter which accumulates on the surface being removed before the surface is harrowed. In the fall the beds are ploughed and the surface is left in ridges and furrows, so that the ice forming upon the beds rests on the ridges and protects the sand from freezing, the sewage running in the furrows beneath this ice. The beds receive no attention in the winter in regard to surface management, but in the spring they are raked and then ploughed, harrowed, and graded, and remain level throughout the summer. The average rate of filtration at this area approximates 100,000 gallons per acre daily. The following table gives a fairly average analysis of the sewage applied to and the effluent from this area:

TABLE III.—PARTS PER 100,000.

	Sewage.	Effluent.
Residue on evaporation –		
Total	61.0000	24.8000
Loss on ignition	37.0000	......
Ammonia –		
Free	2.4000	.0203
Albuminoid –		
Total	.5800	.0328
In solution	.2000	......
In suspension	.3800	......
Chlorine	5.8000	5.0000
Nitrogen as –		
Nitrates	......	.5400
Nitrites	......	.0171
Oxygen consumed	3.9000	.3400

The average purification by these beds is about ninety-four per cent.; that is, ninety-four per cent. of the organic matter in the applied sewage does not appear in the effluent from the filters.

Chemical Precipitation.—In the early days of sewage disposal, when it was considered that in most instances the removal of the larger portion of the matters in suspension in sewage was efficient purification, the coagulation of these matters by means of chemical precipitants was a favorite process, and very many costly works were erected in England and on the Continent, to be used in purifying or clarifying sewage in this way. The chemicals most generally used in chemical precipitation are lime, sulphate of alumina, and salts of iron. These chemicals by decomposition form, with other elements present in the liquid, gelatinous bodies like aluminum hydrate, which entangle or coagulate a considerable percentage of the organic matters in suspension in the sewage, together with some of the matters in solution. The specific gravity of the precipitant and coagulated sludge causes more or less satisfactory sedimentation to occur. The supernatant liquid is then run off, and the accumulated sludge either passed to sludge beds or to filter presses, or both. The filter press is simply a machine in which the sludge is placed to undergo compression whereby it is freed from a considerable percentage of its water, while the solid matters are retained by the cloth bagging in which the sludge is placed. Sometimes this sludge, when sufficiently dry, will be carted away by farmers, to be used as a fertilizer, but generally only after having had a very large percentage of its water removed from it by pressing; and more frequently it cannot be disposed of in any way except by the expense (chargeable to the operation of the works) of carting it away to be composted, or used in filling in low ground. This method of sewage treatment is in use in many places in England and on the Continent, and in a few places in this country. Its successful use, however, is generally confined at the present day to such locations as London, England, or Providence, R. I., where all that is at present considered necessary in the treatment of the sewage is the removal of the suspended matters;

this being so at these places on account of their proximity to large bodies of salt water and the opportunity thus offered for the removal and dissipation of the sewage by dilution and tidal currents.

At Worcester, Mass., is a good representation in this country of a well-managed chemical precipitation plant. Worcester is a city of about 110,000 people, the natural drainage of which is into a river which flows through the city. The plant for chemical treatment of the city's sewage was constructed largely in 1891, although additions have been made to it since, as the growth of the city and the increase in the volume of sewage to be disposed of have required. At these works there are sixteen precipitation tanks, about 100 feet long, 66.7 feet wide, and 7 feet deep. When the works were first put into use, the volume of sewage treated was about 3.83 million gallons per day, and in 1901 it was 9.76 million gallons per day. The sewage on its way to the tanks passes through screens, and is there mixed with chemicals. From these screens it passes through a mixing channel to the first precipitation tank and then continuously through the series of tanks, at the end of which it is discharged over a weir. Lime and sulphate of alumina are generally used for precipitation. The sewage, however, is of a rather unusual character owing to the discharge into the sewers of much waste from iron and wire works, in which large quantities of acid are used. On account of this the sewage is sometimes acid and contains sulphate of iron. When in this condition no sulphate of alumina is used, lime alone being added in sufficient quantities to decompose the sulphate of iron and allow precipitation. In the addition of the chemicals they are powdered and then passed through hoppers into agitators, where they are well mixed with a small amount of sewage. From these agitators this sewage containing the chemicals is discharged into the main body at the head of the mixing channel. About one ton of chemicals per million gallons of sewage treated is used. During 1901 the purification effected by this plant was shown by the following table:

TABLE IV.—PARTS PER 100,000.

	Sewage.	Effluent.
Ammonia—		
Free	1.7500	1.6260
Albuminoid—		
Total	.6210	.3180
In solution	.2390	.2620
In suspension	.3820	.0560
Chlorine	9.1800	8.9500
Oxygen consumed	8.6700	4.1000

This table shows that approximately forty-nine per cent. of the organic matter determined as albuminoid ammonia was removed, and about fifty-three per cent. of the organic matter determined by the oxygen-consumed method. By operating the plant in the manner followed at Worcester the volume of wet sludge produced amounts to about 1.5 per cent. of the total volume of sewage treated.

A series of experiments upon the removal of organic matter from sewage by means of chemical precipitation was made at the Lawrence experiment station, continuing from 1890 until 1898, and the results showed that generally about fifty per cent. of the total organic matter could be removed from the Lawrence sewage by this treatment, and a considerably greater percentage of the matters in suspension only. As good results were obtained with the normal alkaline sewage of Lawrence when using one thousand pounds of chemicals per one million gallons as when using a greater amount, and, of the various precipitants tried, sulphate of alumina gave on the whole the best results. The chemicals used in precipitation are of low cost per pound, but when a large volume of sewage is to be treated, this expense amounts to a serious sum. At Worcester during 1901 the cost of operating the precipitation plant was $43,771 or $12.27 per one million gallons of sewage treated, a very large portion of this expense being for the chemicals used and for treatment of sludge.

By chemical precipitation the amount of organic matter present in sewage can be reduced very greatly before the main body of sewage is allowed to run to waste, as the figures already quoted show. The organic matter in solution, however, is affected but slightly by this treatment, and this is really the matter which is in the proper condition to putrefy first—that is, it is the most offensive matter in the sewage as the sewage undergoes decay. On this account clarification by chemical precipitation is but a partial purification at best, and in order really to purify the sewage, a further treatment of the effluent of the precipitation tanks must be resorted to. That is, this is necessary if a stable or non-putrefying effluent is to be obtained. Up to the present time this has usually been accomplished by filtration through sand. Almost with the inception of the work upon chemical precipitation at the Lawrence experiment station sand filters were put into operation to receive the sewage clarified in this way. For example, the supernatant liquid from treating Lawrence sewage with sulphate of alumina, at the rate of one thousand pounds per one million gallons and allowing four hours for sedimentation after the addition of the chemical, was applied for over four years to a sand filter containing five feet in depth of sand of an effective size of 0.17 mm., and at an average rate of 200,000 gallons per acre daily. This rate was from two to three times as great as could have been followed successfully upon the area used if untreated Lawrence sewage had been applied. A well purified, well nitrified, clear, and stable effluent was always obtained, and at the end of the experiment the filter used was in good condition. The upper few inches of sand were somewhat clogged with organic matter at the end of this period, but no more so than was to be expected when filtering sewage at this rate.

At Worcester it has been recognized that the effluent from the filtration plant would not have the desired effect in rendering the river into which the sewage formerly flowed very much less objectionable unless further treatment was given the sewage, especially as the volume of sewage is increasing steadily as the population of the city increases. On account of this, sand filters are being constructed there, upon which a portion of the sewage runs after chemical treatment. At the end of 1901 the city had 14.5 acres of filter beds. These filters received during the year 220,000 gallons per acre daily of partially purified sewage, and when the chemical effluent alone was being passed to them, they were at times operated at the rate of 300,000 gallons per acre daily. Owing to the fact that the Worcester sewage is often slightly acid, the results obtained by these beds have not, of course, been as good as would have been the case if the sewage was alkaline. Nevertheless, they add very materially to the efficiency of the plant.

Mechanical Straining of Sewage.—In the process just described a large body of sludge is formed, this sludge consisting of the precipitated matters, chemicals and water—that is, it consists of about five to ten per cent. of mineral and organic matter, mixed with ninety to ninety-five per cent. of liquid. By filter-pressing the sludge can be further freed from the liquid until the weight of water and that of solid matter are about equal—that is, fifty per cent. of each. This is expensive, however. This fact being recognized, experiments were early inaugurated at the Lawrence experiment station, looking toward some method of freeing sewage so thoroughly from the organic matter in suspension in it, that this matter would contain but a small percentage of water; that is, investigations were made looking toward producing high rates of filtration through sand filters by removing the matters in suspension in sewage as well as or better than by chemical precipitation, and at as low or lower cost per one million gallons of sewage treated. These experiments seemed to indicate that coke strainers could be constructed which would accomplish this result. Accordingly, in 1894 a coke strainer was put into operation, containing six inches in depth of coke "breeze." This breeze is the screenings from commercial coke. Strainers of this sort and of a varying depth were kept in operation for seven or eight years, and resulted in removing from the applied sewage nearly as much organic matter as is removed by chemical precipitation. The organic matter, moreover, removed in this way is left in a semi-solid mass upon the surface of the strainer or in the upper layers of coke, and can be easily removed, together with some of the coke, if necessary, when the strainer becomes clogged on account of its accumulation, and subsequently dried and burned. That is to say, instead of having the suspended matters in the sewage left in the bottom of a tank mixed with a large volume of water—so large, in fact, that it forms ninety-five per cent. by weight of this concentrated sewage—we have these matters practically freed from water.

Such strainers were operated at Lawrence at rates varying from 1,000,000 to 2,000,000 gallons per acre daily. A strainer constructed in 1895 was continued in operation for three years, and during this period the amount of coke removed from it amounted to one inch in depth for each 16,400,000 gallons of sewage strained. It was found later, however, that with a slightly coarser grade of coke as good a removal of organic matter from the sewage could be obtained and with an expenditure of not more than half as much coke as the figures given. As a result of straining through coke, about forty per cent. of the total organic matter in the sewage can be removed, and about sixty per cent. of the organic matters in suspension, varying, of course, with the different grades of sewage. The resulting effluent from a coke strainer can, of course, be purified at a rate of filtration much greater than can be attained with a sand filter receiving untreated sewage. At Lawrence a filter receiving strained sewage was continued in operation for a number of years at a rate approximating 300,000 gallons per acre per day, and the average effluent was about as follows, showing good nitrification and purification:

EFFLUENT OF SAND FILTER.

PARTS PER 100,000.

Color	0.1300	Nitrogen as—Nitrates	2.3800
Ammonia—		Nitrites	.0001
Free	.0145	Oxygen consumed	.2300
Albuminoid	.0207	Bacteria, per cubic centimetre	85.0000
Chlorine	7.0800		

A purification plant of this description has recently been constructed in the town of Gardner, Mass., where the sewage is first passed through a coke strainer with an area of one-half acre, and then to sand filter beds. Strainers of fine anthracite coal in operation at the experiment station have of late done better work upon an experimental scale than coke filters.

Filters of Coarse Material at Rapid Rates of Filtration.—Sedimentation, chemical precipitation, and straining are not, of course, in the true sense proper sewage purification. They are but preliminary methods taken to remove and concentrate a certain amount of the organic matter in sewage, and thus make it possible to filter the main volume at high rates upon sand or other filters. It is only in fortunate localities, however, that sand filters can be constructed at a low cost. In New England in most instances sandy areas are available. Throughout a large section of this country, however, areas of sand are not to be found, and sewage filters must be built on different lines. This is also the condition of affairs in England. Because of this, elaborate studies and experiments have been made of late years upon other means of purifying sewage than by sand filtration: all these methods having, of course, as their main feature the possibility of purifying large volumes of sewage upon relatively small areas. Sand filters are comparatively inexpensive of construction, costing in New England not more than from a few hundred to four or five thousand dollars per acre, according to the locality in which they are built and other conditions. All high-rate filters, however, are of necessity constructed of material, the expense of gathering which together or of preparing it for use varies greatly, and in some instances exceeds the cost of a like area of sand filter beds.

Of the first attempts upon filtering sewage at high rates, the passage of this sewage through aerated gravel or broken stone filters, with nitrification aided by a current of air forced into the filters, appeared to be the most interesting and practical. Such filters were operated at the Lawrence experiment station as early as 1892, and at experimental plants in other places soon after this date. At Lawrence average rates of 500,000 gallons per acre per day were obtained by this method, covering a period of five years, and good nitrification occurred in the filters, the sewage being applied to these filters in small doses at frequent intervals. The effluents of the filters, however, contained much organic matter in suspension and in solution, and the purification obtained was considered only preliminary to sand filtration, or, in other words, it was simply a method for increasing the rate at which sand filters could be satisfactorily operated, but with an idea of destroying, more effectively than could be done by chemical precipitation or coke straining, the organic matters in suspension in the sewage. The highest average rate obtained at the station by this combination of aerated gravel filters and sand filters was 250,000 gallons per acre daily. Owing to the grade of gravel used and the lack of proper underdrainage, these filters clogged badly from time to time, necessitating the removal of filtering material, washing, and replacing. The sand filter also became badly clogged from time to time, necessitating the removal of surface sand. The cost of aeration by means of a forced current of air was considerable. Later studies at Lawrence, moreover, have shown that the method of filtration and aeration followed in the gravel filters, although causing nitrification and thus partially purifying the sewage, undoubtedly rendered the organic matters coming through these filters in suspension in their effluents of a more stable, less easily decomposed nature than when applied in the sewage to the filters. For this reason, when these effluents were applied to sand filters, although the liquid passed below the sand readily and was well purified, these stable matters, instead of being readily passed into solution and nitrified by bacterial action, accumulated within the upper layers of the sand. Disposal plants based upon this method of procedure are, however, in operation in several places in this country with more or less success.

Contact Filters.—Contact filters are sewage filters constructed of any coarse material such as coke, cinders, slag, broken stone, gravel, broken bricks, etc. The method of operating these filters is to close the gate at the outlet of their underdrains, gradually fill the open space of the filter with sewage, allow a period of standing full, then drain, rest for a more or less prolonged period, and again fill. In this manner the entire depth of the filter is brought into contact with the sewage applied each day; that is to say, the entire open space of the filter is filled with sewage daily or even several times daily, and a high rate of filtration obtained. It is evident that filters constructed of these materials and operated in the way outlined cannot produce the results given by good sand filters; in other words, they are not good strainers, and the sewage passes through them too quickly for prolonged bacterial action to occur. Nevertheless, very satisfactory purification results can be obtained by their use, especially if the system of beds is so constructed that double contact of the sewage is given—that is, a system of beds in two sets, all sewage passing through two filters.

In operating these filters the method of filling may be continuous or intermittent; that is to say, the sewage may be allowed to pass into the filter continuously until the entire open space is filled from the underdrains to the surface, or the sewage may be run in at frequent intervals. When the latter plan is followed and the sewage is well distributed, the method introduces more air into the pores of the filter than the continuous method, and better purification ensues. When the effluent flows from the filter, air is drawn into the filter again and fills the open space. It is evident that, if the action of the bacteria upon the sewage in the filter is to be that of oxidation, the sewage should be withdrawn some time before the exhaustion of this oxygen occurs. When the filter is emptied, the oxygen drawn in causes a partial oxidation of the organic matter left within the filtering material, nitrification ensues, and we have a filter really working all the time, although flooded but a portion of the time. If the filter is constructed of rough material, such as cinders, coke, slag, etc., much organic matter is strained out from the applied sewage by being caught on this rough material, to remain in the filter and to become oxidized and nitrified when the filter is empty. Experiments with this class of filters were first made in England.

Long-continued investigations have been made at the Lawrence experiment station studying this class of filter. Filters of different materials have been in operation, different methods of flooding have been followed, and double contact has been compared with single contact. These studies have shown that the best results can be obtained with filters constructed of rough material, such as cinders and coke, that in such filters, when well operated, good nitrification occurs, and that fairly stable effluents are obtained. With filters of broken stone much poorer results are obtained. The rates of filtration followed have reached one million gallons per acre per day with filters of coke five feet in depth, and rates fully as great as this with filters of broken stone. In all these filters there is a tendency for the open space to become clogged more or less with the matters removed from the sewage, thus decreasing the rate of operation, and the prevention of this is the most serious problem presented in the satisfactory and permanent operation of contact filters. In fact, it is quite generally recognized at the present time that, if filters of rough material are to be used successfully in this way for any long period, a larger portion of the matters in suspension in the sewage must be removed as a preliminary to filtration. In the life of filters of this nature, but constructed of smooth material, this preliminary treatment is not so essential, as the material in the filter can be so graded and the underdrains left so open that much of this matter will pass from the top to the bottom of the filter and flow out from the underdrains. Such filters of smooth material, however, do not, as has been said, give as good results as the filters of rough material.

Contact filters are being adopted and constructed in many places, especially in England. At Manchester, England, a plant for the purification of 30,000,000 gallons of sewage per day upon contact filters is now being built, the sewage first being treated in septic tanks which will be spoken of later. To show the purification results obtained by this manner of filtration, the following figures are quoted, giving the average analyses of the effluents of two coke contact filters at Lawrence, operated during 1901 at rates of 910,000 and 850,000 gallons respectively. To the first filter sewage was applied which had first been passed through a coke strainer, and to the second filter sewage just as pumped from the sewer.

Table V. Parts per 100,000.

	Filter No. 1.	Filter No. 2.
Color	0.5200	0.5500
Ammonia		
Free	1.6400	1.7200
Albuminoid —		
Total	.1716	.1842
In solution	.1238	.1250
In suspension	.0478	.0592
Chlorine	11.4600	10.1300
Nitrogen as		
Nitrates	1.3400	.8900
Nitrites	0197	0096
Oxygen consumed	1.0700	1.0600
Bacteria per cubic centimetre	131,500	397,000

The effluents here averaged are somewhat better than can be obtained, generally speaking, by contact filtration. The purity of these effluents, however, does not compare favorably with those which can be obtained by sand filtration. The organic matter present in them is, nevertheless, often oxidized to a more or less stable condition, thus rendering them well enough purified to run to waste at many places.

Septic Tanks.—A septic tank is simply a brick or concrete tank, covered or uncovered, through which sewage passes slowly, allowing time for sedimentation and for the action of those bacteria which disintegrate, hydrolize, and by this means destroy or change organic matter by passing it into solution in the liquid or causing it to escape into the air in the form of gas. On a previous page a statement has been made regarding the difference between fresh and stale sewage. To carry on even further the bacterial action causing this change is the theory of the septic tank treatment. In many instances, however, of so-called septic tanks, the sewage when entering is so fresh and the period allowed in the tank so short that little more occurs toward changing the sewage than that which occurs when the sewage passes through a considerable length of sewer before reaching the filtration area. To explain the action of the tank in other words, we can say that, when oxygen is exhausted from sewage, bacterial life continues active and putrefaction ensues, following the process of decomposition, which occurs in the presence of oxygen. All of the organic matter in the effluent from a septic tank is supposed to be changed by the action of the bacteria to a condition in which it is more easily oxidized by the aerobic bacteria in sand or other filters.

While several claims to the first installation of a tank of this kind have appeared, it was in modern times and under modern studies probably first put into operation in Exeter, England, and soon adopted in other places in that country. Its success or failure as an addition to a sewage disposal or purification system appears to depend largely upon the nature of the sewage to be treated. It is evident from long-continued experiments in Lawrence and elsewhere, that with some sewages passage through the tank is of undoubted advantage in connection with the disposal of sludge, and that the sewage is as easily or more easily purified than without the tank action. Other experiments at Lawrence have shown that there is danger, in the treatment of some sewages in the tank, of so oversepticizing them, so to speak,—that is, of carrying the work of the anaërobic bacteria to such an extent—that the effluent of the tank can be filtered only with considerable difficulty and after good aeration. A small tank has been in operation for five years at the Lawrence experiment station, treating the sewage pumped there, and after these years of use the accumulated sludge within the tank amounts to about thirty per cent. of the tank capacity, the tank not having been cleaned out during the course of the experiment; and further than this, the effluent of this tank has contained only about one-half as much crude organic matter as the sewage entering. The time of passage of the sewage through the tank has averaged about sixteen hours. At a filtration area in Massachusetts a tank was continued in operation for several years, and the sewage reaching this area was really more difficult to filter after treatment in the tank than before. The reason was that the sewage was very rotten when entering the tank, and when issuing from it was of a character which seemed to retard nitrification within the filter, unless thoroughly aerated preliminary to filtration.

The effluent from the septic tank at the Lawrence station has been applied for the past five years to two experimental filters, one of these being an intermittent sand filter and the other a coke contact filter. High rates of filtration have been maintained with each filter. During 1902 the rates and the average analysis of the septic sewage applied to and the effluents from these filters were as shown in the preceding table.

At Manchester, England, very extensive experiments were carried on for two or three years, investigating this process. Tanks with a capacity of 500,000 gallons per day were operated, both covered and closed tanks being used, with little difference in the results obtained, and the city of Manchester is now building a sewage disposal system whereby the sewage will first be treated in septic tanks and then upon double contact filters. At this city in 1900 the volume of sewage to be disposed of reached 30,000,000 gallons per day. From the operation of their experimental tanks it was estimated there that it would be fair to assume that fully thirty-five per cent. of the sludge would not become liquefied in the tanks, but would have to be removed from time to time. That is to say, where they were in 1899 carrying 237,000 tons of wet sludge to sea per year, it was estimated that only about 75,000 tons would have to be carried to sea after the construction of the system; the remaining organic matter being disposed of by bacterial action in the tanks and on the filters.

At Worcester, Mass., this method of treatment has been experimented with for several years, a tank of 350,000 gallons capacity having been used. Through this, sewage has been made to flow at a rate varying from 300,000 to 500,000 gallons per day. The sewage at Worcester is generally acid, but this has not interfered entirely with the tank action, as about twenty-five per cent. of the total solid matter has generally been removed by the tank. The odor from this tank has been very considerable, and also from the beds when this sewage has been applied to them.

Plainfield, N. J., among other places, has recently adopted this system of sewage disposal. This is a city of about 16,000 people, and has the so-called separate system of sewers. It formerly disposed of its sewage on sand filters, but these were not particularly successful owing to the extreme fineness of the sand. Hence a change was made. Two septic tanks have been constructed, fifty feet wide, one hundred feet long, and six feet deep, both being under one roof. The sewage, after it passes from these tanks, goes to a double set of contact filter beds. The average flow of sewage per day at the present time is about 800,000 gallons, and it reaches the disposal plant through a fifteen-inch pipe. At this place it enters a small influent chamber, where the flow may be diverted to either tank. The sewage enters the tanks about two feet above their floor level. In front of the inlets to the tanks are baffle walls, to deflect the flow of sewage and distribute it evenly across the whole width of each tank. The sewage flows from outlet openings, twelve in number in each tank, placed below the surface of the sewage and above the floor of the tank. In leaving the tanks the sewage passes upward over a weir into a channel to the first set of contact beds. Air and light are excluded from the septic tank, but the sewage is supposed to be aerated after passing from the tank by flowing into and through a channel extending the full length of each tank. The gate-house and roof over the septic tanks are of wood, with tar and gravel covering, all the remainder of the construction of the tank and weir being of stone, brick, or concrete. The contact beds are in two sets of four each, the first set being 5.42 feet above the level of the second set. Each bed is ninety-two feet wide, one hundred and six feet long, and five feet deep. On the concrete floor of each bed fourteen lines of four-inch horseshoe tiles are laid, radiated from the gate-chamber, and coarse stone is spread beneath and over them six inches deep. The first set of beds contain, above this coarse stone, three and one-half feet in depth of trap rock, the pieces of rock varying in size from one-fourth to one and one half inches in diameter. The second set of beds are of practically the same depth, but slag and cinders are used as filtering materials instead of the broken stone. Distribution pipes are laid in the upper foot of the material, through which the sewage is distributed over the surface of the beds. The sewage runs continuously from the septic tank through a twelve-inch pipe, built in the top and middle wall of the gate-chamber at the intersection of the division walls. Here it is diverted by wooden gates to each of the four beds in succession. After one bed is filled the sewage is turned on to the next, and so on; the height of the sewage in the beds being indicated by tell-tale balls above the roof of the gate chambers. The sewage remains in each bed an hour or more, is drawn off through a sluice-gate and passes through a pipe to the gate-chamber of the second set of beds, from which it is discharged, after a period of contact, into a brook. Each bed is at rest an hour or more between fillings. Sludge can be drawn from the tanks through eight-inch pipes to sand filters. In a year's operation of this system it was necessary to remove sludge from the septic tanks several times. The price of construction of this system of disposal is said to have been about $40,000.

Intermittent Continuous Filtration.—In the continuation of studies upon rapid methods suitable for the purification of sewage, filters of coarse material have been constructed, through which sewage is passed in a practically continuous stream. The coarseness of the material used in these filters is so great, however, and the rate of application of the sewage to them so regulated, that the surface of the filter is always practically free from sewage, and a large portion of the open space in the filtering material is always filled with air. Such filters may be constructed either of rough material such as coke, slag or cinders, or of smooth material, such as coarse gravel or broken stone. By the method of operation the sewage applied passes in thin streams or layers over the filtering material, and is in contact with air from its entrance at the surface of the filter until it passes away in the underdrains. With a filtering material of such a coarse nature, operated under conditions which assure an abundance of air within the filter, wonderful activity of the oxidizing and nitrifying bacteria is induced, and the production of nitrates is exceedingly rapid. Filters constructed in this manner, containing from eight to ten feet in depth of filtering material, can be operated, on an experimental scale at least, at rates approximating two million gallons per acre daily, and produce a highly nitrified effluent. Much of the organic matter in suspension in the sewage when it enters these filters passes away in suspension in their effluents, but in a very different and inoffensive condition from that in which it exists when applied to the filters. That is, if the filter is well constructed and properly operated, a large portion of this matter adheres for a considerable period to the filtering material throughout the entire depth of the filter, and its more easily decomposed constituents are either passed into solution, or disappear as gas, while the remainder is oxidized to a more stable form. Effluents of successful filters of this class contain organic matter in such a stable form that they are little subject to putrefaction even under adverse conditions, except after a considerable interval, and more often than otherwise they improve in character after issuing from the filter. Their steady improvement is assured if they run into a considerable body of water containing free oxygen. Filters of this class were first put into operation at the Lawrence experiment station in 1899, and have since been studied quite extensively there. Studies upon their operation and the results produced by them have also been carried on in England of late years upon a considerably larger scale than at the experiment station. They have not as yet, however, been installed on any considerable scale for the practical treatment of the sewage of a town or city. Such a filter was operated at Lawrence during 1903 at a rate, at times, of 2,250,000 gallons per acre per day, and produced an effluent often turbid, but always well nitrified and fairly stable. The average analysis of this effluent is shown in the following table, of many analyses made during the year:

TABLE VII.—PARTS PER 100,000.

Rate—gallons per acre daily	1,820,000
Color	.5700
Ammonia—	
Free	1.7400
Albuminoid	.1392
Chlorine	8.6100
Nitrogen as—	
Nitrates	2.7600
Nitrites	.0071
Oxygen consumed	1.0800
Bacteria per cubic centimetre	46,000

Résumé.—In the preceding pages nine methods of sewage disposal or purification have been described, covering the most important methods in use at the present time. They include those methods by which sewage is purified by natural means—that is, by bacteria and air—and which have promise of such developments in the future as adequately to cover all sewage purification problems. The methods are as follows:

1. Disposal by dilution.
2. Sewage farming or irrigation.
3. Filtration through intermittent sand filters.
4. Chemical precipitation, followed by filtration.
5. Mechanical straining, followed by filtration.
6. Filtration through gravel or other filters of coarse material, with forced aeration.
7. Contact filters.
8. Septic tank treatment, followed by filtration.
9. Intermittent continuous filtration.

Summarizing these methods, it can be said that disposal by dilution is extensively practised and entirely satisfactory at such places as those mentioned in the previous text.

Sewage farming is successful in many places, especially with a concentrated English or European sewage.

Filtration through intermittent filters of sand or other fine material is a process which is already extensively used and is certainly destined to be used very largely in the future wherever such filters can be built at a reasonable expense. They are entirely successful wherever used, if the material of which the beds are constructed is suitable, and if such beds are properly operated.

Where a large amount of sewage must be taken care of upon a small area, or where some clarification must be made before sewage is disposed of by dilution, chemical precipitation is of undoubted value and will be used for many years in meeting such problems.

Straining sewage through coke or other materials of a like nature is undoubtedly successful on a small scale, and the future will show whether it can be applied to larger problems.

Forced aeration and filtration through gravel is hardly entitled to serious consideration in this connection, but as it was really the first step in the various processes of rapid filtration, it has been included in the previous text. It can undoubtedly be made practical and of use where the volume of sewage to be purified is small, and where cost is a secondary consideration.

The use of contact filters will increase undoubtedly at places where sand filters cannot be easily or inexpensively constructed. If they are properly built and properly operated, good results can be obtained by their use.

Septic tank treatment is also a proved success in some cases, and will undoubtedly be used much in the future. It must never be considered, however, as it is sometimes now considered by those ignorant of the subject, that the septic tank treatment is a purification. It is simply a clarification, and a preliminary treatment whereby sludge may be destroyed and the sewage may be so changed that either purification is made more easy by subsequent filtration, or the rate of filtration made greater than could be secured without this treatment.

Intermittent continuous filters seem to have very much of promise in them, and they will undoubtedly be adopted more and more at places where sewage must be disposed of upon a small area and where the climate does not interfere with their efficient operation. *H. W. Clark.*

SEX.—In the life history of nearly every multicellular organism there is a time when a new germ (oöspermium, or *zygote*) is formed by the union of two cells (*gametes*) of different aspect. The larger, less mobile of the two cells, is the *macrogamete*, egg, or ovum (*q.v.*), and the smaller more active one is the *microgamete*, spermatozoon (*q.v.*) or its equivalent. The ability to produce a macro- or microgamete constitutes the essential distinction of *sex*. The individual which produces the latter is said to be of the *male* sex, the individual producing the former is said to be of the *female* sex. In most of the higher plants and in a few of the lower animals both sexes are included in a single individual, which is then said to be *hermaphrodite*. The union of dissimilar gametes is the essential feature of sexual reproduction (see *Impregnation*). In many of the unicellular animals, Protozoa, there is a temporary union, or *conjugation*, of similar gametes, during which there is an interchange of part of the nuclear substance. In other Protozoa the gametes are of different size and the union is complete and permanent. Thus in these lowly forms we see foreshadowed the sexual process of the higher organisms.

If our definition of sex be correct, it follows that the quality of sex cannot be an attribute of the gametes, but only of the parent organism, except in so far as the sex of the offspring may be determined by some characteristic of one or both of the gametes. This view is borne out by what is known of the history of the germ cells, which has been shown elsewhere to be identical in all essential features in the two sexes (see *Reduction Division*). The differences between the gametes of the male and those of the female are confined to the cytoplasmic structures, and are associated with a physiological division of labor; the cytoplasm of the egg being more or less laden with food yolk and unprovided with locomotor apparatus, while the spermatozoon has practically all of its cytoplasm modified into a locomotor apparatus, by means of which it may actively seek the egg. This explanation is not in accordance, however, with the views of Geddes and Thomson, who see in the visible difference between egg and sperm evidence of the same differentiation of sex that is found in the adult. They regard sex as a quality of protoplasm. It is for them a question of metabolism. In the female the anabolic processes are predominant, while the katabolic processes are predominant in the male. These characteristics are passed on to the eggs and spermatozoa respectively, and fertilization "restores the normal balance and rhythm of cellular life."

It is difficult to follow the physiology of this conception of sex, for, if the male is predominantly katabolic, one would think it might be hard for him to grow; one might almost expect him to shrink. Havelock Ellis (1894) has gathered the published data in regard to the differences in metabolism of men and women, and he finds differences in certain phases, but the general result is inconclusive. Thus, men have a larger percentage of hæmoglobin in the blood and greater lung capacity in proportion to stature; but, on the other hand, women have a higher pulse rate. It is very probable that in the period of early maturity in women there is less katabolic activity than in men as is shown by the greater tendency to store up fat. But, if the words mean anything, a predominant condition of katabolism is inconsistent with increase of weight or with life itself beyond a very limited period, and therefore can hardly be accepted as the essential feature of "maleness."

We may follow Ellis in dividing the characteristics that distinguish the sexes into primary, secondary, and tertiary. The primary characteristics are those associated with the organs concerned in the production and union of the gametes. And these organs may be divided again into the essential and the accessory reproductive organs. The former are the gonads, called ovary and testis in female and male animals respectively. In low forms, like the jelly-fishes, there are no other reproductive organs. But we need to go very little higher in the scale to find developed accessory organs that assist in the discharge and union of the gametes. Such are the oviducts, the vasa deferentia, and the appendages of these organs. Morphologically these tubes may be modified nephridea, or they may be newly developed structures. In all strictly terrestrial animals and in many of the higher groups of aquatic forms fertilization takes place within the oviduct. This is associated with a marked structural differentiation of the sexes. The male is usually provided with a special organ for the introduction of the spermatozoa. This may be a prolongation of the sexual orifice, forming a penis, or, as in the rays and higher crustacea, it may be in part a modified limb. In the female, on the other hand, the oviduct is either provided with glands to secrete a protective covering for the egg, or is modified to shelter the developing embryo, or even, as in the placental mammals, to nourish it during its fœtal life.

The secondary sexual characters are those that clearly distinguish the sexes without being directly concerned in the reproductive function. Among these characters we may distinguish clasping organs, weapons, ornamentation, voice, and appliances for the shelter or nutrition of the offspring. In a large number of animals, especially among the crustacea and insects, there are to be found special modifications of one or more limbs of the males which serve to hold the female in firm embrace during coitus. Many males are provided with weapons, as tusks, horns, spurs, or the like, which are employed in fighting with other males for the possession of the females. Often the males alone are provided with such weapons, and when they are possessed by both sexes, they may differ in the two sexes. Thus the cow has long, pointed horns adapted for defense against carnivorous enemies, while the bull has shorter, thicker horns, probably more useful for fighting with rivals.

In some cases structures that probably arose as weapons are now developed as ornaments. The most notable examples of this are the antlers of the deer family. In most cases, however, the ornamentation has arisen independently of the weapons, and consists of the most varied forms of coloring and modification of structure. Ornamental secondary sexual characters are found widely distributed among the insects, amphibia, reptiles, birds, and mammals. They are especially conspicuous among the birds. They are usually possessed by the adult males only, and reach their highest state of perfection during the mating season. After this season the deer shed their antlers, and many male birds, like the bobolink, exchange their bright plumes for the sober protective coloring of the female. This exuberance of growth and coloring in the males, together with the song of male birds, and other instances of greater activity, like the superior eagerness of the male in courtship, are taken by Geddes and Thomson as evidence for their conception of maleness as a preponderance of katabolic activity. But they leave out of consideration the fact that these conditions are not always characteristic of the male sex. In the species of phalarope—birds not uncommon on our shores—the female is the more brightly colored, the more pugnacious, and more ardent in courtship; in short, she has all characteristics usually found in a male, except that she lays eggs. The male, on the other hand, is relatively dull colored, is courted by the female, incubates the eggs, and takes entire care of the young.

The characters that we are considering are called ornamental, not because they appear beautiful to us—often they are quite the contrary—but because, according to Darwin's theory of sexual selection, they are supposed to have been developed through the choice, conscious or unconscious, of the courted sex (see *Evolution*).

In man we find ornamental secondary sexual characters in both sexes, which would seem to indicate that the courting is not all done by one sex. The chief of these characters in men is the beard. While women have longer hair on top of the head, and this is associated typically with an entire absence of visible hair on other parts of the body, except on the axilla and pubes. The layer of subcutaneous fat that develops in young women upon reaching maturity, and gives them the characteristic rounded contours of that period, may have become a fixed character of the species by the action of natural selection, owing to its value as a provision for the nutrition of prospective offspring; but, at any rate, it now forms one of the chief ornaments of women.

Sexual differences in the voice or in the method of using it are common, as every one knows, in amphibia, birds, and mammals. Witness the piping of the frogs, the song of birds, and the deep voice of men. Usually the modification of the voice is found in the males, and first appears, as in man, at the beginning of maturity. In fact, it is a general rule that when the male possesses special weapons, ornaments, or peculiarities of voice, these characteristics are not developed until about the time of the first ripening of the spermatozoa, and the immature males resemble the females. For this reason it has been inferred that the female, at least so far as these characters are concerned, represents a more primitive type than the adult male.

Devices for sheltering eggs or young are developed after different patterns in various groups of the animal kingdom, and they are usually confined to the females. Thus in most species of crustacea the female is provided with some means of carrying the eggs until they hatch. The female marsupials have a fold of the skin forming a pouch, in which the imperfectly developed young are placed at birth and are carried there until they are able to run about. The most characteristic organs of the mammalia and the ones from which the group has received its name, the mammæ, or milk glands, are possessed by the females of all species from monotremes to man. While functional only in the females, these organs are present in a rudimentary condition in the males also. Their importance as a means of rearing the young is so great that it has been questioned as to whether they should not be regarded as primary rather than secondary sexual organs. That they are essentially secondary, however, is shown by the practices of civilized women, who have largely relegated them to the position of ornaments—to the detriment of the best races of the human species.

In addition to the well-marked secondary sexual characters that distinguish males and females, there are other usually slight differences that Ellis classifies as tertiary sexual characters. We know very little in regard to these differences in the sexes of the other animals, but, thanks to Ellis, we have in his book, "Man and Woman" (1894), a very interesting and complete summary of these characters, anatomical, physiological, and psychical, in men and women. It would be impossible to summarize even his summary in the limits of this article. We can notice only a few of his conclusions and must refer the reader to the book for more.

Among the anatomical differences women show a greater youthfulness of physical type, as is common among females generally; but they show another anatomical peculiarity not found in other female mammals, and that is an enlargement of the pelvis. This, in the higher races of men, might be regarded as a secondary sexual character. A study of the brain and of the intellectual process in men and women gives the impression that the observed intellectual differences may be as much due to differences of training as to any innate differences between the sexes. In their senses women appear to be less discriminating, but more irritable, and in their emotions they show a greater affectability. Ellis thinks that women are more variable than men, but that this is true for all characters is denied by Pearson.

It is a general rule that in most species the two sexes are approximately equal in number of individuals, but in a few forms in which parthenogenesis is common there may be a large preponderance of females. From the records of 59,350,000 births in European countries Oesterlen (1874) calculated that the normal proportion of boys to girls is 106.3 to 100, and in the single countries the proportion of boys varied only between 105.2 and 107.2.

The following statistics of the numerical proportion of the sexes in other animals were collected by Darwin ("Descent of Man," Amer. ed., vol. i., pp. 293–307):

	Number of cases.	Proportion of males to 100 females.
English race-horses	25,560	99.7
Greyhounds	6,878	110.1
English and Scotch sheep	59,650	97.7
Cattle	982	94.4
Fowls (pure Cochins)	1,001	94.7
Lepidoptera, various species	1,635	122.7

These figures are all taken from records of births except in the case of the sheep, in which the sex was recorded at the time of castration, and in the case of the lepidoptera, in which the sex of the imagos was recorded after emergence from the chrysalis. In the pigeons, which have two young in a brood, there is usually one of each sex, but occasionally both will be males, more rarely both females.

The question as to the factors that determine whether any given individual shall be a male or a female has excited the greatest interest since early times, and it is probable that there is no subject within the domain of biology on which so much nonsense has been written. According to Beard, it has been estimated that there are over five hundred theories, or rather hypotheses, of sex; and still we know practically nothing as to the cause of the determination of sex in the individual. It is manifestly impossible to review any considerable number of these hypotheses within the limits of the present article, and we will confine our attention to a few that deserve special attention because they are either very recent or are founded on experimental evidence.

Waldeyer (1903) divides the hypotheses into three groups which he calls progamous, syngamous, and epigamous. 1. According to the progamous theories the sex of the future individual is determined before the fertilization of the egg from which it is to develop. (*a*) According to some authors the differentiation takes place in the spermatozoon, (*b*) while others think that it is in the unfertilized egg that this occurs. 2. The syngamous theories hold that the sex of the embryo is determined at the time of fertilization, while (3) the supporters of the epigamous theories hold that the zygote and the embryo in its early stages are sexually indifferent, and that the sex is determined by external factors acting upon the embryo during its development.

There is evidence for the progamous determination of sex in the fact that some animals like the rotifer, Hydatina; the worm, Dinophilus; and the plant louse, Philloxera, produce two forms of eggs, the larger of which always develop into females, and the smaller into males. In Dinophilus the eggs are fertilized, but in the other two they are parthenogenetic, and thus in them there can be no question of the influence of spermatozoa. Each female of Hydatina lays normally but one kind of egg, and Nussbaum has shown that if females are well fed from the time of hatching they will produce exclusively female eggs; if poorly fed, male eggs.

Beard (1902) has attempted to formulate a general theory of sex based on the idea of two kinds of eggs. He thinks that sex is determined in the oögonia or in the synapsis stage of the oöcytes (see *Reduction Division*), and denies that the spermatozoa have anything to do with the determination of sex. The basis for this view is chiefly his discovery that in very young embryos of the skate, *Raja batis*, the number of primary germ cells in females is double that in males. His argument, however, is far from clear, and is by no means convincing.

The contrary view, that it is the spermatozoon that determines sex, is expressed by McClung (1902). In certain insects there is found in the primary spermatocytes an accessory chromosome that behaves differently from the others during synapsis. It divides but once during the maturation divisions, and the halves are distributed to two of the spermatids only (*x*, Fig. 3941, in article *Reduction Division*). Thus there are formed two kinds of spermatozoa in equal numbers, and McClung suggests that the ones containing the accessory chromosome are male and the others female, the accessory chromosome not being found in female germ cells. While this hypothesis may apply to the insects in question, it is inapplicable to the forms already mentioned in which the spermatozoa can have no effect.

Allied to these theories is the view that the determination of sex is a phenomenon of heredity. This is not a new idea, but it has been brought out recently again by two authors.

Orschansky (1903) distinguishes two types of families —in one a majority of the children are male, in the other female; and he tries to show that the other characters of the parents, especially predisposition to disease, are distributed among the children in the same way that the sexual characters are. But his conclusions are not obtained by precise methods, although he deals with large numbers.

Castle (1903) attempts to explain the determination of sex on Mendel's theory of heredity (see *Reversion*). His argument is briefly this: (1) Sex is an attribute of every gamete, whether egg or spermatozoon, and is not controlled by environment. It is inherited according to Mendel's law. So the formula for the second generation should be $M + 2MF + F$. (2) But we do not get hermaphrodites usually, nor do we get pure males or females. The characteristics of one sex are always latent in the other. So the actual formula is $M(F) + F(M)$. (3) To explain this it is necessary to assume that a gamete of one sex can unite in fertilization only with a gamete of the opposite sex. (4) But one sex must be dominant and the other recessive or we should get hermaphrodites. It cannot be that one sex is always dominant. So it is necessary to assume that "Dominance, in diœcious species, is possessed sometimes by the male character, sometimes by the female." In other words, it is assumed that some organisms are male and some are female, which is the fact that we were trying to explain,—a good example of circular reasoning, and one not likely to lead us to a definite conclusion.

The only experimental evidence of the syngamous determination of sex is furnished by the bee. As was first shown by Dzieron, whose conclusions have been fully confirmed by Weismann and Petrunkewitsch, the question as to whether a given egg shall develop into a male or a female is determined by its being unfertilized or fertilized. The fertilized eggs develop into females, the unfertilized into males; another case in which McClung's theory would not apply.

Among the theories of the syngamous determination of sex are to be placed those in regard to the effect of the relative age of the parents or of the gametes, the relative sexual vigor of the parents, etc. Statistics have been gathered to show the effect of these factors. But they show at most a slight change from the normal numerical proportion of the sexes, and O. Schultze (1902) concludes from a series of experiments on mice, extending over two years, that these factors have no effect in the determination of sex. Included in this group is also the once much-heralded theory of Schenk. He thought that the sex of the zygote depends on the relative vigor of the gametes, and sought to influence this by improving the metabolic condition of the mother. His results were obtained from experiments on two or three women only, too few to afford a basis for sound generalization.

There is considerable evidence for the epigamous determination of sex by the state of nutrition of the embryo or larva. One of the earliest experimenters in this field was Mrs. Mary Treat, of Philadelphia. She divided a brood of caterpillars into two lots, and during the period between the last moult and the pupa stage one lot was well fed and the other was kept on the lowest possible diet. When the imagos emerged she found in the starved lot seventy-six males and three females, while the well-fed lot produced four males and sixty-eight females. These results were confirmed by Landois, who experimented on a thousand caterpillars of Vanessa; but doubt has been thrown on these results by Poulton, who finds that starvation produces a much higher death rate among females than among males.

Similar conclusions to those of Mrs. Treat and Landois were obtained by Yung from experiments on tadpoles. He found that normally about fifty-seven per cent. of the tadpoles developed into females. By feeding one lot with beef he raised the percentage to seventy-eight; by feeding a second lot with fish he raised the percentage still higher to eighty-one per cent.; and by feeding with the flesh of frogs he obtained as many as ninety-two per cent. of females. But these experiments, like the others, have been criticised by Pflüger and other writers as being inexact, possible factors beside nutrition having been neglected.

However, in the fresh-water polyp, Hydra, which is usually hermaphrodite, Nussbaum found that by good feeding he could stimulate the exclusive production of ovaries, and that in the ponds in the fall, when the food is becoming less, he found a greater number of males. Moreover, we know that in the plant lice sex is correlated with the condition of the food supply.

There are a good many experiments to show that in the lower plants sex may be regulated by food in the same way. On the other hand, Strasburger holds that it is impossible to influence the sex of diœcious phanerogams after the seed is formed from which the plant is to develop.

Whatever are the influences that determine sex they act primarily upon the essential reproductive organs, which in turn form the necessary condition for the development of the secondary sexual characters, as is shown by the effect of castration. If the gonads are removed before maturity the appropriate secondary sexual characters fail to develop, as in the familiar cases of horses, oxen, and capons. Moreover, diseases or removal of these organs after maturity affect the structure of the secondary sexual characters. Castration is employed sometimes by surgeons to reduce an hypertrophied prostate, and in women and in hens disease or removal of the ovaries has been observed to induce a partial development of latent male characters. How the gonads influence the rest of the body is not known, but from analogy with the thyroid gland, it is supposed to be by means of an internal secretion.

SEXUAL ORGANS, FEMALE.—The female organs of generation comprise the two genital glands or ovaries that produce the sexual elements, the two oviducts that convey them, the single uterus that protects them after impregnation, and the single vagina and vulva that serve as organs of copulation (see Fig. 4191).

Development.—Originally the male and female organs are indistinguishable, both being developed out of an undifferentiated form. In many lower vertebrates the genital gland, the oldest and primary organ, empties its products (ova, spermatozoa) directly into the peritoneal cavity, whence they pass out by means of openings in the belly wall called abdominal pores. In the next higher forms these become associated with other organs of elimination and removal. Tubular canals termed *nephridia* communicate with the peritoneal cavity by means of a funnel-shaped opening or *nephrostome*, each having also a side branch that envelops an arteriole, thus forming a glomerulus and becoming an excretory duct for urine. The nephridia are, originally, arranged metamerically and are therefore sometimes called segmental organs. This arrangement gradually disappears by the increase of the canals which come to be assembled in distinct organs, successively developed; the *pronephros*, or head kidney, very simple in structure, the only functional urinary organ in amphioxus, persisting throughout life in some fishes, but disappearing early in man, and the *mesonephros*, primitive kidney or Wolffian body (Caspar Friedrich Wolff, 1735–94), which appears behind the pronephros, and which likewise consists of a series of nephridial tubules to each of which a glomerulus is attached, and which open into a duct (segmental duct, Wolffian duct) that, in common with the intestine, discharges into the cloaca, a short receptacle for excreta just above the anus.

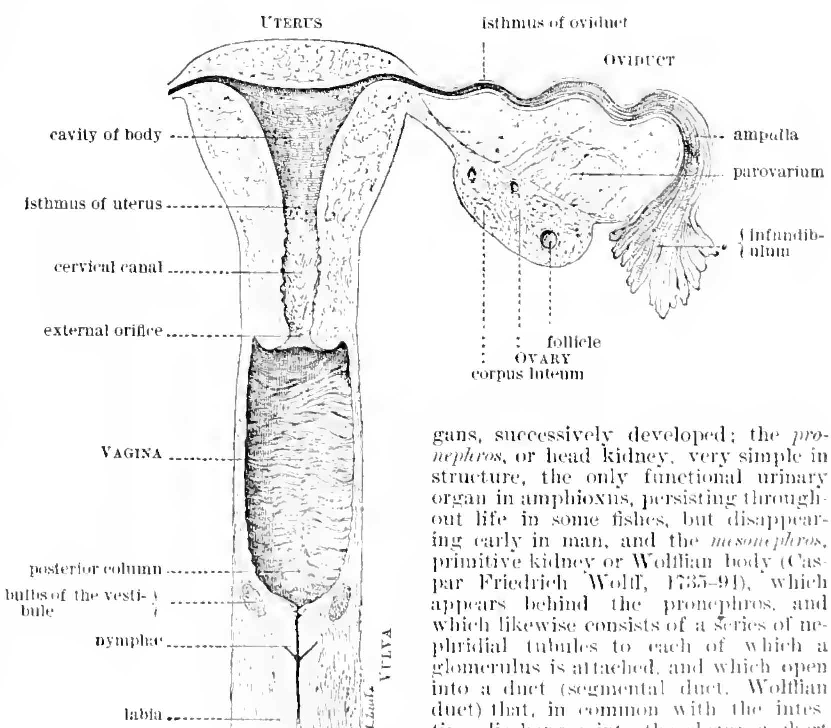

FIG. 4191. Diagrammatic Frontal Section of the Female Genital Organs passing through the Orifice of the Vagina. The oviduct and the ovary are lifted up. (Henle, modified by Rieffel.)

In some fishes and amphibians the Wolffian body remains throughout life a functionally active urinary organ, and, in amphibians, carries on the duplicate function of urinary organ and genital duct. In the higher vertebrates the

urinary function is taken on by the permanent kidney and the Wolffian body, as such, atrophies, portions of it remaining, however, as ducts for removing the sexual products.

The first rudiment of the genito-urinary apparatus is the genito-urinary ridge (Fig. 4192, *P.gén.*), a thickened, longitudinal band of epithelium that appears in the em-

FIG. 4193. Wolffian Body and the Genital Gland. Human embryo 17 mm. long. bryo of the fifth week near the spine and the primitive mesentery. This gradually increases in size, assumes an oval form, and detaches itself from the body wall as the Wolffian body (Fig. 4193, *R.pr.*) with its excretory duct (Fig. 4193, *C.W.*). Close beside this duct and following the same general course there develops a second tubule, Müller's duct (Johannes Müller, 1801–58) (Fig. 4194, *M*). It has a nephridial character, opening into the abdominal cavity by a nephrostome (Fig. 4194, *m'*), but has no glomerulus connected with it. In the female it becomes the oviduct; in the male it soon atrophies, only vestiges of it remaining. It is the Wolffian duct, however, that atrophies in the female, a trace of it remaining as the ductus epoophori longitudinalis, and the duct of Gärtner.

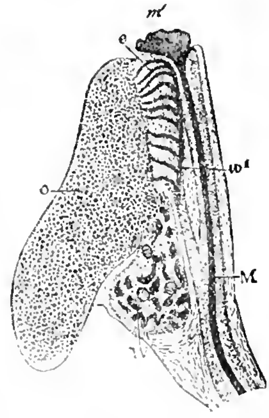

FIG. 4194.—Longitudinal Section through Genito-urinary Ridge of Human Female Embryo of about Fourteen Weeks (3.5 in. long). (Waldeyer.) *o*, Ovary; *e*, tubes of upper part of Wolffian body forming the epoophoron; *W*, lower part of Wolffian body, forming paroophoron; *w'*, remnant of Wolffian duct; *M*, Müller's duct; *m'*, its funnel-shaped peritoneal opening or nephrostome.

Not all of the genito-urinary ridge goes to form the Wolffian body. A portion of it, along its ventral aspect, is destined to form the genital gland proper. This portion is termed the genital ridge or fold, and is covered with large-celled epithelium (germinal epithelium) that produces the essential sexual elements, ova or spermatozoa. In mammals, the Wolffian body atrophies in large part, the genital ridge assumes an oval form and becomes either an ovary or a testis. A vestige of the upper part of the ridge becomes, in the female, the suspensory ligament of the ovary; a vestige of the lower end becomes, in the male, the gubernaculum of the genital gland (ligamentum genitoinguinale), which, in the female, becomes attached to Müller's duct where the latter crosses over it, and thus becomes divided into the ligament of the

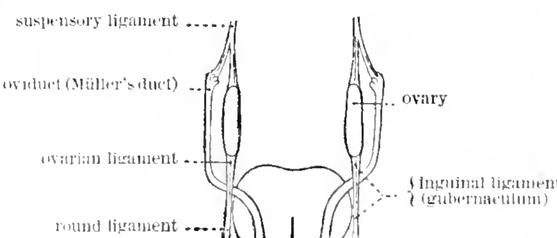

FIG. 4195. Scheme showing the Genesis of the Primitive Broad Ligament or Mesonephridium. From a human embryo 5.5 cm. long. (Fredet.) Müller's duct should pass *over* the inguinal ligament. The mesonephridium stretches longitudinally from the diaphragm to the inguinal region on each side of the pelvic cavity, ensheathing the structures shown in the diagram.

ovary and the round ligament of the uterus, which pass respectively from the ovary to the uterus, and thence to the groin.

As the Wolffian and Müllerian ducts converge from either side toward the median line, they become united in a common cord, the genital cord, and, before reaching the cloaca, the Müllerian ducts blend in a single passage which, by enlargement and thickening of the walls, becomes the uterus and the vagina. Occasional traces of the Wolffian duct are found along the sides of these organs, forming the so-called duct of Gärtner, described by the Danish anatomist Gärtner in 1822 in the sow, but previously noted in 1681 by Malpighi in the cow.

Sexual Organs.

The genito-urinary ridge, like the rest of the walls of the body cavity, is covered over with peritoneum. As the Wolffian body becomes detached it is still held to the walls by a fold of peritoneum—the *mesonephridium* of Waldeyer, which invests both the free portions of the Wolffian and the Müllerian ducts and the upper part of the genital cord (Figs. 4195, 4196, and 4197). The mesonephridia of opposite sides are therefore continuous with each other across the median line, and, as the Wolffian body atrophies and the uterus develops, there is thus formed the large transverse fold of peritoneum known as the broad ligaments of the uterus, which invest the remains of the Wolffian body, the ovaries, the oviducts, and the upper part of the uterus.

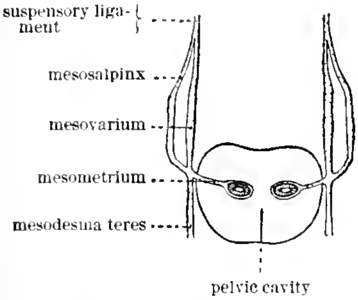

FIG. 4196.—Diagram of Section of the Mesonephridium at its Base. (Fredet.) The duct of Müller descending into the pelvic cavity forms a primitive mesometrium.

A change in the position of the ovary occurs, arising from the difference in the growth of the ovarian attachments and that of the general body. This, the "descent of the ovary," is analogous to the descent of the testis in the male, but is not usually so complete, because of the interposition of the uterus by the attachment of the gubernaculum thereto (Fig. 4197). It places the organ in the pelvic cavity. Rarely it has been known to proceed along the course of the round ligament of the uterus and reach the interior of the labium majus, the analogue of the scrotum of the male.

In the female there develop, from the deeper layers of the germinal epithelium, cells of two kinds, one of which, large, with reticular nuclei, becomes the sexual cells or ova; others, smaller and more cubical, surround the former and separate them from the invading mesodermal connective tissue. The sexual cells form, at first, chaplet-like strings known as egg columns or Pflüger's tubules (E. F. W. Pflüger, born 1829); later these are broken up, each sexual cell forming, with its investing elements, a primitive follicle or ovisac (Fig. 4198).

The cloaca or common passage into which the intestine and the genito-urinary ducts discharge is at first closed from the exterior by a thin partition termed the cloacal

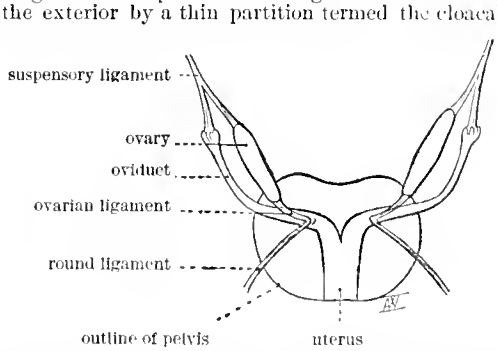

FIG. 4197.—Diagram showing Formation of the Permanent Broad Ligament. (Fredet.) The mesodesma suspensorium (peritoneum around suspensory ligament), the mesovarium, the mesodesma teres (peritoneum around round ligament), and the mesosalpinx, which form at first a continuous fold on either side (the primitive broad ligament) are drawn together and united across the middle line (mesometrium) by the union of the ducts of Müller. The oviduct should pass *over* the round ligament.

membrane, extending from the rudimentary coccyx forward, and marked by a slight depression of the exterior surface known as the cloacal fossa (Fig. 4199). In front of this there forms a conical outgrowth known as the genital eminence (*eminentia genitalis*) which increases rapidly in size and forms at its top a rounded projection (*tuberculum*

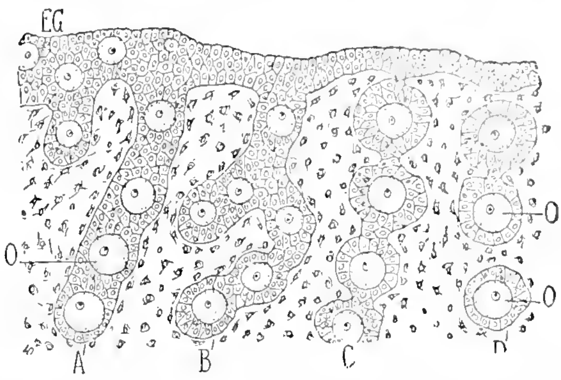

FIG. 4198.—Egg Columns or Pflüger's Tubules, showing the Divers Phases in the Production of the Ovisacs. (Duval.) *EG*, Germinal epithelium with the primordial ovisacs; *A*, egg column or tubule of Pflüger in its primitive state; *B* and *C*, tubules assuming a chaplet-like form; *D*, breaking up of the chaplet, the ovisacs become independent; *O, O, O*, ova.

genitale) that becomes, later, either the clitoris or the glans penis (Fig. 4199). Behind this occurs a slit-like depression of the cloacal membrane, the urogenital cleft (*rima genitalis*) bounded on each side by two folds, the inner genital folds (*plicæ genitales*), which finally become, in the female, the nymphæ and the frenulum of the clitoris.

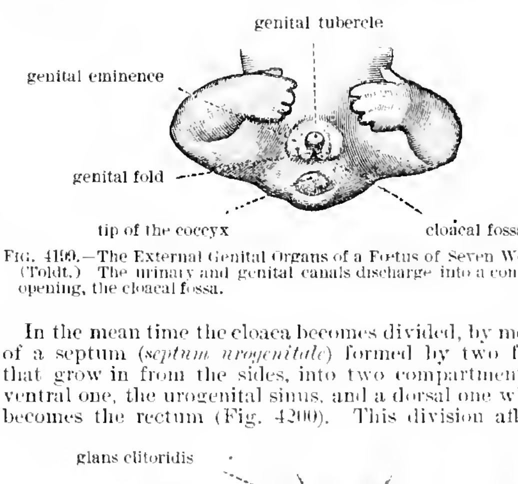

FIG. 4199.—The External Genital Organs of a Fœtus of Seven Weeks. (Toldt.) The urinary and genital canals discharge into a common opening, the cloacal fossa.

In the mean time the cloaca becomes divided, by means of a septum (*septum urogenitale*) formed by two folds that grow in from the sides, into two compartments, a ventral one, the urogenital sinus, and a dorsal one which becomes the rectum (Fig. 4200). This division affects

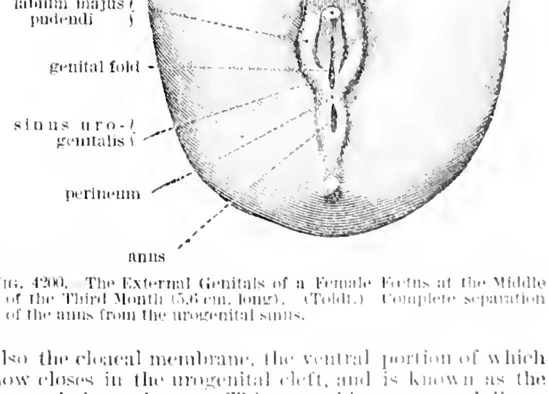

FIG. 4200. The External Genitals of a Female Fœtus at the Middle of the Third Month (5.6 cm. long). (Toldt.) Complete separation of the anus from the urogenital sinus.

also the cloacal membrane, the ventral portion of which now closes in the urogenital cleft, and is known as the urogenital membrane. This soon thins away and disappears so that the cleft opens immediately into the uro-genital sinus.

There now arise, at the base of the genital eminence on either side, two rounded folds, the outer genital or labio-

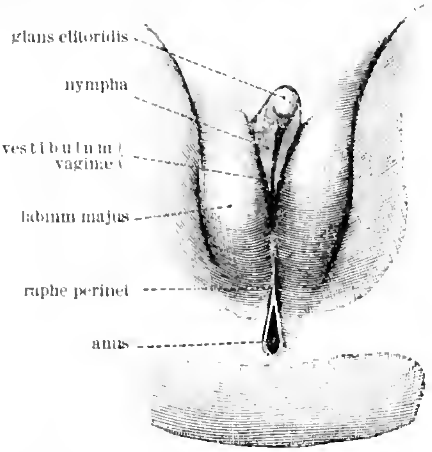

FIG. 4201.—The External Genitals of a Female Fœtus at the End of the Fifth Month (11.5 cm. long). (Toldt.)

scrotal folds (*tori genitales*), which extend backward as far as the anus and join each other in front around the genital eminence. These become the labia majora of the female or the scrotum of the male (Fig. 4201).

THE OVARIES.—*Etymology.*—From the Neo-Latin *ovarium*, a derivative from *ovum*, an egg. Greek, ὠοφόρον, from whence many compounds arise, such as *oophorectomy*, *oophoralgia*, *oophoritis*, etc. French, *ovaire*; Italian, *ovario*; German, *Eierstock*. The name was first used in 1667 by the Danish anatomist, Nil Stensen, who supposed the ovisacs to be ova. The ancients, recognizing their analogy to the male genital glands, called them testes muliebres.

History.—The Alexandrian anatomists probably knew them, and they were described by Soranus of Ephesus (A.D. 117) who considered them as useless bodies, and also by Galen, who supposed them to secrete a female semen, very fluid and "cold," which was conveyed to the uterus by the oviducts. Athenæus (A.D. 69) denied this, as did afterward Fallopius. It was, however, generally held up to the time of De Graaf, who, in 1672, insisted that their proper use was to generate ova, to nourish them, and to bring them to maturity.

The ovisacs were known and mentioned under various names by Vesalius, Fallopius, Bartholinus, and others. Jan Van Horne, professor at Leyden, was the first to call them *ova*, and thus emphasize the egg producing function of the ovary. The veritable ovum was not discovered until 1827, when von Baer described it.

Definition.—The organs of the female, in which are developed the ova, or essential sexual products. They differ from ordinary secreting glands in that they do not form new products, but merely develop and mature structures that already exist in them, in a rudimentary condition, at birth.

Form.—The human ovary (Fig. 4202, *4*) is a solid, almond-shaped body, about 4 cm. long by 2 cm. wide and 1 cm. thick ($1\frac{1}{2} \times \frac{4}{5} \times \frac{1}{3}$ in.) in the adult (Fig. 4203); in childhood and old age considerably less. It may vary from this typical form and be disc-like, cylindrical, triangular, or irregular. The right ovary is slightly larger than the left. The attached edge of the ovary is nearly straight, the free edge usually curved. Its extremities, also called poles, are distinguished as inferior, or uterine, and superior, or tubal, the latter being attached to the infundibulum of the oviduct.

Color.—This is a soft, dull, reddish-gray, like that of a mucous membrane, easily distinguished from the smooth, glistening appearance of the neighboring organs due to their peritoneal covering. The peritoneum, forming the broad ligament and the mesovarium, abruptly ceases at the attached edge of the ovary at a crenulated line (Fig. 4203, *1*, Farre's line; Arthur Farre, physician of London, *circa*, 1840), and the organ presents its bare surface in the abdominal cavity, being the only one that, in the strict sense of the word, is within the peritoneal sac. The reddish tint increases during the hyperæmia preceding menstruation and decreases after the menopause.

Consistency.—Although in youth quite dense and resistant to pressure, the development of the vascular tissue in the ovaries is such as to make them slightly spongy, and at puberty they are not as firm as the testes of the male. Their density increases after the menopause. Before menstruation the surface is smooth, but afterward the development and rupture of the ovisacs produce on the surface elevations and depressions that have been compared to those of a peach stone or to the convolutions of the brain (*ovarium gyratum*, Abel).

Weight.—This naturally varies with the size of the ovary, being 50–60 cgm. at birth, 4 or 5 gm. at puberty, 6–8 gm. in the adult, and decreasing gradually to a gram or less in old age. It is thought that a rapid increase of weight occurs from the hyperæmia of the menstrual period.

Attachments.—The cavity of the pelvis is transversely divided into two compartments by the broad ligament, a fold of peritoneum that encloses the uterus and the oviducts. The ovaries are attached edgewise to the postero-superior surface of this fold by a short peritoneal duplicature termed the *mesovarium* (Fig. 4202, *c*, Fig. 4203, *2*), which is continued upward from the superior pole of the ovary as a triangular band, the suspensory ligament (Fig. 4201), containing the ovarian vessels and nerves, some unstriped muscular fibres, and a long fimbria from the

extremity of the oviduct (Fig. 4202, *7*). At the inferior pole is attached the ligament of the ovary (Fig. 4202, *5*), a fibro-areolar structure containing some muscular fibres, that extends in the folds of the broad ligament to the

uterus. The ovary has considerable mobility, turning, hinge-like, around its mesovarian margin, and is also subject to displacement by a stretching of its attachments and the dragging of the broad ligament itself, which is affected by the position of the uterus.

Situation.—Varying greatly in weight under different normal conditions and at different periods of life, it is not surprising to find the ovaries varying also in position. This is influenced by a variety of conditions, such as posture, pregnancy, the state of repletion of the bladder and rectum, and inflammatory conditions which may cause adhesions between the ovary and the surrounding viscera. However, in the adult female, when the uterus is normally placed, the ovary, if not affected by repeated pregnancies or by pathological conditions, usually lies in a nearly vertical position (Fig. 4204) in a shallow depression, the fossa ovarica, on the lateral wall of the pelvis, in the acute angle made by the superior vesical (hypogastric) artery externally, and the ureter and uterine artery internally. Anteriorly it is sustained by the shelf-like broad ligament. The oviduct, bending around its lateral and medial surfaces and upper end, leaves a pouch-like depression of the broad ligament between itself and the ovary, which is termed the bursa ovarii. The external iliac vessels and the psoas muscle lie to the outer side of the fossa ovarica, and under its floor, covered by peritoneum and surrounded by subperitoneal fat, run the obturator vessels and nerve, these separating the ovary from the obturator internus muscle. In a standing position the mesovarian margin looks forward and outward, but is concealed by the oviduct. Its free margin looks inward and backward toward the rectum and is in relation with the ureter.

Often the ovary is not easily seen upon casual inspection of the pelvic contents. A line connecting the two ovaries lies behind the body of the uterus when that organ is in its normal position. Therefore, when the ovary, by increasing in weight, stretches its attachments, if not adherent it usually falls into the recto vaginal pouch.

Referred to the exterior of the body the site of the ovary is usually behind a point on the abdominal wall about two inches medially from the anterior superior spine of the ilium. The sagittal plane that cuts it is midway between the spine and the symphysis. The frontal plane tangent to the promontory either cuts it or passes close behind it, while the frontal plane corresponding to the ischiatic spines passes considerably behind it. Horizontally, it is above the lesser sciatic foramen and on a level with the infrapyriform foramen and the upper margin of the acetabulum (see article *Pelvis*).

The ovary may be reached by both vaginal and rectal examination. In the vaginal method the patient is placed in dorsal decubitus with the thighs flexed, and one or more fingers, pushed into the posterior cul-de-sac of the vagina, explore the pelvic wall. With the other hand the surface of the abdomen is depressed over the region above described as the site of the ovary. The internal border of the psoas may usually be made out as a rounded ridge, and the ovary will be found to the inner side of this, and may usually be grasped between the internal and external fingers.

Structure.—A section of the ovary (Figs. 4205, 4206) shows that besides its investing epithelium (derived from the germinal epithelium of the embryo) its substance, or stroma, may be divided into an external, cortical, or ovigenous layer, crowded with small round bodies, varying in size from that of a mustard-seed to that of a pea; and

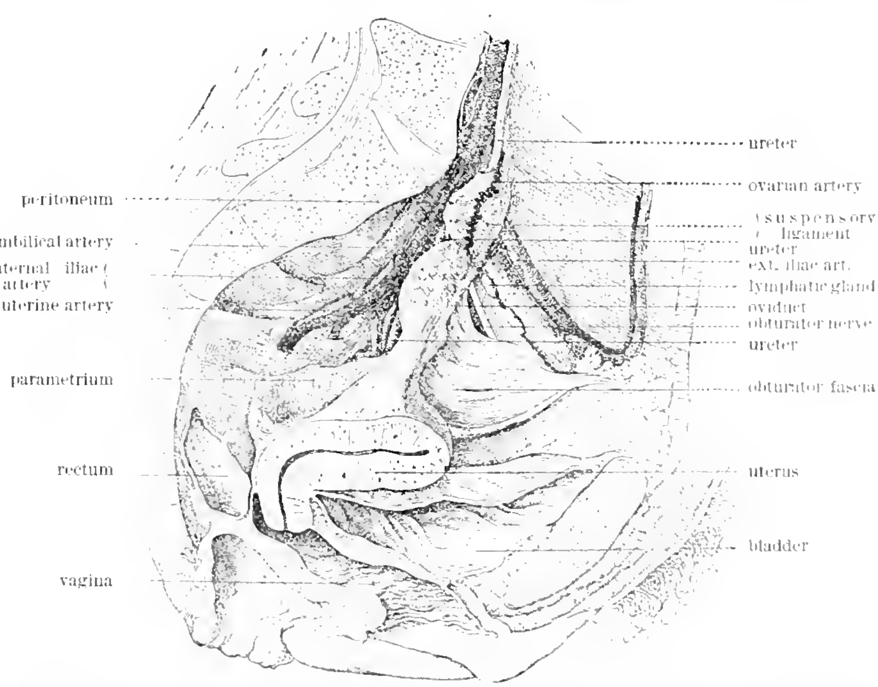

FIG. 4204. Median, Antero-posterior Section of the Pelvis of an Adult Female. (Rieffel.) The uterus is low and very near the coccyx. The anus is gaping, the vagina open and the bladder much spread out. The peritoneum is removed in front and behind the suspensory ligament of the ovary, to show the subjacent organs. The ovary is in place.

a medullary layer rich in vessels and nerves, with spindle-shaped connective tissue cells, some elastic fibres and plain muscular tissue. The round bodies are the ovisacs (Figs. 4205, 4206, 4207—Graafian follicles, from the Dutch anatomist, Regnier de Graaf, 1641–73), already mentioned as derived from the epithelial layer. The smaller ones (primordial ovisacs, *A A A*, Fig. 4206; *A*, Fig. 4207) contain no fluid, but the larger ones are distended by an al-

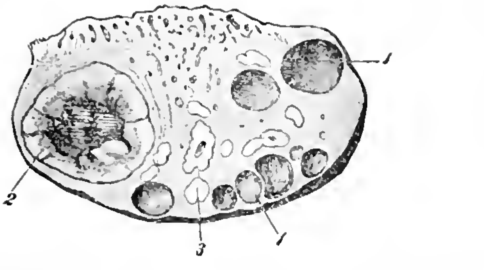

FIG. 4205.—Section of a Human Ovary. (Nagel.) 1, Ovisac; 2, corpus luteum; 3, corpus albicans (several such are seen on the surface of the section).

buminous liquid, the *liquor folliculi* (7, Fig 4207). Within each ovisac is a large sexual cell or ovum, surrounded by a layer of smaller cubical cells that form an epithelial investment termed the membrana granulosa. The larger ovisacs have a distinct connective-tissue investment (*theca folliculi*) derived from the stroma and richly supplied with blood-vessels. This consists of two layers, the *tunica externa* and *interna* (4, 5, Fig. 4207). The former blends with the surrounding stroma; the latter is composed of cells resembling those of embryonal connective tissue, many of which are large, rounded, and infiltrated at maturity with yellow granulations (4', Fig. 4207). These have been termed lutein cells, and are believed to be connective-tissue cells transformed for the nutrition of the follicles.

The liquor folliculi is secreted from the membrana granulosa, whose cells multiply and come to be arranged in several layers, surrounding the ovum, which remains single, always attached to the side of the follicle by an accumulation of the cells (*cumulus oophorus*, Fig. 4207, 6.) The ovisac continues to swell, both by the multiplication of the granulosa and by the increase of fluid, and thus gradually pushes its way outward and appears on the surface of the ovary as a fluctuating vesicle. Blood vessels ramify abundantly on its walls, except at a superficial pole called the *stigma*, where they are wholly wanting. It is at this spot, and probably from some increase of vascular tension, that the vesicle finally ruptures. Preceding this the granulosa attaching the ovum to the wall of the vesicle becomes softened, probably by invasion of lutein cells, and, at the rupture, the ovum with a portion of the cumulus adhering to it is thrown out of the sac. Some slight hemorrhage from ruptured capillaries occurs into the empty sac. This act is known as *ovulation*.

At birth the ovary is crowded with primordial ovisacs. Waldeyer estimates their number at 100,000, while some observers place it much higher, Sappey noting a case in which they exceeded 1,000,000. Most of them degenerate, however, there being not more than 30,000 or 40,000 at puberty, and but few of these ever come to maturity. Olshausen could find but from 50 to 100 follicles visible to the naked eye in an adult female. They entirely disappear after the menopause.

Corpora Lutea.—Some of the follicles that thus abort acquire a certain degree of development before disappearing, and, without rupturing, form, apparently by a multiplication of the lutein cells, a yellowish body known as a *corpus luteum* (*corpus luteum atreticum*). In completely matured and ruptured follicles, the formation of a corpus luteum is much more marked (Fig. 4208). It is produced by a hypertrophy of the walls of the follicle, these becoming imbricated and vascularized about the

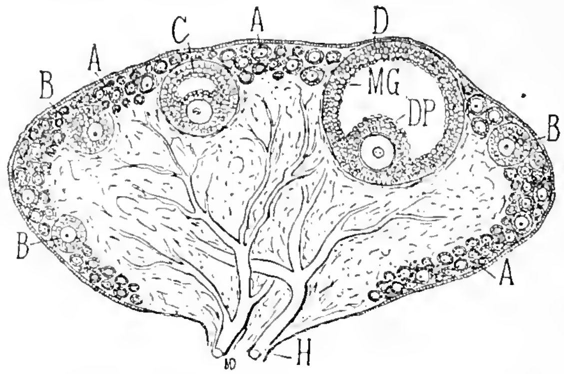

FIG. 4206.—Diagrammatic Section of the Ovary showing its Cortical or Ovigenous Layer, Formed of Ovisacs in various Stages of Evolution. (Duval.) *A, A, A*, Primordial ovisacs; *B, B, B*, ovisacs further developed; *C*, ovisac approaching maturity; *D*, ripe ovisac with its proligerous disk (*D P*) containing the ovum; *M G*, membrana granulosa; *H*, hilum of ovary.

central clot, which contracts. The folds finally become united with each other and a yellowish body is formed, having a size considerably greater than that of the original ovisac. If pregnancy intervenes after the discharge of the ovum, the corpus luteum persists during a greater part of the period, and usually attains a great size (*corpus luteum graviditatis, corpus luteum verum*); but if there is no pregnancy it begins to atrophy, and disappears in the course of two or three weeks (*corpus luteum menstruationis, corpus luteum spurium*). It was formerly believed that certain information regarding a pregnancy could

Sexual Organs.

be obtained from examination of the corpora lutea, but this is not strictly correct, for the structure of the two is identical, and cases have been noted in which the corpus luteum of menstruation equalled in size that of pregnancy.

On microscopic examination it is found that a corpus luteum is made up of very large cells with rounded angles, having an appearance very like that of liver cells. These are lutein cells, so called from granules of a yellow substance found within them, associated with fat and known as lutein. The tunica externa of the theca remains, and there develop from it radiate septa that extend throughout the body to a central nucleus, representing the site of the original clot, where crystals of hæmatoidin are often found. By fatty degeneration and absorption the lutein cells finally disappear; the connective tissue contracts to a whitish mass (*corpus albicans*), and finally to a fibrous remnant (*corpus fibrosum*), which is at last also removed by hyaline degeneration.

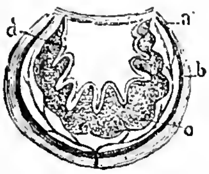

FIG. 4208.—Diagrammatic Section of a Recent Corpus Luteum. (Balbiani.) *a*, Ovarian stroma; *b*, tunica fibrosa or external layer of the ovisac; *c*, internal tunic hypertrophied and folded; *d*, remains of the membrana granulosa. *e*, vessel supplying the ovisac.

Observers are not fully in accord as to the origin of the lutein cells. Sobotta, after very careful observations on the mouse, concludes that they are of epithelial origin, arising from a hypertrophy of the granulosa (Fig. 4209), and in this he is supported by Bischoff, Pflüger, and many others. Another view, is that they are of connective-tissue origin, arising from the cells of the tunica interna, and that the granulosa wholly disappears. Observations on abortive ovisacs seem to support this view, which is warmly defended by Clark, Minot, Paladino, and others. The matter cannot be definitely settled until human material, showing the earlier stages, is more fully investigated.

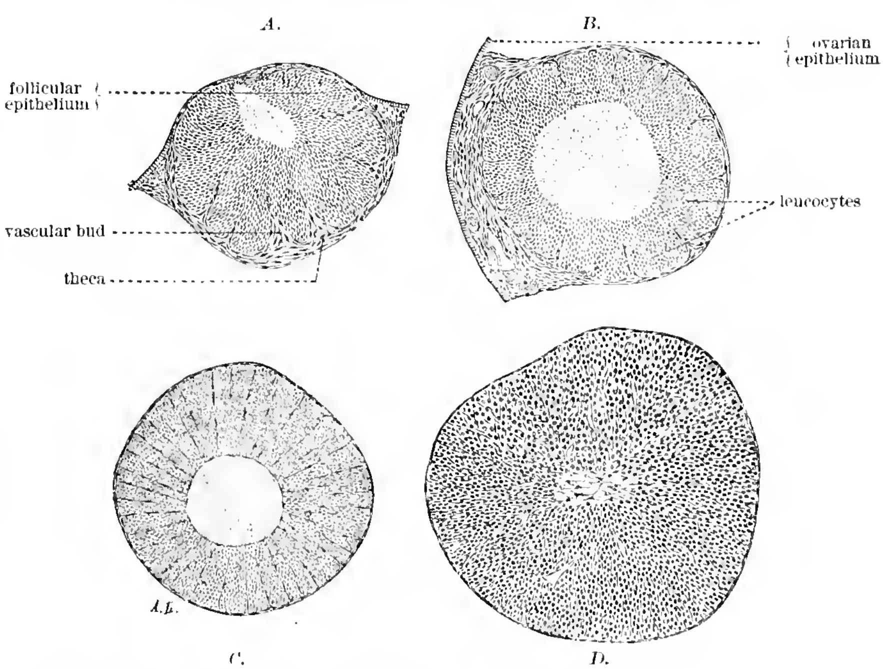

FIG. 4209.—Formation of the Corpora Lutea according to Sobotta. Four successive stages in the mouse. *A*, Vascular budding of the tunica interna invading the hypertrophied follicular epithelium; *B*, the vascular buds converge toward a central cavity. Between them the follicular cells, which are rapidly multiplying, are arranged in columns. Among these cells leucocytes are found. *C*, A more advanced stage; the columns are now narrower and the trabeculæ more numerous. *D*, The central cavity is now occupied by a gelatinous connective tissue; the trabeculæ, by anastomosing with each other, have destroyed the columnar arrangement of the lutein cells.

The function of the corpus luteum has been the subject of much discussion. Born, struck with the resemblance of its structure to that of the suprarenal capsule, advanced the hypothesis that the organ is a ductless gland that modifies the blood so as to produce the changes in the uterus necessary for the encapsulation and subsequent nutrition of the ovum. He argued that the corpus luteum is much larger than would be necessary for the mere restoration of the ovarian tissue, and that the growth of the uterus during pregnancy is not due to distention by the growing ovum, but is accompanied by profound structural changes, which may be initiated without the ovum being in the uterus at all, as in the well-known case of extra-uterine pregnancy. Further, mammals that have a placenta which becomes firmly attached to the uterus have a well-developed corpus luteum, while the aplacental mammals (monotremes, marsupials) have only a rudimentary one or none at all. Fränkel and Cohn found that in rabbits the removal of both ovaries within six days after copulation always prevented pregnancy. According to this view, the corpus luteum of menstruation may have an effect upon the restoration of the uterus.

Clark and others contend that the organ is required to maintain the peripheral circulation and proper surface tension in the ovary by preventing the formation of cicatricial tissue at the point of discharge of the ovum. If each rupture of an ovisac were followed by a typical scar, the entire surface of the ovary would soon be reduced to inactivity.

Arteries.—The ovary is supplied by the ovarian artery, which arises from the abdominal aorta just below the renal arteries, and descends by a flexuous course into the pelvis through the suspensory ligament of the ovary, its long course being explained by the fact that the ovary was primitively an abdominal organ. It gives off a tubal branch that supplies the fimbriated extremity of the oviduct, ten to fifteen ovarian branches, and is continued to make a free, anastomotic loop with the uterine artery. During pregnancy, when it is greatly enlarged, it is an important supplementary source of supply for the rapidly growing uterus. The small ovarian branches penetrate the ovary along its attached border, the place of entrance, which also serves for veins, nerves, and lymphatics, being called the hilum. Their course is helicine or corkscrew-like, not only in the broad ligament, but also in the substance of the organ. In the medullary portion they form the rich anastomoses which cause this to be named the vascular zone; and at the confines of the cortical and medullary portions they form imperfect arcades from which arterioles are given off which pene-

like those of erectile tissue. In the hilum, mesovarium, and neighboring folds of the broad ligament the veins form a vascular protuberance called by Rouget the bulb of the ovary, and believed by him to have some function in ovulation. Leaving the broad ligament, the veins unite to form the pampiniform plexus and finally discharge into the uterine and ovarian veins.

Lymphatics.—These are very numerous. They originate in the stroma and about the ovisacs, some of the smaller sacs being often nearly surrounded by a lymph sinus. Converging to eight to ten trunks, they pass out at the hilum, accompany the vessels and discharge into glands situated in front of the aorta.

Nerves.—These are derived from a sympathetic plexus that is given off from the renal plexus and accompanies the ovarian artery. The exact terminations are imperfectly known. They have been traced to the walls of vessels, to smooth muscular fibres, to the surface epithelium, and to the tunica interna of the Graafian follicles.

Vestigial Structures.—There remain within the ovary, in the folds of the broad ligament and elsewhere, certain vestiges of the fœtal condition of the organs that it is necessary to briefly mention. These are as follows:

The *epoophoron, parovarium,* or *body of Rosenmuller* (Fig. 4210, *B*, Fig. 4211) consists of six to twelve nearly parallel tubes containing a clear fluid, which are found within the folds of the mesosalpinx. They converge toward the hilus of the ovary, and may in young animals be traced into its substance (see Fig. 4210 *B*, *C.s.*). Toward the oviduct they end in a longitudinal canal, the remains of the Wolffian duct. They represent vestiges of the sexual part of the Wolffian body, and are homologous with the seminiferous tubules and vasa efferentia of the male.

The *paroophoron* is a similar series of tubes found in the broad ligament nearer the uterus, and representing the unused urinary part of the Wolffian body (*Glm*, *A*, Fig. 4210). They are of a yellowish color and usually disappear early.

Gärtner's Canal.—This is the remains of the lower part of the Wolffian duct occasionally found in the wall of the uterus and vagina. It is homologous with the vas deferens of the male.

Hydatids of Morgagni.—In about twenty per cent. of subjects there is found connected with the infundibulum of the oviduct, usually with the ovarian fimbria, a small hollow cyst known as the hydatid of Morgagni. Similar structures may be found in the folds of the broad ligament in connection with the epoophoron. Their homologies and origin are obscure.

THE OVIDUCTS.—*Etymology.*—From the Neo-Latin *oviductus*, derived from the Latin *ovum*, an egg, and *ductus*, a leading, a passage. Greek, σαλπιγξ, from whence many compounds, such as *salpingitis*, *salpingotomy*, etc.; French, *oviducte, trompe uterine;* Italian, *oviduto, tromba de Falloppio;* German, *Eileiter, Muttertrompete.* The name was first used by De Graaf, about 1672. The older anatomists styled them *vasa deferentia.* Often called the Fallopian tubes, from Gabriello Falloppio (1523–62), professor at Ferrara, Pisa, and Padua, who compared their expanded ends to that of a brazen *tuba* or trumpet. This name was first given them by Riolanus about 1618. In the nomenclature of the German Anatomische Gesellschaft they are known as the *tubæ uterinæ.* Some authors restrict the term oviduct to the genital passages of animals possessing no uterus. There seems no good reason for this.

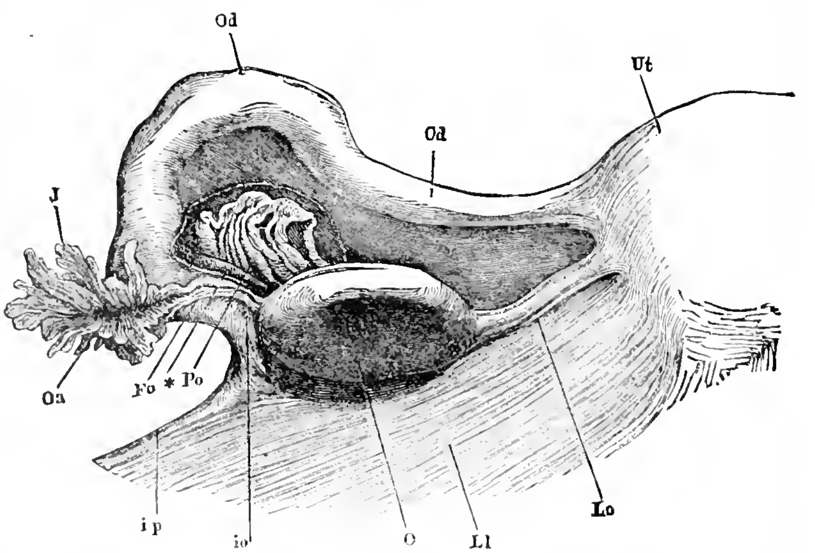

FIG. 4211. View of Lateral Angle of Uterus with Broad Ligament from Behind. (Henle.) *Ut*, Uterus; *Ll*, broad ligament; *Od*, isthmus of oviduct; *Od'*, ampulla of oviduct; *J*, infundibulum; *Oa*, abdominal opening of oviduct; *Fo*, ovarian fimbria; *ip*, suspensory ligament; *Po*, epoophoron laid bare by removal of part of the posterior lamella of the broad ligament.

History.—They were probably known to Herophilus

Sexual Organs.

(335–280 B.C.). Eudemus (290 B.C.) described the fimbriated extremity. Rufus of Ephesus demonstrated them in the sheep about A.D. 50. They were generally supposed to convey the product of the ovary, the hypothetical female semen. Fallopius showed that they did not closely connect with the ovaries, and considered that "fuliginous vapors" exhaled from the uterus through them into the abdomen. Others supposed them to be spiracles through which "spirits" could pass from the mother to the fœtus.

Definition.—Paired tubular structures, extending from near either ovary to the uterus, by which the mature ova are conveyed from the peritoneal cavity to the latter organ. They differ from the ducts of secreting glands in being detached from the organ whose products they are intended to convey.

Form.—The general shape of an oviduct (see Fig. 4191) is that of a gradually expanding, sinuous trumpet, extending laterally from either angle of the uterus, of which it appears to be a continuation. This is even more striking in the lower animals, in whom the fusion of the Müllerian ducts is not so complete, and who consequently possess a bicornuate uterus.

Divisions.—Starting from the uterine cavity we may distinguish (Figs. 4191 and 4202): (1) a uterine, intramural, or *interstitial* portion, passing through the walls of the uterus, in which the lumen of the duct is reduced to very small dimensions; (2) the *isthmus*, a narrow, comparatively straight portion, having no well-defined limit, but generally reckoned as about one-third the length of the duct; (3) the *ampulla*, an enlarged, sinuous portion which terminates by (4) the *infundibulum* or *fimbriated extremity*, a funnel-shaped expansion surrounded by a fringe-like border by which the duct opens into the peritoneal cavity. The junction of the infundibulum with the ampulla, sometimes slightly constricted in young persons, is occasionally called the *neck*.

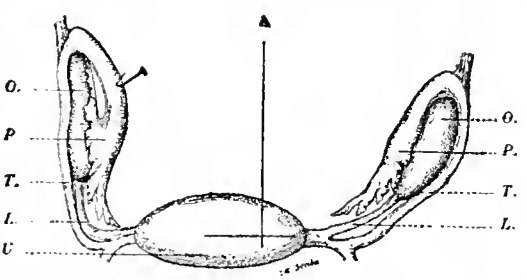

FIG. 4212.—Relations of the Ovary and the Oviduct. (His.) *O*, Ovary; *P*, infundibulum; *T*, oviduct; *L*, ovarian ligament; *U*, uterus. The annexa are held up by the suspensory ligament. The fundus of the uterus deviates somewhat from the median line.

The uterine orifice is small, inextensible, and often stopped by a plug of mucus. It is practically impossible to catheterize it, and fluids injected into the cavity of the uterus do not readily pass through it. The abdominal orifice is larger and extensible. It is said to be closed in tubes cut from the living, but open after death. We may, with Waldeyer, consider the oviduct according to the directions which its different parts assume. A *horizontal* portion extends from the angle of the uterus outward and a little backward to the inferior pole of the ovary, an *ascending* portion, nearly at right angles to the preceding, which mounts vertically along the pelvic wall and the mesovarian margin as far as the superior pole, and a short *descending* portion which makes an acute angle with the latter, passing downward and inward, forming the so-called tubal loop, the infundibulum embracing the internal face and posterior border of the ovary (Fig. 4212). These portions are, however, by no means of fixed dimensions, as they depend largely upon the position of the uterus and upon the various influences that may displace the ovary and the folds of the broad ligament. The oviduct, with its attached peritoneum, often so covers the internal face of the ovary that that organ is not perceived when the pelvic cavity is opened.

Dimensions.—The following table shows the principal measurements of the oviduct:

Average length	12 to 14	cm.
Minimum length	6	"
Maximum length	20	"
Length of interstitial portion	1	"
Length of isthmus	3	"
Length of ampulla	8	"
Length of infundibulum	2	"
Length of ovarian fimbria	2.5 to 3	"
Length of other fimbriæ	1 to 1.5	"
Calibre of uterine orifice	.05 to .1	"
Calibre of interstitial portion	.05	"
Calibre of isthmus near uterus	.3	"
Calibre of ampulla, maximum	.8	"
Calibre of peritoneal orifice	.2 to .3	"
Thickness of walls, average	.2 to .3	"

At its uterine termination the tube so gradually expands into the cavity of the superior cornu that its exact point of termination is difficult to determine.

Attachments.—Continuous with the angle of the uterus at its inner extremity, the oviduct lies in the superior or free edge of the broad ligament, hereafter to be described, and is attached at its lateral end by one of the fimbria, longer than the others (ovarian fimbria, *fimbria ovarica*, Figs. 4202 and 4203), to the suspensory ligament of the ovary. The triangular fold of the broad ligament that encloses it is known as the *mesosalpinx* (Fig. 4202, *b*). At its extremities the duct shares the movements of the organs to which it is attached, while its intermediate portion may move independently, its freedom depending upon the length of the duct and the laxity of the mesosalpinx.

Interstitial Portion.—In nulliparæ the oviduct is clearly seen to be a contracted continuation of the superior cornu of the uterus, and the narrowest point is not at the uterine orifice, but a little beyond. In multiparæ, however, the orifice is the narrowest portion. While passing through the uterine wall the duct is slightly bent with downward concavity. A layer of connective tissue separates it from the uterine substance proper.

Isthmus.—This resembles the vas deferens in its cord-like, resistant character and cylindrical form. It lies in the para-uterine fossa of Waldeyer, the round ligament of the uterus being before and below, the ovarian ligament and tubo-ovarian artery behind.

Ampulla.—This portion, slightly flattened from before backward, has a thinner wall and softer consistence than the isthmus. It is slightly irregular in calibre, with flexuosities which are more marked in the young. Its loop runs in front of the ovarian vessels and its descending branch is close against the external iliac vein.

Infundibulum.—This funnel-like expansion (Fig. 4202, *c*) is cut into twelve to fifteen laciniate, fringe-like processes or fimbriæ, and is hence often called the *fimbriated extremity*. The French, carrying out the similarity of the duct to a trumpet, call it the *pavillon*, a name also applied to the flaring mouth or bell of a trumpet. The ancients compared its gnawed appearance to the premorse root of the *Scabiosa succisa*, popularly known as the "devil's bite," the legend being that the arch enemy, angered at the good done by the medicinal virtues of the root, attempted to destroy it by biting it off, but only succeeded in leaving a ragged edge showing the marks of his attack. It is from the resemblance of the infundibulum to this root, and not from any evil influence it was supposed to exert, that it was called the *morsus diaboli*. It has also been compared to the corolla of a flower with a double row of petals (Henle), to a crinoid or sea-lily (Nagle), and to a medusa head.

The single fimbriæ are lanceolate, ovate, or filiform, not infrequently with irregularly notched edges, so that there may arise fimbriæ of the second or third order. Sometimes they may be fenestrated or form a lattice-work. One of them, larger than the others, has already been referred to as the ovarian fimbria (Fig. 4202, *f*). Attached to a groove in the suspensory ligament, it does not usually quite reach the ovary, and from its termination there may extend, along the suspensory ligament, supplementary fringes (tubo-ovarian fimbriæ). The primary fimbriæ are usually plicated, the folds corresponding to those of the mucous membrane of the interior of

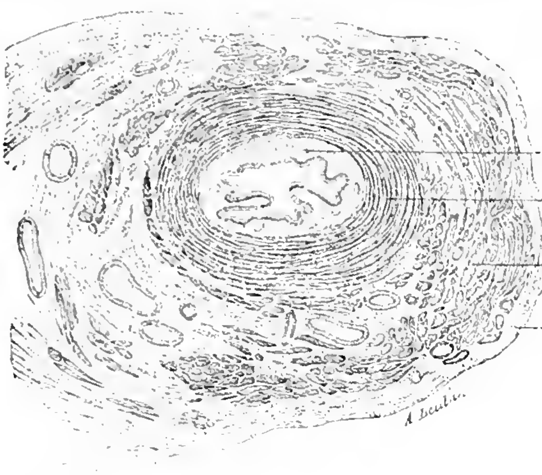

FIG. 4213.—Cross-Section of the Oviduct near the Uterine Orifice. (Orthmann.)

the tube. In consequence of this arrangement, the abdominal orifice of the tube is not usually visible, at least in nulliparæ. It can, however, always be displayed by parting the plications, and is large enough to admit a small probe.

It is by this orifice that the ova leave the abdominal cavity, and many attempts have been made to clearly explain how they come to enter it. It was formerly supposed that at the time of ovulation the infundibulum suffered a species of erection by vascular congestion, and that then it clasped itself firmly around the ovary and prevented the escape of the ovum into the peritoneal cavity. Injection of the vessels in the cadaver does not confirm this, and, as Henle says, it is difficult to see how the infundibulum can select the exact place upon the ovarian surface where a follicle is about to rupture, or how it can be depended upon to execute such an act in view of the pressure and movements of the intestines. Others have supposed that there must exist in the ducts, in the fimbriæ, or in the broad ligaments muscular fibres by which adaptation of the infundibulum to the surface of the ovary is effected. This, too, appears to be without foundation. Excitation of the muscular coat of the oviduct in living animals merely produces vermicular movements, the direction of the fibres of the muscular tissue of the broad ligament is such that they draw the ovaries together rather than bring the infundibulum to the ovary, and the existence in the fimbriæ of special fibres capable of clasping the ovary cannot be demonstrated.

Experiments upon animals have shown, however, that both ova and semen may pass from one side of the abdomen to the other, and that it does not necessarily follow that, because an ovum does not at once reach the infundibulum, it may not eventually do so. Its movement is doubtless directed by the ciliated epithelium that lines the interior of the infundibulum and the ovarian fimbria. Notwithstanding this there is unquestionably a great loss of ova owing to the lack of accurate adaptation between the mouth of the oviduct and the ovary.

Interior Configuration.—The interior of the oviduct is lined with mucous membrane continuous with that of the uterus, but destitute of the glands that are so prominent a feature of that organ. This membrane has a striking peculiarity in that it is arranged in numerous longitudinal folds that form an intricate series of narrow passages—the tubal labyrinth (Figs. 4213, 4214)—affording a free though retarded passage to fluids and minute bodies that pass from the abdominal cavity to the uterus. These folds appear in the interstitial portion as two or three small crests which are, in the isthmus, prolonged and multiplied as *principal* folds, which, however, disappear on distention of the tube, and attain their greatest development in the ampulla, where they no longer disappear on distention and vary greatly in size, some passing across the lumen of the tube to the opposite side and developing on their faces secondary and tertiary folds, so that a cross-section of them resembles the arbor vitæ of the cerebellum. These folds are continued, much reduced in size, upon the infundibulum.

The arrangement seems admirably adapted for retarding the movements of the ovum and the spermatozoa, which probably meet each other at this point. It indeed seems likely that the ampulla is a *receptaculum seminis*, and that it becomes, after repeated copulations, charged with spermatozoa, which may remain there in an active state for several days, so that when a matured ovum once enters, its fecundation is practically assured.

Investigations on animals show that the ovum is from three to eight days in passing through the oviduct. Hyrtl found a human ovum in the uterine end of the duct four days after menstruation. The period of eight days cannot be much exceeded in the human species, as the ovum attains in the second week a diameter of 3–6 mm., which is greater than that of the uterine orifice of the tube.

On the other hand, the progress upward of the spermatozoa is comparatively rapid. Having a flagellate movement of their own, they are able to travel without the assistance of the female organs. In guinea-pigs they have been known to reach the middle of the oviduct within fifteen minutes after copulation, and from what is known of their rapidity of progress in other situations, it

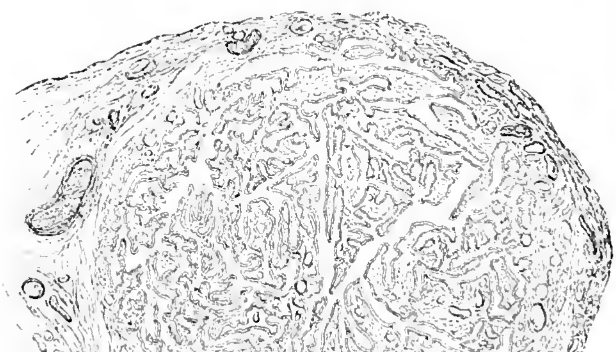

FIG. 4214.—Cross-Section of the Oviduct near the Abdominal Orifice. The folds of the mucous membrane are very numerous and complicated, forming the tubal labyrinth; the muscular coat is very thin but rich in vessels. (Orthmann.)

seems probable that in the human species they require about two hours for a similar migration.

Structure.—The oviduct is a muscular tube outwardly invested with a serous layer derived from the peritoneum, inwardly lined with a mucous membrane. The serous coating forms a complete investment, the vessels entering

Sexual Organs.

along its inferior border through the folds of the mesosalpinx. It is continuous internally with the serous investment of the uterus, and externally is continued over the external surface of the fimbriæ. A loose, subserous, connective tissue unites it to the muscular coat.

The muscular tunic is composed of smooth fibres arranged in two layers, an inner one of circular fibres and an outer one in which the fibres are arranged longitudinally. The circular layer is a continuation of the similar fibres of the uterus, is thicker at the uterine extremity, and at the infundibulum forms a sphincter-like ring. The longitudinal fibres are continuous with the transverse fibres of the uterus and are continued as a very thin sheet upon the infundibulum, one fascicle extending upon the fimbria ovarica, and constituting what is sometimes called the *musculus attrahens tubæ.*

The mucous membrane is composed of a layer of ciliated epithelium seated upon a submucous connective tissue containing some round cells resembling those of the uterus, and which are believed to assist in forming a decidua in the case of tubal pregnancy. It possesses no glands. The epithelium increases somewhat in thickness toward the abdominal orifice. The direction of the ciliary wave is toward the uterus, and experimental injections of minute bodies into the abdominal cavity show that it is an efficient cause of the progression of the ovum through the duct. The epithelium lines the interior of the infundibulum and becomes continuous at the edge of the fimbriæ with the peritoneum. Upon the ovarian fimbria or along the suspensory ligament it is continued as far as the ovary, becoming continuous there with the cubical epithelium of that organ.

Arteries.—From the anastomotic loop formed by the ovarian and uterine arteries three branches are given off for the supply of the oviduct. These are, respectively, the *external tubal*, derived from the ovarian, which passes in front of the fimbria ovarica and ascends along it, supplying it and sending a branch to each of the other fimbriæ, and ending by anastomosing with the middle or internal tubal; the *internal tubal*, derived from the uterine, supplying the interstitial portion and isthmus of the oviduct, and curving outward to form by anastomosis with the external tubal the infratubal arch; and the *middle tubal*, usually given off from the uterine a little farther out. It passes in front of the ovary and divides into two branches, which anastomose with the external and internal tubal, forming a second infratubal arch.

Veins.—These also form a vascular arcade with more frequent anastomoses. They discharge into the uterine and ovarian veins. One branch runs along the round ligament of the uterus and communicates with the epigastric vein.

Lymphatics.—These take origin from the mucous membrane, from a subperitoneal network, and discharge into two or three trunks which extend along the oviduct, unite with others coming from the uterus, and ascend along the suspensory ligament to the lumbar glands.

Nerves.—These are derived from the ovarian plexus and are closely connected with the uterine nerves. They unite under the peritoneum to form what is called by Jaques the *fundamental* plexus, from which finer fibres penetrate between the muscular layers, forming a second or intramuscular plexus which supplies the muscle fibres; from this again fibres are distributed to the epithelium.

THE UTERUS.—*Etymology.*—From the Latin *uterus*, the womb, probably connected with *uter*, a skin bottle or bag. The later Latin appellation, *matrix*, is also sometimes used. This originally meant a breeding animal. Greek *μήτρα*, *ὑστέρα* (the last, the uterus being the last organ that presents in the pelvis), whence come many modern derivatives, such as metralgia, metritis, metrorrhagia, hysteria, hysterectomy, etc. Another Greek appellation, used by Hippocrates, was *δελφύς*, whence are derived several terms used in zoological classification, such as Monodelphia, Didelphia, Ornithodelphia. French, *uterus, matrice;* Italian, *utero, genitura;* German, *Gebärmutter, Mutter, Fruchthälter.* The Talmudists called the uterus "the sleeping chamber," of which the cervix was "the porch."

History.—It was probably known to the ancients from an early period, though it would seem that at first no very clear distinction was made between it and the vagina. The Greek physicians supposed it to be movable, ascending upward toward the diaphragm when excited and thus producing a variety of disorders. Plato calls it a wild beast which never follows reason, and which, through non satisfaction of its desires, roams about in the body and also excites inordinate lust. That this view existed also among the Hebrews may perhaps be inferred from Prov. xxx. 15, 16. Soranus first showed that its attachments were such that this movement was impossible, yet the error did not disappear from medical science

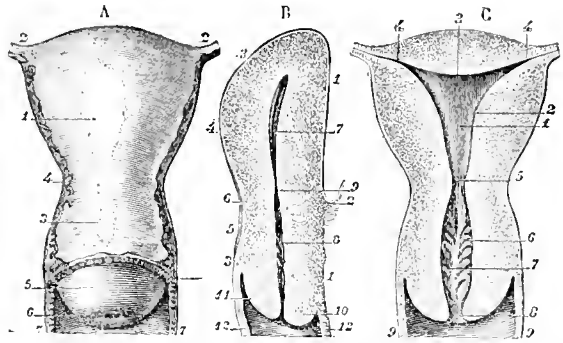

FIG. 4215.—Virgin Uterus of Twenty-two Years. (Sappey.) *A. Anterior face*—1, Body; 2, 2, superior angles; 3, cervix; 4, isthmus; 5, intravaginal portion of cervix; 6, its external orifice; 7, vagina. *B. Median section*—1, 1, Profile of anterior face; 2, vesico-uterine cul-de-sac of peritoneum dividing this face into two nearly equal parts; 3, 3, profile of posterior face; 4, body; 5, cervix; 6, isthmus; 7, cavity of body; 8, cervical canal; 9, internal orifice; 10, anterior lip of the os uteri; 11, posterior lip; 12, 12, vagina. *C. Frontal section*—1, Cavity of body; 2, its left lateral border; 3, its superior border; 4, 4, its lateral angles; 5, its inferior angle forming the internal orifice; 6, cervical canal; 7, arbor vitæ of its posterior wall; 8, its lower extremity; 9, vagina.

until the practice of dissection became general. Galen, considering that the female should possess all the organs of the male, supposed it to be the homologue of the penis, withdrawn from sight in accordance with the colder nature of the sex. The muscular character of the uterus was first demonstrated by Arantius (1530–89).

Definition.—A single, hollow, median, and symmetrical structure, peculiar to mammals, situated in the cavity of the pelvis between the rectum and the urinary bladder. It is formed by the thickened confluence of the Müllerian ducts, and serves as the organ of gestation and parturition. It receives the impregnated ovum, maintains it during embryonic and fetal development, and expels the fœtus at maturity.

The function of child-bearing, which appears to be the most important one of the female economy, has a remarkable effect upon the organ that contains and nourishes the developing embryo, affecting profoundly its size and its anatomical organization. It is also subject to a series of rhythmic changes, habits impressed upon it as a periodical preparation of gestation and known as menstruation. This function of gestation, and in a minor degree that of menstruation, entail anatomical variations greater than are found in any other organ of the body.

Form.—The nulliparous uterus (Fig. 4215) has the shape of an inverted flask, flattened and slightly bent, from behind forward. The older anatomists compared it to a *cucurbitula* or cupping glass, so called because of resemblance in shape to a small gourd or cucumber. Indeed, the shape of the uterus is quite accurately represented by that of a short cucumber, slightly larger at one end than at the other, and bent near the smaller end.

Divisions.—Its expanded upper portion is the *body* or *corpus*, its narrower, lower part the *neck* or *cervix*, while the slight constriction between these is the *isthmus*. From either side of the organ, at its upper part, are given off the so-called *annexa:* the oviduct, the round and ovarian ligaments, which latter connect with the ovaries (see Fig. 4202). The part of the uterine body above the plane passing horizontally through the insertions of the annexa is termed the *fundus*, and the part below that plane is sometimes distinguished as the body proper (*corpus proprium*).

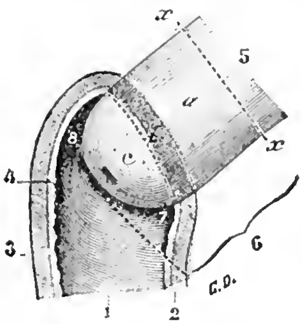

FIG. 4216.—Junction of the Uterus and the Vagina, showing the Segments of the Cervix. (Testut.) 1, Vagina, with 2, its anterior wall; 3, its posterior wall; 4, its mucous membrane; 5, body of the uterus; 6, cervix of uterus, with *a*, its extravaginal portion; *b*, its vaginal portion; *c*, its intravaginal portion of os uteri; 7, anterior cul-de-sac; 8, posterior cul-de-sac; *x*, *x*, separates the body and the neck of the uterus.

The lower part of the neck is embraced by the vagina, like a sleeve, the line of adherence running obliquely and extending farther down in front than behind (Fig. 4216). The cervix is thus divided into a *supravaginal* and a *vaginal* portion. To the palpating finger the vaginal portion feels like a hard, smooth projection with a central depression or slit, the *orificium externum*, or external orifice of the cavity of the uterus. Its peculiar shape and consistence led Lieutaud to call it the *museau de tanche*, the tench's muzzle, or, in Latin, *os tincæ*, which has become by usage *os uteri* or *os uteri externum*, the mouth of the uterus. It will be perceived that this term applies to the entire vaginal portion of the cervix rather than to the orifice itself. This orifice is rounded in nulliparæ, and in those who have borne children is a short, transverse slit, often with somewhat irregular edges, the *lips* or *labia* (Fig. 4217). The anterior lip is the thicker and the lower. Both lips are in contact with the walls of the undistended vagina (Fig. 4218).

From the sides of the uterus its peritoneal investment is continued laterally in the form of the broad ligament, between whose layers are the vessels and nerves for the supply of the organ, which thus penetrate at what may be called its lateral edges.

The body comprises about two-thirds of the entire organ. Its upper end, the fundus, is free and covered by closely adherent peritoneum. It is smooth and glistening, and the superincumbent coils of intestine glide over it with a minimum of friction. In nulliparæ it has but little convexity, but after repeated pregnancies it becomes markedly rounded both antero-posteriorly and

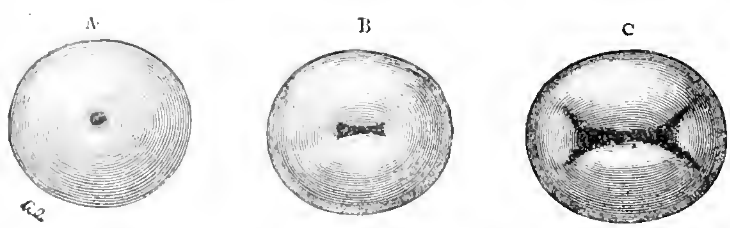

FIG. 4217. The Os Uteri and its Orifice. (Testut.) *A*, In the virgin; *B*, in a primipara; *C*, in a multipara.

from side to side (Fig. 4219). By its continuity on either side with the oviducts are formed the *angles* of the uterus. In most lower animals these angles are much more marked owing to a less complete fusion of the Müllerian ducts. In the human species also a bicornuate uterus is occasionally seen. The posterior surface of the body, rounded and smooth, can be seen from above when the pelvic cavity is opened and the intestines are removed; the anterior surface, however, is not visible, it being in contact with the bladder, which imparts to it a slight flattening.

The cervix is of a nearly cylindrical form, slightly enlarged at the middle in nulliparæ, much less or not at all in those who have had repeated pregnancies.

The vaginal (intravaginal) portion of the cervix or os uteri is a rounded projection, having under physiological conditions a rosy color and a firm consistence. Its base is circular in virgins, slightly elliptical in those who have borne children (Fig. 4217). The external orifice varies much in shape and in the appearance of its lips. Rounded in the virgin, it becomes a slit in the primipara, and after repeated pregnancies is gaping, irregular, and puckered, the lips often presenting scars or fissures. In these cases the cervix undergoes considerable absorption.

Cavity. — The walls of the uterus are from 10 to 15 mm. thick in nulliparæ (Fig. 4215, *B*, *C*), somewhat greater in multiparæ (Fig. 4219, *B*), diminished a little at the neck and at the orifices of the oviducts. This thickness nearly obliterates the lumen, but there is a virtual cavity divisible into two parts: an upper, triangular, transversely placed cleft, the *cavum uteri*, belonging to the body of the uterus; and a lower, fusiform portion, the *cervical canal* (*canalis cervicis*) belonging to the neck. A contracted pass, the *internal orifice* (*os uteri internum*), unites the two.

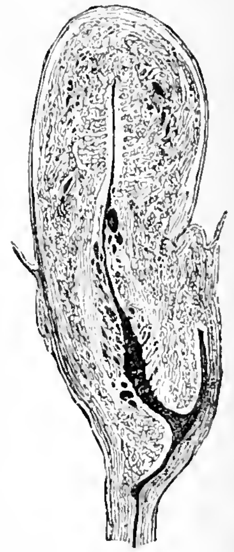

FIG. 4218.—Section through the Middle of the Uterus and Upper Part of Vagina. (Henle.)

The shape of the cavum uteri is triangular, or, more accurately, it is formed by three slender triangles united by their bases; the two upper ones, the cornua, leading to the orifices of the oviducts, the third leading downward to the internal orifice. In multiparæ this shape is somewhat modified, the cornua enlarging at the expense of the lower triangle. Traces of the primitive union of the Müllerian ducts can usually be found in young persons, either as a marked raphe or as a triangular depression on the anterior and posterior walls. Sometimes the entire cavity is divided and the uterus thus becomes bilocular like that of rodents. Among the older, fanciful views with reference to generation, was one that male children were developed on the right side of the uterus, females on the left, the male seeking the warmth of the liver (Galen). It has been suggested that the rare cases of superfœtation that have been noted can be explained by an anomalous, bilocular condition of the uterus.

The internal orifice, often called the internal os, is really a passage 4 or 5 mm. in length, corresponding to the isthmus of the uterus. It frequently is smaller than the external orifice, and offers more resistance to the probe. The columns of the next section are prolonged into it.

The cervical canal expands somewhat on passing from either end toward the middle. The mucous membrane of its anterior and posterior surfaces presents series of remarkable folds, constituting the *arbor vitæ uterina* of the older anatomists (Fig. 4220). Running axially along each wall is a slightly elevated ridge or *column*, from which arises a series of

Sexual Organs.

penniform folds, the *plicæ palmatæ*, which may divide and subdivide, the whole presenting an appearance somewhat like the ribs of a leaf. The folds are so arranged that those on opposite sides of the neck fit into each other.

The capacity of the cavity of the unimpregnated nulliparous uterus is but slight, the walls being for the most part everywhere in contact or separated by a thin layer of mucus. It is estimated at from 2 to 5 c.c., or fl. ℥ ss. to fl. ℥ 1⅛. In multiparæ it increases to from 5 to 8 c.c., or fl. ℥ 1⅛ to 2⅛ (Guyon).

Dimensions.—The following table represents averages from measurements made by Rieffel, Waldeyer, and others.

	Nulliparæ. Millimetres.	Multiparæ. Millimetres.
Total length	60	70
Length of body	35	45
Length of neck	25	25
Length of vaginal portion of neck	10	10
Breadth between insertions of oviducts	40	45
Breadth at isthmus	20	30
Breadth at middle of cervix	25	30
Thickness (antero-posterior diameter) of body	20	30
Thickness (antero-posterior diameter) of neck	20	25
Total length of cavity	55	60–65
Length of cavity of body	25	31–40
Length of cavity of isthmus	5	3–5
Length of cavity of neck	25	20–24
Breadth of cavity between oviducts	24	30–35
Breadth of cavity at isthmus	4	
Breadth of cavity at middle of cervix	8	9
Depth (antero-posterior diameter) of cavity	[illegible]	12
Thickness of walls of body	10–15	20
Thickness of walls of neck	8–10	15

	Millimetres.
Total length of uterus of child	25–35
Total length of senile and atrophied uterus	30
Pregnant uterus in the last month:	
Greatest length	360
Breadth of body	250
Thickness of body	240
Length of cervix	45–50

As a general, rough estimation it may be said that the adult, nulliparous uterus is three inches long by two inches wide and one inch thick.

Weight.—According to Rieffel the weight of the nulliparous uterus averages 40 gm., ranging from 32 to 50.

A B

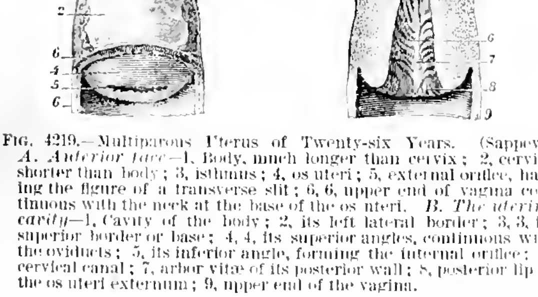

FIG. 4219.—Multiparous Uterus of Twenty-six Years. (Sappey.) *A. Anterior face*—1, Body, much longer than cervix; 2, cervix, shorter than body; 3, isthmus; 4, os uteri; 5, external orifice, having the figure of a transverse slit; 6, 6, upper end of vagina continuous with the neck at the base of the os uteri. *B. The uterine cavity*—1, Cavity of the body; 2, its left lateral border; 3, 3, its superior border or base; 4, 4, its superior angles, continuous with the oviducts; 5, its inferior angle, forming the internal orifice; 6, cervical canal; 7, arbor vitæ of its posterior wall; 8, posterior lip of the os uteri externum; 9, upper end of the vagina.

The weight of the multiparous uterus is considerably greater, averaging 55 gm. and varying from 48 to 70. Waldeyer reports the weight of the uterus during the last month of pregnancy as from 900 to 1,200 gm. Roughly speaking, it may be said that the weight of the uterus varies from one ounce avoidupois in the unimpregnated female to two pounds in the parturient one. The specific gravity of the uterine substance is 1.052.

Consistence.—During life the uterus is soft, depressible, and flexible, especially at the isthmus. This is more marked in nulliparæ. After death, from cadaveric rigidity and the emptying of the vessels, it becomes more firm and unyielding.

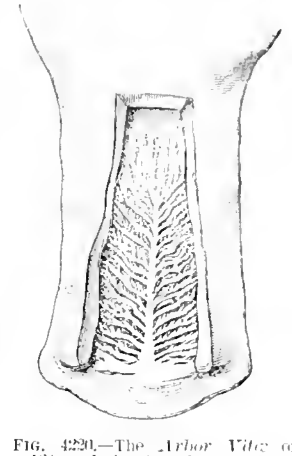

FIG. 4220.—The *Arbor Vitæ* or *Plicæ Palmatæ* of the Wall of the Cervical Canal shown by Cutting a Section from the Wall. (Nagel.)

Position.—The uterus, not being rigidly bound, is subject to a wide range of variations in position, many of which are compatible with health. Thus it may, as a whole, be turned forward, backward, or sideways (anteversion, retroversion, lateroversion); it may, as a whole, be displaced in the horizontal plane (anteposition, retroposition, lateroposition); it may be raised or lowered (elevation, depression); it may be bent upon itself (anteflexion, retroflexion, lateroflexion), the bending usually occurring at the isthmus; or it may be twisted upon its own axis (torsion). Several of these displacements are often combined. It is not surprising, therefore, that there should have been much discussion as to the normal position of the organ. Nagel, Waldeyer, Rieffel, and most recent writers hold that the *typical* position of the uterus, as derived from a study of its embryonic development and general tendencies, is as follows:

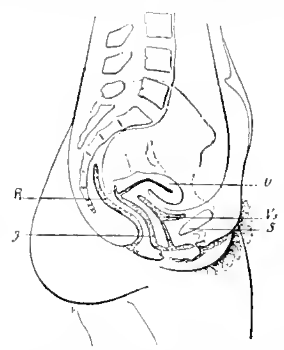

FIG. 4221.—Normal Position of the Uterus in the Virgin. (Schultze.) *R*, Rectum; *U*, uterus; *Vg*, vagina; *Vs*, bladder; *S*, symphysis.

In the healthy and normal adult female, standing in the erect position, with rectum and bladder approximately empty, the uterus is anteverted and anteflexed (Figs. 4204, 4221, 4222, 4223). The axis of the cervical canal corresponds nearly to the axis of the pelvis, the external orifice being at the height of the top of the symphysis pubis. The axis of the body is nearly horizontal, the fundus does not reach the plane of the superior strait, and is some distance behind the symphysis.

This typical position may be altered by a variety of causes and thus a number of secondary positions be produced, all of which may be normal in the sense that they in no way interfere with the functions of the uterus nor with those of the surrounding organs. Thus it may be pushed backward by a distention of the bladder (Fig. 4223), or forward by a distention of the rectum, or considerably elevated by a distention of both at the same time (Fig. 4221). The posture of the subject, acting upon

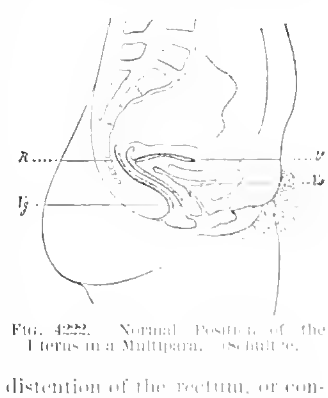

FIG. 4222.—Normal Position of the Uterus in a Multipara. (Schultze.)

the abdominal contents as well as upon the uterus, has some effect. Thus the knee-elbow position of gynæcologists throws the viscera toward the diaphragm and causes the fundus of the uterus to be directed more toward the umbilicus. The expulsive action of the muscles of the abdominal wall, by pushing downward the intestines, affects the anteflexion and anteversion, and at the same time depresses the organ. Even the action of respiration has a slight effect. The state of tonicity of the pelvic floor and the vaginal walls and the repletion of the vessels have also considerable influence.

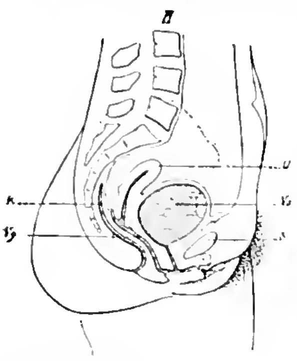

FIG. 4223.—Situation of the Uterus during Repletion of the Bladder. (Schultze.)

Fixation. — The position of the uterus is maintained by the following connections: (1) with the vagina and bladder; (2) with the pelvic fascia by means of the parametrium and its vessels; (3) with the pelvic peritoneum by the broad ligament; (4) by special bands known as the round and utero-sacral ligaments.

The attachment of the vagina (Fig. 4216) is along a zone from 6 to 8 mm. in breadth, and is very intimate, the muscular and connective tissue and the mucous membrane of the two organs being continuous, as might be expected, considering that both were originally developed from the same tubular structure.

The neck of the uterus is attached to the fundus of the bladder by loose connective tissue containing numerous veins. The vesico-uterine fold of the peritoneum closes the connection above. This usually descends only as far as the isthmus of the uterus (Fig. 4215, *B*, 2), but in multiparæ is occasionally seen to reach the vagina, in which case the uterus has no immediate union with the bladder.

The pelvic fascia, or sheet of connective tissue that lines the pelvic cavity, has necessarily important relations with the uterus, since that organ is itself a portion of the pelvic floor. This fascia varies greatly in its consistency, in some situations being loose and offering but little resistance; in others being condensed into bands and sheets that fix and restrain the organs with which it is united. It is particularly associated with the great vascular trunks, and often contains in its meshes masses of fat. Virchow proposed the name *parametrium* for the extensions of this fascia that invest and are immediately adjacent to the uterus. They reach the viscus by the base of the broad ligament, along the branches of the uterine artery, and cover its lateral edges and the supra-vaginal portion of the cervix, extending upward a varying distance under the peritoneal covering and gradually disappearing as they reach the upper part of the body.

Behind, a utero-sacral sheet can be traced along the sides of the rectum to the sacrum and the coccyx; in front a utero-pubic sheet passes to the bladder and thence to the pubis. Some thickened bands of this have been called the vesico-uterine ligaments. Laterally, through the base of the broad ligament, along the vessels and nerves that enter here and themselves constitute an elastic band, can be traced sustaining bands that have been called by Kocks the cardinal ligaments. It will be seen that the neck of the uterus is thus suspended hammock-wise in a network of connective-tissue cordage.

The broad ligaments (*ligamenta lata uteri*, Figs. 4202, 4226, 4227) are formed by reflections of the pelvic peritoneum upon the uterus and the annexa. Together they constitute a common mesentery for these organs. When spread out each has the appearance and shape of a membranous wing, which led De Graaf to style it the *ala vespertilionis*, or bat's wing; and the French anatomists still use the term *ailerons*, or little wings, for its subordinate divisions (Fig. 4202, *a*, *b*, *c*). The external insertion or hilum—that is to say, the line where the ligament is reflected upon the lateral wall of the pelvis—is about 2 cm. behind the transverse diameter of the superior strait, a little in front of the internal iliac artery. It passes up over the psoas and the external iliac vessels, surrounding the suspensory ligament of the ovary and the ovarian vessels and nerves, where it is lost. Waldeyer has given to this upwardly extending process the name of *mesodesma suspensorium*. Its inferior or basal insertion is broad and situated on the pelvic floor nearly in the biischiatic line (Fig. 4228). Its upper edge contains the oviduct, and, beyond the ovary, is continued upon the suspensory ligament. From its anterior surface is raised a small fold containing the round ligament (*mesodesma teres* of Waldeyer), while from its posterior surface the ovarian ligament and the ovary itself are suspended by the *mesovarium*. The portion above this fold is thin, contains the remains of the Wolffian body and its ducts with but little connective tissue, and is known as the *mesosalpinx*; that below is thicker, and,

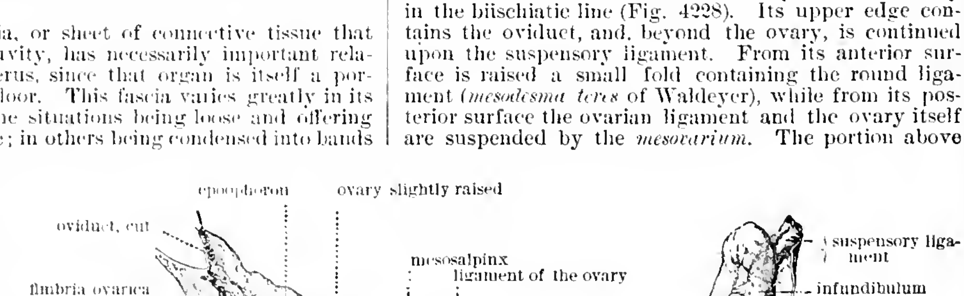

FIG. 4225. The Uterus, Oviducts, and Ovaries, seen from Behind. (Spalteholz.)

Sexual Organs.

since it affords the special investment of the uterus, is called the *mesometrium.* There is here found a considerable amount of loose connective tissue (parametrium),

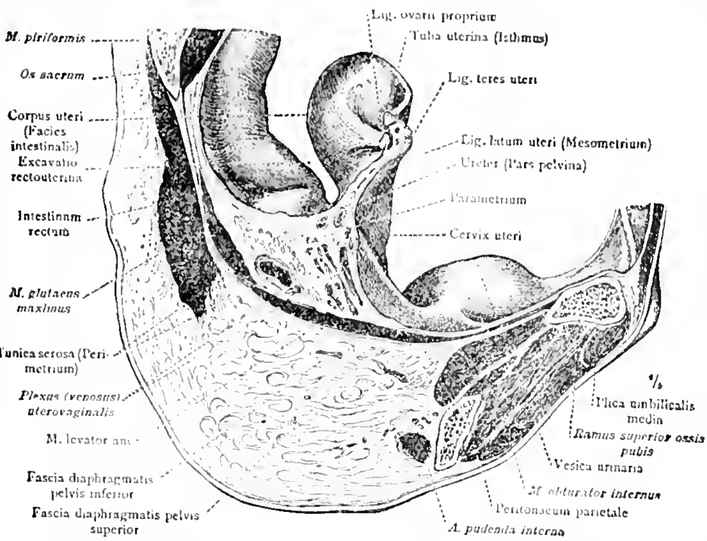

FIG. 4226.—Antero-posterior Section through the Female Pelvis 4 cm. to the Right of the Median Line. (Toldt.) The section cuts the broad ligament and shows the continuity of its two peritoneal layers with the parietal peritoneum of the pelvic floor. It also shows the parametrium, the pelvic diaphragm, and, under it, the fatty tissue of the ischio-rectal fossa. The uterus is shown more erect than normal. Made from a frozen preparation.

the uterine vessels and nerves and the ureter, besides a thin layer of smooth muscular fibres continuous with the muscular tissue of the uterus.

The anteflexed position of the uterus bends forward the two ligaments so that they form a shelf that supports the intestines (Fig. 4225), and which, while almost vertical at the sides, is nearly horizontal in the middle. It divides the pelvis into two cavities or pockets, a recto-uterine behind and a vesico-uterine in front.

The portion of the mesometrium that immediately invests the uterus is called the *perimetrium.* Behind, it is continuous with the peritoneal covering of the rectum; in front, with that of the bladder. In the latter situation it reaches the uterus about at the isthmus, forming the *utero-vesical fold,* and is then reflected over the anterior surface of the body, the fundus, the posterior surface of the body, and the supravaginal surface of the neck, passing thence to the upper part of the vagina and then being reflected upon the rectum, forming the *recto-vaginal fold* (fold of Douglas, Fig. 4226). This fold is interrupted laterally by two bundles of smooth muscular fibres which pass from the uterus along the sides of the rectum to the sacrum. These, the *utero-sacral ligaments,* do not reach as low as the bottom of the fold, and there is consequently formed between them a well-marked pocket, lying between the uterus in front and the rectum behind, which is known as the *recto-vaginal* pouch or pouch of Douglas (*excavatio recto-uterina*), from James Douglas, professor of anatomy and surgery in London (b. 1642, d. 1675). This pouch is the lowest portion of the abdominal cavity, and any effusions are likely to collect there. It can easily be palpated through the vagina.

It has already been mentioned that the ovarian and round ligaments represent portions of the genito-inguinal ligament or gubernaculum of the genital gland, which, instead of remaining free throughout its course, has become attached to the uterus—that is to say, to the enlarged Müllerian duct (Fig. 4197). Accordingly the ovarian ligament is inserted upon the uterus behind the superior cornu, while the round ligament arises from in front of the same, a little below the insertion of the oviduct. The round ligament then passes down between the layers of the mesometrium and the parametrium, above the ureter, the uterine, the vesico vaginal, the obturator, and the external iliac vessels to the internal abdominal ring, lifting up the peritoneum as it passes to form a slight investment (*mesodesma teres,* Waldeyer). It then passes through the inguinal canal, sometimes surrounded by a peritoneal diverticulum, called the canal of Nuck (Anton Nuck, professor at Leyden, 1650–92) and having about the same relations as the spermatic cord of the male. Finally its fibres separate to be inserted in the subcutaneous tissue of the labium majus. The round ligaments deserve that appellation only in the middle of their course; in their upper part they are flattened, below expanded in a fan-like manner. They are 12–15 cm. in length, about 3–5 cm. broad, and are composed mostly of muscular tissue, having, therefore, no great tensile strength. During pregnancy they increase to four times their normal size.

The utero-sacral ligaments have already been mentioned. They are fibro-muscular bundles that pass, from just below the isthmus of the uterus, backward along the sides of the rectum to the sacrum. Occasionally secondary *utero-lumbar* bands are seen that are inserted on the last lumbar vertebra.

Relations.—The antero-inferior surface of the body is often called the vesical surface because of its contact with the bladder. It appears normally to remain in contact with that organ, lying upon it as upon a water-bed and adapting itself to

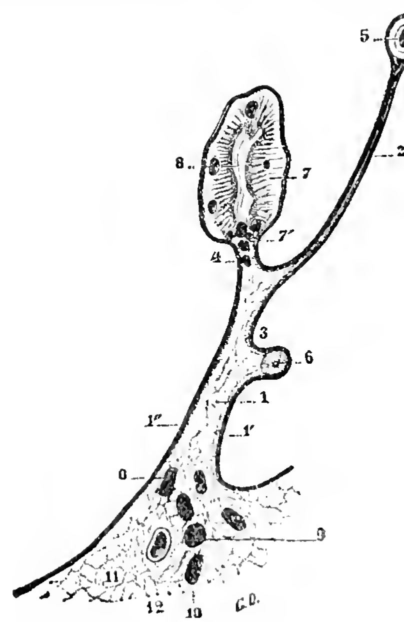

FIG. 4227.—Sagittal Section of the Broad Ligament (right side, inner surface of section.) (Testut.) 1, Broad ligament, with 1′, its anterior layer; 1″, its posterior layer; 2, mesosalpinx; 3, mesodesma teres; 4, mesovarium; 5, oviduct; 6, round ligament; 7, ovary, with 7′, its hilum and vessels; 8, ovisacs; 9, uterine artery; 10, uterine veins; 11, areolar tissue of pelvis; 12, ureter.

its states of repletion and depletion. Coils of intestines rarely insinuate themselves between these organs. The supero-posterior surface is called the intestinal surface because it is covered with coils of the small intestine or of the pelvic colon. These never descend, however, into the pouch of Douglas.

The principal relations of the neck of the uterus are with the ureter and the uterine artery. The ureter, passing down obliquely through the base of the broad ligament, crosses the external border of the neck a little below its internal orifice, passes along the cervical attachment of the vagina for about 1 cm., and reaches the anterior wall of the vagina at about the level of the external orifice of the cervix. It is here surrounded by loose connective tissue

FIG. 4228.—Scheme showing the Relations of the Uterus to the Skeleton. (Rieffel.) *x*, *y*, Axis of pelvic cavity; *a*, *b*, plane of superior strait; *c*, *d*, line from superior fourth of symphysis to sacrococcygeal articulation; *e*, *f*, horizontal through union of fourth and fifth sacral vertebræ; *M*, vertical through fundus; *N*, vertical through internal orifice; *P*, vertical through external orifice.

and by veins. In this course the ureter may lie immediately against the cervix and is rarely more than 2 cm. from it. The uterine artery crosses the ureter about at the level of the vaginal portion of the cervix and at an average distance of 2 cm. from its border.

The relations of the uterus to the skeletal framework have already been mentioned. From Fig. 4228 it will be seen that the external surface of the cervix is situated near the point where a line drawn from the upper fourth of the symphysis pubis to the sacrococcygeal articulation intersects the pelvic cavity. It is really slightly behind this point and therefore a little nearer the posterior wall of the true pelvis. According to Waldeyer it is in the frontal plane passing through the two spines of the ischium. In the figure it is shown slightly forward of this plane. The fundus is about 20 to 25 mm. behind the symphysis pubis. The lowest point of the uterus—that is to say, the anterior lip of the os—is on a level with the superior third of the symphysis and the last coccygeal vertebra. The highest part of the uterus in its typical position is not the fundus but the posterior surface of the body. It corresponds to a horizontal plane carried through the fourth sacral vertebra (Waldeyer) or a little below (Rieffel). A vertical through the internal orifice of the cervix passes a little behind the middle of the perineum. Another through the external orifice passes through the posterior fourth of the perineum. According to Waldeyer, a vertical passing through the anterior part of the fundus reaches the middle of the urethro-vaginal septum. In the figure it is thrown a little forward of that. As the uterus is subject to considerable changes of position, these data can only be approximate.

Structure.—The walls of the uterus are formed of a serous coating derived from the peritoneum—the *perimetrium*; a subserous layer of loose connective tissue—the *parametrium*; a thick mass of unstriped muscular fibres—the *myometrium*; and the mucous membrane or *endometrium* that lines the interior. These distinctions are of especial value in studying the pathological conditions of the organ.

The peritoneal investment has already been considered. Its attachments to the subjacent layer, or parametrium, are of considerable importance. Where the latter tissue is abundant, as upon the posterior portion of the cervix, the peritoneum can be readily lifted into folds or stripped off by the finger or the handle of the scalpel. Where entirely wanting, as on the fundus and the greater portion of the body, the peritoneum cannot be readily removed from the subjacent muscular layer. Between these areas there is an intermediate zone both on the anterior and on the posterior surfaces of the uterus, in which the parametrium is scanty, but still in sufficient quantity to permit one to dissect off the serous layer. These zones are crescentic in form, the points of the crescent being at the insertion of the round ligament in front and the ovarian ligament behind. The posterior crescent extends rather farther downward than does the anterior one. The application of these facts to operative surgery is obvious.

The *myometrium* or muscular tissue of the uterus constitutes almost its entire mass. Indeed it may be said that the whole organ is one dense, closely knit muscle, composed of fibres interwoven with each other in every direction, interspersed with bundles of white fibrous and yellow elastic connective tissue. The elastic fibres are especially numerous near the external orifice, and are believed to be of advantage in the expansion of the os that occurs during labor.

While it is not possible to make an accurate separation of the muscular tissue into sheets distinguished by the direction of the fibres, as is done in other hollow viscera, it is convenient and customary to speak of three layers. Of these the middle one is the most important, as it is distinguished by the presence of large venous trunks, the uterine sinuses, which have given it the name of the *vascular layer*. The muscle bundles surround the vessels in every direction, so that when they contract the blood is practically squeezed out, thus affording an important means of stopping hemorrhage after labor. This arrangement is particularly noticeable in the fundus, the usual seat of the placenta, and is not found upon the cervix.

The external layer is also composed of fibres having every direction; it is not, however, so rich in vessels. It is extended outward beyond the uterus proper upon the attachments of the organ: the broad, round, ovarian, and utero-sacral ligaments, the oviducts, the vagina, the bladder, and the rectum. The internal layer is thin and formed of a network of longitudinal, oblique, and circular fibres, the latter forming sphincter-like rings around the entrance of the oviducts. At the internal orifice of the cervix they form an annular bundle sometimes called the cervical sphincter.

The *endometrium*, or mucous lining, has, in the healthy uterus, a grayish-pink appearance, is soft, and easily torn. At the oviducts and vagina it is continuous with the mucous membrane lining those organs. It is composed throughout of a ciliated epithelium which is well developed only during the period of sexual activity, the direction of the ciliary wave being toward the external orifice. The epithelium is seated upon a membrana propria, but without any submucosa, a matter which should be remembered in the curetting of the uterus, as the instrument readily passes through into the muscular layers and may produce extensive lacerations and even perforation.

Some differences occur between the lining of the body and that of the cervix. In the body the epithelium is cylindrical, its nuclei being placed at about the middle of the cell; the protoplasm is easily stainable. The membrana propria is a network of connective-tissue fibres with stellate cells, and in its meshes are found cells having the character of leucocytes, so that the tissue appears to have a lymphoid character. On the surface of the membrane are seen, spaced at distances of about 0.1–0.2 mm., the openings of tubular glands, resembling in form the glands of Lieberkühn of the small intestine. These are

Sexual Organs.

usually simple but sometimes branched. They are lined with ciliated epithelium, the direction of the ciliary wave being from the fundus toward the mouth of the gland. Their secretion is not, in a healthy state, very abundant, as the surface is merely moistened with mucus which has an alkaline reaction.

In the cervix the epithelial cells are longer, thinner, and narrowed at the base; their nuclei are either in several rows or situated nearer the base, and the protoplasm is not readily stained. The glands here are more utricular in character and incline to be branched. They secrete an extremely viscid mucus, difficult to remove, which fills up the cervical canal, especially during pregnancy and before menstruation is established. There are not infrequently found here small retention cysts caused by the closure of the blind ends of these glands. These are the so-called ovules of Naboth, being described by Martin Naboth of Leipsic (1675–1721), who supposed them to be veritable ova.

Toward the cornua of the body the epithelium becomes less elongated and gradually merges with that of the oviducts. There is also a gradual transition at the internal os, between the epithelium of the body and that of the cervix. At the external orifice the ciliated epithelium disappears gradually, giving place to the many-layered epithelium of the vagina. The line of demarcation is, in the virgin, at the external orifice, but after repeated pregnancies it is found higher up within the cervix.

Arteries.—The uterine artery is the principal one that supplies the organ, but blood also reaches it by the ovarian artery and the artery of the round ligament.

The uterine artery arises from the anterior trunk of the internal iliac, often in common with the superior vesical artery. It passes down along the lateral wall of the pelvis nearly to the level of the spine of the ischium, then curves forward, enters the base of the broad ligament, and proceeds almost horizontally toward the supravaginal portion of the cervix. It then ascends along the lateral border of the uterus as far as the fundus, where it curves back and enters the mesosalpinx, and divides into its terminal branches. In its course it lies alongside the ureter which is on its inner side, separating it from the peritoneum. In order to reach the uterus it must cross this conduit, which it does about 2 cm. from the lateral edge of the cervix, a little below the isthmus. Its pulsation can sometimes be felt during vaginal examination. Its course along the sides of the uterus is tortuous, especially in multiparæ. It gives off branches to the broad ligament and to the ureter, a cervico-vaginal branch of considerable size that descends from the upper part of the vagina, numerous branches for the cervix and body of the uterus, and finally divides into two branches, one for the fundus and one for the oviduct—the internal tubal. The free anastomosis with the ovarian artery has already been mentioned. This is so free during pregnancy that some authors have considered that the ovarian vessel gives the principal supply to the uterus.

The artery of the round ligament is analogous to the cremasteric artery of the male. It is derived from the epigastric artery and sends a small branch upward along the ligament to the uterus.

Veins.—The veins of the uterus are extremely numerous. They have very thin walls, so that on section they stand open and appear not unlike the sinuses of the dura mater. From the vascular layer of the uterine wall they pass out as trunks of considerable size, uniting along the edge of the organ into a rich network—the utero-vaginal plexus—which extends along the entire length of the uterus and the vagina, surrounded by connective tissue and smooth muscular fibres. This discharges at the height of the external orifice into the uterine veins, which pass outward, following the general course of the artery.

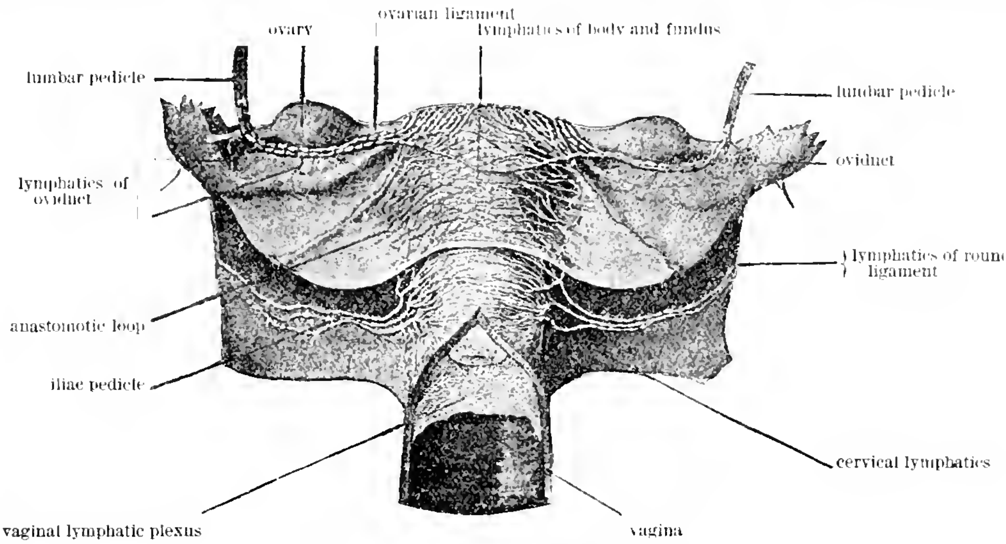

FIG. 4229.—Lymphatic Vessels of the Uterus. (Poirier.)

Lymphatics.—The lymphatics of the uterus (Fig. 4229) arise from three plexuses: one submucous, another muscular, and a third subserous. The trunks from these all unite in the subperitoneal tissue to form a fourth plexus, from which are given off efferent trunks that reach the lumbar glands.

Nerves.—These are derived from the hypogastric and ovarian plexuses of the sympathetic and from the third and fourth sacral nerves of the cerebro-spinal system. The fibres are mostly of the non-medullated variety, though a considerable number of medullated fibres appear, most of them fine but some of considerable size. They unite near the vaginal junction to form the utero-vaginal plexus, which contains a plexiform ganglion, the cervical ganglion, or ganglion of Lee (R. Lee, 1842). Other ganglia are said to occur near the uterine attachment of the ovarian ligament. Rein found, in rabbits and guinea-pigs, numerous small ganglia about the cervix, and was led to believe that no nerves reached the organ without passing through a ganglion. This has not, as yet, been shown in the human species. As to the endings of the nerves, Gawronsky and Kalischer saw rounded and plate-like endings in the epithelium and the muscular tissue, and Herlizka describes medullated fibres that end with free dendrites in the uterine wall. These would appear to be sensitive, cerebro spinal nerves, required for reflex action.

THE VAGINA.—*Etymology.*—From the Latin *vagina*, a sheath or covering, particularly the scabbard of a sword. It was only occasionally and figuratively used to indicate the sexual passage. The older anatomists did not use it in this sense, but designated the organ as the *collum uteri*. Its modern use was established by De Graaf. Greek, *κόλπος*, a sinus, the womb; whence colpitis, colpocele, colporrhagia, etc.; also *ἔλυτρον*, a case, a sheath; whence elytrotomy, elytroptosis, elytroplasty, etc. French, *vagin*; Italian, *vagina*; German, *Scheide*, *Mutterscheide*.

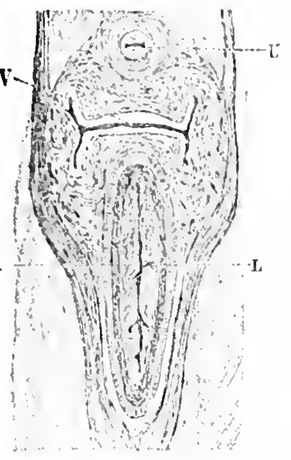

FIG. 4230.—Cross-section of the Vagina. (Henle.) *L*, Levator ani; *R*, rectum; *U*, urethra, cut obliquely; *V*, vagina.

Definition.—The dilatable, musculo-membranous conduit that extends from the uterus through the pelvic floor to the vulva. It serves as an organ of copulation, as a passage for the evacuation of menstrual and other fluids from the uterus, and for the delivery of the child at term.

Form.—The vagina is a collapsible tube whose walls are in contact with each other, and whose cavity exists only when it is distended. In general appearance it is not unlike some parts of the alimentary canal, and it has, indeed, been called the "genital intestine." The arrangement of the apposed walls is affected by the neighboring organs. Above, where they surround the os uteri, a transverse section shows the tube to be nearly circular; at the middle, where the muscular walls of the ureter in front and of the rectum behind impinge upon them, a section has the form of a transverse slit with vertical branches at either end, like a letter **H** with a long transverse bar (Fig. 4230); at the lower end, where the tube unites with the antero-posterior cleft of the vulva it becomes stretched in a sagittal direction, and in virgins is usually partially closed by a fold of mucous membrane termed the *hymen*. In children the tube may present a stellate appearance on section, and after frequent parturition it may become quite irregular.

When distended the cavity tapers slightly from above downward, being narrowest at its lower extremity. The widest part is, however, a little above the middle.

Division.—The upper part of the vagina, where it encircles the cervix (Fig. 4216), is known as the *fornix* or vault. This extends higher behind than in front, owing to the anteverted position of the uterus. It is usual to designate the different portions of this ring-like space as the *anterior*, *posterior*, and *lateral* fornices or *culs-de-sac*. The main portion of the tube is called the *body* of the vagina (*corpus vaginæ*); its widest part is the *ampulla*, and the entrance, visible when the labia are separated, the *external orifice* or *introitus*.

Dimensions.—Measured from the introitus to the external orifice of the uterus, the average length of the vagina

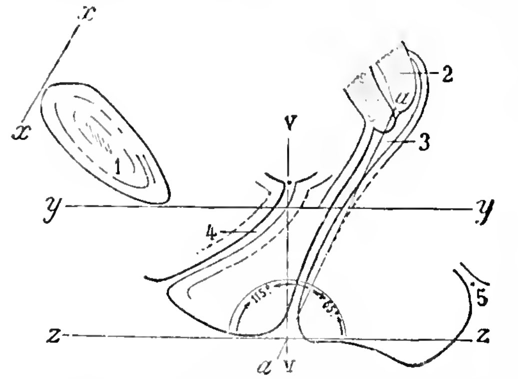

FIG. 4231.—Direction of the Vagina (frozen subject, twenty-four years.) (Testut.) 1, Symphysis pubis; 2, cervix of uterus; 3, vagina; 4, urethra; 5, anus; *x*, *x*, plane of the superior strait; *y*, *y*, subpubic horizontal; *z*, *z*, horizontal drawn through inferior orifice of vagina; *v*, *v*, vertical drawn through that orifice; *a*, *a*, axis of the vagina, inclined about 60° to the horizontal.

is 7 cm. (2¾ in.), varying between 4 or 5 cm. and 14 cm. This is one-fifteenth that of the entire body, exclusive of the limbs. In the new-born the length is 2.5–3.5 cm., which is relatively greater, being one-ninth of the body length (Luschka). The length of the shorter or anterior wall is from 6.5 to 7.5 cm. (2½ in.) while the longer, posterior wall is from 8 to 8.5 cm. (3¼ in.). In girls of thirteen years Symington found the anterior wall to measure 5.5 cm., the posterior 6.5 cm. The anterior cul-de-sac is shallow, being only from 2 to 5 mm. in depth, while the

Sexual Organs.

posterior cul-de-sac is much deeper, being from 10 to 25 mm. The vagina is susceptible of enormous dilatation without injury, enlarging sufficiently to permit the passage of the fœtal head during labor. Its calibre is somewhat greater in those who have borne children.

Situation and Direction.—In its passage through the pelvic floor the vagina lies between two other great conduits: that for urine, represented by the bladder and the ureter, being in front: the alimentary canal, represented by the rectum, behind. Divergent below, these approach each other above (Fig. 4231). The vagina is usually bent backward a little below and forward above, having a course like a much elongated reversed italic *S*. It does not depart widely from the axis of the pelvic cavity, but at least half of its length is extrapelvic, being below a line drawn from the lower border of the symphysis to the tip of the coccyx. Its direction is nearly parallel to the plane of the superior strait, varying somewhat with the state of repletion of the bladder and the rectum. Its axis makes nearly a right angle with that of the uterus when that organ is in its typical anteverted position and the bladder is not more than half full (Fig. 4232).

Fixation.—The vagina penetrates both the pelvic diaphragm (levator ani and coccygeus with associated fascia) and the genito-urinary diaphragm (triangular ligament with associated muscles) and receives support from both.

The upper part has much the same suspensory apparatus as has been already described for the cervix of the uterus. In addition, muscular fibres pass from the vagina to the sacrum behind and to the pelvis in front. Its adherence to the bladder is quite firm, but to the rectum much less, owing to the intervention of the pouch of Douglas.

The levator ani descends from the sides of the pelvis funnel-wise (Fig. 4233), and its fibres pass along the vagina, without becoming attached to it, to be inserted upon the rectum. They thus limit, to some extent, the displacements of the tube, without interfering with its distention.

Both sheets of the triangular ligament are firmly inserted upon the vaginal walls, affording them a fixed support. In addition, the lower part of the vagina is united to the rectum by means of the perineal body and still more closely adherent to the urethra. It will be seen, therefore, that the organ is more effectively supported in its lower segments than at any other portion.

Relations.—The anterior wall may be divided into a detachable, *vesical* portion above, connected with the fundus and trigone of the bladder, and a non-detachable, *urethral* portion below. The vesico-vaginal septum is about 3 cm. long and wedge-shaped in vertical section, being 6–7 mm. thick below and increasing upward. Exploration for stone is readily made along this wall, and it is here that vesico-vaginal fistula forms, usually from injuries received during labor. The upper part of this septum, composed of loose areolar tissue containing numerous veins, is continuous above with the cervico-vesical septum and like it can be easily separated into two layers corresponding to the related viscera. It has already been remarked that, after repeated pregnancies, there may be sufficient separation to permit the vesico-uterine fold of peritoneum to extend as far down as the upper part of the vagina. Over the trigone the tissue is denser and separation becomes more difficult, while along the urethra the two canals are so closely united that anatomical isolation becomes impossible. The urethro-vaginal septum is from 5 to 12 mm. thick.

The posterior wall is divisible according to its relations into three portions: *peritoneal*, above; *rectal*, in the middle; and *perineal* below. The peritoneal portion is from 10 to 15 mm. in vertical extent and comprises the part in contact with the pouch of Douglas. This may contain convolutions of the intestine, or a prolapsed ovary or oviduct. The recto-vaginal septum is about 4 cm. long and 3–4 mm. thick, and contains veins and lymphatics. The two tubes are readily separable. Below this portion of closest contact the rectum bends sharply backward to end in the anal canal, leaving between itself and the vagina a space triangular in section, about 25 mm. in length from above downward, and the same in thickness. This is called the perineal body and is composed of the external sphincter of the anus, the transversus perinei superficialis muscle, and the thin muscular bands called the constrictor vaginæ, all being intimately united.

Laterally we may also distinguish three portions: *pelvic*, above the levator ani; *intramuscular*, where it passes through that muscle; and *perineal*, below it. The pelvic

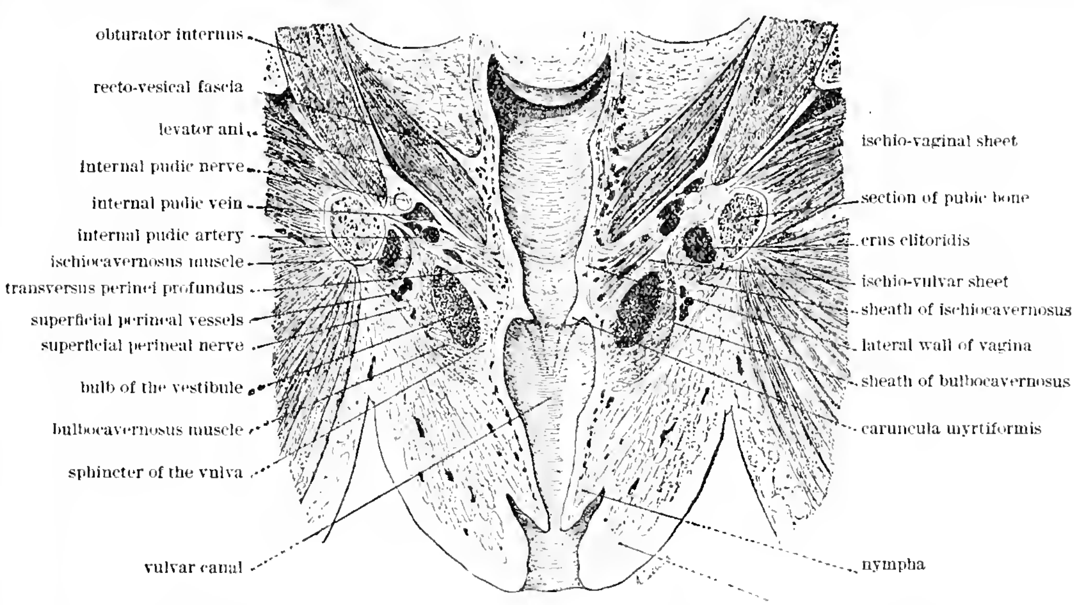

FIG. 4233.—Lower Part of a Vertical Transverse Section of the Female Pelvis, showing the Urogenital Diaphragm, the Vagina, and the External Genital Organs. (Farabeuf.) The former position of the hymen is indicated by dotted lines.

portion is composed of areolar tissue like that which forms the parametrium, of which it is a continuation. It is often called the paravaginal tissue. Waldeyer proposes for it the term *paracolpium*, which is etymologically more correct.

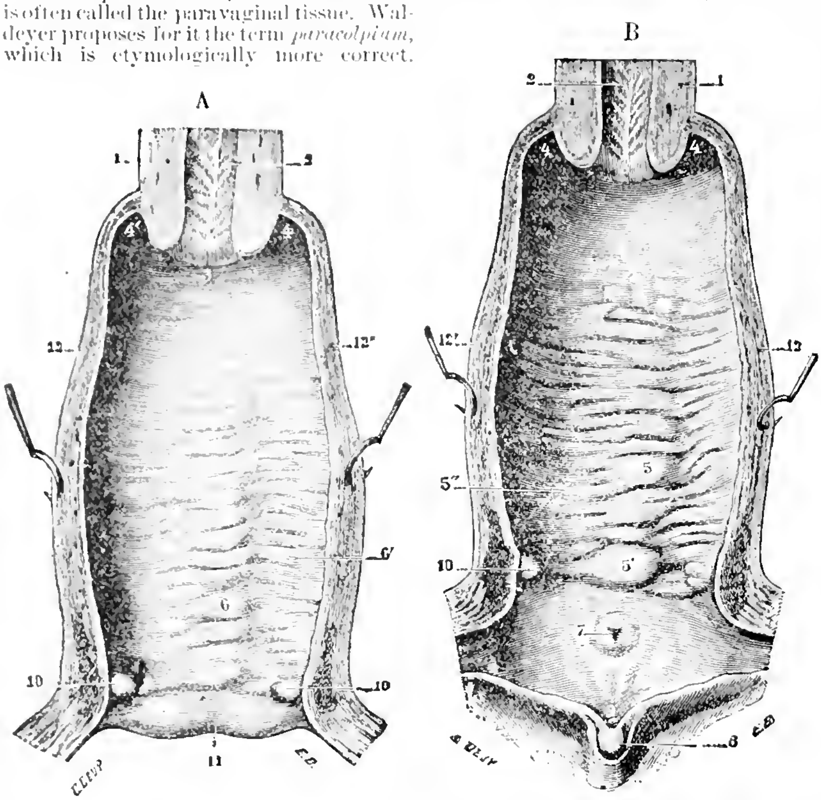

FIG. 4234. Section of the Vagina through its Lateral Borders. (Testut.) *A*, Posterior segment showing posterior wall; *B*, anterior segment showing anterior wall; 1, cervix uteri; 2, cervical canal with arbores vitæ; 3, external orifice; 4, 4', lateral culs-de-sac of the vagina; 5, anterior column, with 5', the vaginal tubercle, and 5", the transverse folds of the anterior wall; 6, posterior column, with 6', transverse folds of the posterior wall; 7, meatus urinarius; 8, clitoris; 9, vestibule; 10, 10, carunculæ myrtiformes; 11, fossa navicularis; 12, 12', sections of the lateral walls of the vagina.

It contains abundant plexuses of veins surrounding the vaginal, cervico-vaginal, and vesico-vaginal arteries. Sometimes the loop of the uterine artery itself descends to this level, lying about 15 mm. outside the vaginal wall. The ureters are at first about 15 cm. from the lateral cul-de-sac. As they pass forward they approach the wall and finally almost touch it anteriorly. The ganglion of Lee lies against the upper lateral portion, and remnants of the Wolffian duct, known as the ducts of Gärtner, are occasionally found there. The fibres of the levator ani cross obliquely, adherent only by loose areolar tissue. By its contraction the muscle closes the vaginal passage. The tissues below this crossing belong to what is known as the urogenital diaphragm, which is composed of the two layers of the triangular ligament, here distinguished as the ischio-vaginal and the ischio-vulvar sheets, and the muscles which lie between them, viz., the transversus perinei profundus and the constrictor urethræ. Below the diaphragm and impinging upon the vulva are found the vulvo-vaginal glands and the bulbocavernosus muscle surrounding the bulbs of the vestibule, hereafter to be described.

Interior Configuration.—In the young person who has not borne children the interior of the vagina is by no means smooth (Fig. 4234). At its lower part it is crossed by transverse folds or rugæ, which thin away laterally but medially thicken to form a longitudinal elevation on both the anterior and the posterior wall. These are known as the *columns* of the vagina (*columnæ rugarum*). Both the columns and the rugæ are better developed below and on the anterior wall than above and behind.

The anterior column follows quite closely the course of the urethra, and on that account is sometimes called the *carina urethralis*. It usually terminates below in a well-marked elevation, the *vaginal tubercle*, situated just behind the meatus urinarius. The column and the tubercle afford an excellent guide to the meatus in catheterization of the urethra. These elevations become gradually less marked toward the fornix and wholly disappear in the upper part of the vagina. In the fœtus of eight or nine months the rugæ are found throughout the entire extent of the canal, and resemble in appearance the valvulæ conniventes of the small intestine. After considerable distention of the vagina they tend to disappear, and only traces of them can be found in multiparæ. They appear to be less frequent among some of the lower human races and are absent in apes.

The adherence of the upper part of the anterior wall to the trigone of the bladder is marked by a smooth, triangular area over which the rugæ and columns are entirely effaced. This is known as the *vaginal triangle*, or triangle of Pawlick (*area trigonalis vaginæ*, Fig. 4235). It is situated 25 or 30 mm. below the external orifice of the uterus. Its two superior angles mark the points where the ureters enter the bladder, and are of importance as guides in the catheterization of those conduits.

In virgins the orifice of the vagina is normally partially closed by a fold developed from its posterior wall, called the *hymen* (*hymen femininus*), from the Greek *ὑμήν*, a membrane, not from the Latin deity who presided over marriage. Much discussion has arisen as to the morphological character of this fold. As it appears to be developed from the Müllerian duct it would seem that it must belong to the vagina. The duct is formed from a solid cord of cells by the degeneration of the centrally situated portions. At the lower end some portions of the cord persist and form the hymen (Fig. 4236).

As might be expected from its peculiar origin, the hymen varies much in its extent and shape. Some of the earlier anatomists denied its existence, and even Ve-

Sexual Organs.

salius considered it rare. It is indeed occasionally absent altogether. Its usual form is that of an unbroken, semilunar fold of sufficient size to occlude the greater portion of the vaginal orifice, leaving an opening large enough to permit the evacuation of the menstrual flow (Fig. 4237, *A*). Frequently it surrounds the orifice in a ring-like manner (*hymen annularis*), the opening being either medially or laterally situated. This opening may, however, take the form of a slit, having two lips laterally situated (*hymen bilobatus, seu bilabiatus* Fig. 4237, *C*). There may be two openings (*hymen biperforatus*, Fig. 4237, *D*), several openings (*hymen cribriformis*, Fig. 4237, *E*), or none at all (*hymen imperforatus*). This latter form requires surgical interference to effect the proper menstrual evacuation. The edges of the hymen may be variously cut (*hymen fimbriatus*, Fig. 4237, *B*), simulating the ruptures seen after defloration. The membrane may be unusually thick (*hymen carnosus*), even resembling cartilage and able to resist rupture.

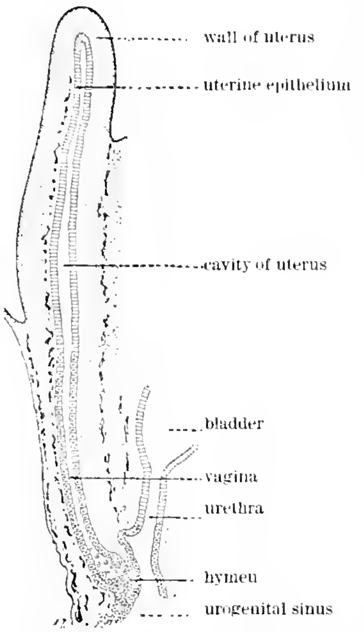

FIG. 4236.—From a Human Fœtus 10 cm. Long. Longitudinal section passing through the genital cord. (Tourneux.)

It is, however, usually ruptured at the first sexual approach. It then shows irregular jagged tears, some of which reach to the outer circumference. After healing, which is not long delayed, there are produced a number of rounded nodules (*lobi hymenales*) united by thickened edges. This form (*hymen defloratus*, Fig. 4238) may be distinguished from the fimbriate variety by the character of the lacerations, which in the deflorate form usually reach the circumference, in the fimbriate are less extensive and united by fine filaments.

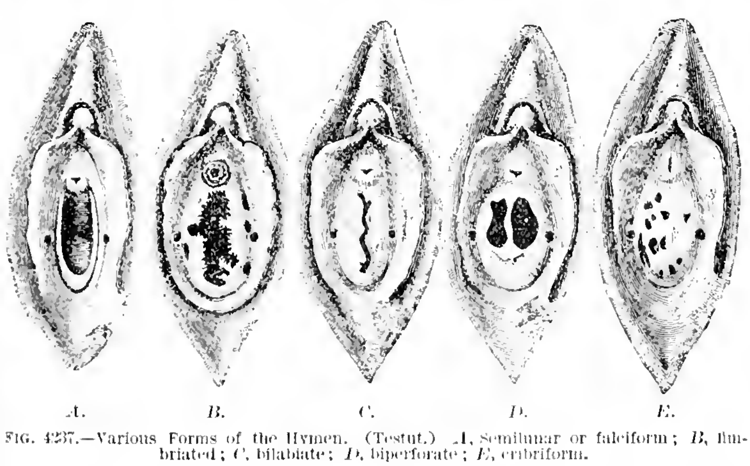

FIG. 4237.—Various Forms of the Hymen. (Testut.) *A*, Semilunar or falciform; *B*, fimbriated; *C*, bilabiate; *D*, biperforate; *E*, cribriform.

When labor ensues, the lobi hymenales are stretched and torn so that they afterward appear as a number of flattened, cicatrized elevations. In this state they are called the *carunculæ hymenales* or *myrtiformes* (Fig. 4240).

A hymen usually contains blood-vessels, and it is popularly supposed that its rupture is always accompanied by hemorrhage. Among the Eastern nations much reliance is placed on this "sign of virginity." The ancient Hebrews appear to have accepted it, as will be seen from Lev. xxii. 13-21. While slight hemorrhage is usual, and dangerous loss of blood has been known to occur, yet it often happens that the membrane is ruptured without such signs, and pregnancy not infrequently ensues with the hymen uninjured. (Fig. 4239.)

The great differences that occur in the hymen—it sometimes being torn by very slight violence, by the fingers or by some accidental circumstance, while at other times it remains intact after sexual approach and even after delivery—detract from its value as a matter of evidence in medico-legal cases. Haberda believes that it is often impossible to determine positively whether coitus has occurred. The carunculæ hymenales are more reliable, as they are found only in those who have borne children.

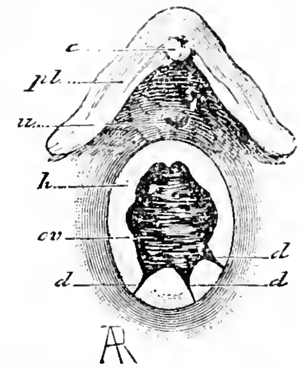

FIG. 4238.—Deflorate Hymen. Condition after first sexual approach. (Budin.) *c*, Clitoris; *pl*, nymphæ; *u*, meatus urinarius; *ov*, orifice of vagina; *h*, remains of hymen; *d*, *d*, *d*, tears.

Structure.—We may consider the vagina as possessing three coats: external, or adventitious; middle, or muscular; internal, or mucous.

The *external* coat can hardly be said to be an intimate part of the tube, but rather the packing of connective tissue that surrounds and connects it with other organs, it being the paravaginal tissue already adverted to. It contains smooth, muscular fibres, elastic fibres, deposits of fat and contorted, vascular plexuses that give it a loose, spongy character.

The *muscular* coat is composed of smooth fibres that cannot, in all parts, be definitely separated into layers. Externally they communicate with the muscular fibres found in the paravaginal tissue. Longitudinal bands lie along the anterior wall, connecting with the bladder above. The inner fibres are, for the most part, circular. They increase greatly in size and number during pregnancy. Above, the muscular tissue is continuous with that of the cervix; below, it is so much thickened that some authors describe a sphincter of smooth fibres. Luschka mentions longitudinal fibres that pass to the triangular ligament, constituting a *levator vaginæ*, said to elevate and dilate the vaginal orifice. A considerable amount of white fibrous and yellow elastic tissue is mingled with the muscular elements of this coat.

The mucous layer resembles the skin, being a stratified, pavement epithelium resting upon dermal papillæ. Its color is pinkish when inactive, red during menstrual or sexual excitement, and purplish red during pregnancy, when it is considerably congested. It is from 1 to 1.5 mm. thick, quite firm and attached to the subjacent, muscular layer without any intervening areolar tissue. During operations it is easily stripped off, but in that case usually carries with it portions of the muscular layer. The papillary part contains many elastic fibres, some scattered lymphoid cells, and occasional closed follicles. The mucous membrane contains no glands, and the acid mucus found on the vaginal walls is either an exudation, or, perhaps, the secretion of the uterine glands altered by bacterial agencies. A number of species of bacteria are found on the membrane, some of which appear to be peculiar to this locality.

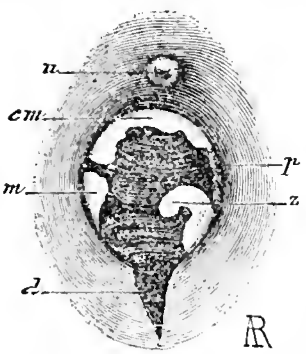

FIG. 4239. — Hymen After Childbirth. (Budin.) *n*, Meatus urinarius; *d*, tear; *cm*, carunculæ myrtiformes; *z*, detached floating tatter of the hymen; *p*, raw edge.

Arteries. — These are derived from several sources. Above, the cervico-vaginal branches of the uterine artery supply the fornix and upper third of the vagina; in the middle portion the vaginal artery proper, from the internal iliac, is distributed; while the lower part is supplied by a twig from the inferior hemorrhoidal, known as the inferior vaginal. The vaginal artery proper often arises in common with the uterine, the middle hemorrhoidal, or the inferior vesical. It is not unusual to find it represented by several branches. The arteries anastomose freely along the walls of the conduit and with the arteries of the neighboring organs. The arteries of opposite sides may unite to form median anterior and posterior vessels, running longitudinally, the so-called *azygos* arteries. Deficiency in one branch of supply is usually supplemented by an increase in the others. Arterioles reach all the layers of the vagina, being especially abundant in the papillæ of the mucous membrane.

Veins.—These are so numerous that they were considered by Kobelt as forming an erectile tissue, but they lack the special characters of that structure. They are particularly developed at the sides of the vagina, forming a large plexus that is continuous with the uterine plexus above, the vesical plexus in front, and the hemorrhoidal plexus behind. Hyrtl has shown that they also communicate with the portal system by anastomosis with the superior hemorrhoidal vein. They may thus discharge in three directions: below the levator into the perineal system, above it into the internal iliac and portal veins. Very few valves are found in these veins. They are surrounded by connective tissue and smooth muscular fibres, which cause them to remain open when cut. Hemorrhage from them is therefore difficult to stop and septic infection is easy.

FIG. 4240. — Hymen Before Childbirth. (Budin.) *n*, Meatus urinarius; *h*, hymen whose edges are intact notwithstanding the sexual approaches.

Lymphatics.—Both the mucous membrane and the muscular coat contain a great number of lymphatics (Fig. 4241). The mucous coat has a fine-meshed plexus that communicates with that of the cervix above and that of the external genitals below. The muscular coat also has a plexus with much larger meshes. The two communicate freely. According to Poirier, they discharge by three groups of collecting vessels: a superior set that ends in glands that lie along the course of the internal iliac artery; a middle set that terminates in glands along the internal iliac; and an inferior set that passes along the sacrum to end in glands near the promontory. By anastomoses with other vessels these may communicate with the inguinal glands. Morau states that communications also exist between the middle set and the glands within the fibrous sheath of the rectum.

Nerves.—The upper and middle portions of the vagina are supplied from the same sources as the uterus. These parts are not very sensitive. The anterior wall, particularly, can be operated on without much pain to the patient. The lower portion is supplied with additional filaments from the internal pudic nerve, and is much more sensitive. Intra-epithelial plexuses and terminations occur as in other stratified epithelium.

THE VULVA.—*Etymology.*—From the vulgar Latin *vulva* or *volva*, a covering or wrap, hence the womb. Derived from *volvere*, to roll around or about. Celsus used it for the combined uterus and vagina. Spigelius derived it from the Latin *valva*, a double or folding door. The more usual Latin term for the external genitals was *cunnus*, probably derived from *cuneus*, a wedge, referring to the shape either of the mons veneris and labia as seen with the thighs closed, or of the expanded genital cleft. A synonym often used is *pudendum*, from *pudere*, to feel shame. French, *vulve;* Italian, *vulva;* German, *Scham*.

Definition.—The external genital organs of the female, including all those derived from the urogenital sinus and found below the urogenital diaphragm. They are a series of related organs rather than the parts of a single one. Together they form an ovoid or wedge-shaped eminence situated on the surface of the body at the lower part of the abdomen, between the thighs. They include: (1) a median cleft like space, the *vestibule*, with the vestibular glands; (2) the *labia* and *nymphæ*, tegumentary folds that limit this on either side; (3) the erectile apparatus, comprising the *clitoris* and *bulbs*. Some authors use the term merely to designate the genital opening with the labia.

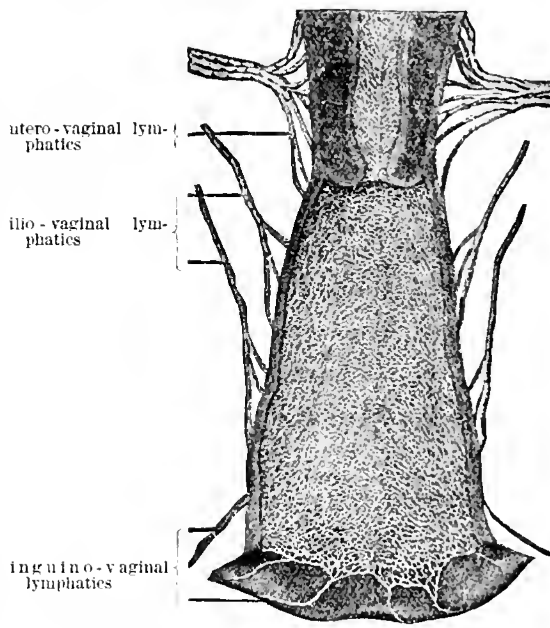

FIG. 4241.—Network of Lymphatics of the Vaginal Mucous Membrane. Efferent trunks of the vagina. (Poirier.)

General Arrangement.—But little of the external genitals is visible when a female is standing erect. Only a fleshy protuberance, covered with hair, the *mons pubis* or *mons veneris*, appears at the lower extremity of the abdomen, limited externally by the thighs and below passing into two fleshy folds, the *labia*, between which is seen

Sexual Organs.

the half-effaced end of the *rima pudendi*, or genital cleft. In some cases the end of the clitoris may protrude at the upper end of the cleft, and, still more rarely, the edges of the nymphæ may be seen.

When the subject is placed in the dorsal position with widely parted thighs, flexed upon the abdomen, the genital cleft is stretched apart and forms a wedge-shaped fossa, rhomboidal in outline, limited on either side by the labia, extending in front to the mons pubis, behind to about 3 cm. in front of the anus (Figs. 4242, 4243). Within this space, running parallel to the labia majora, are seen two reddish folds, the *nymphæ*, which unite anteriorly by embracing a small penile appendage, the *clitoris*. The space between them is known as the *vestibule*. The vaginal orifice may be perceived posteriorly, and beneath the mucous membrane on either side of this are found masses of erectile tissue known as the *bulbs of the vestibule*.

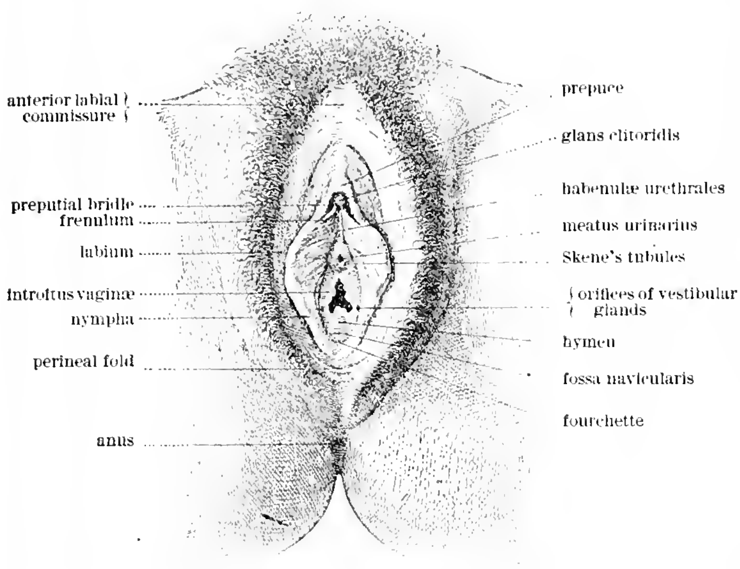

FIG. 4242.—External Genital Organs of a Virgin as seen after Separating the Labia and the Nymphæ. (Rieffel.)

The Vestibule.—This may be defined as the portion of the urogenital cleft that lies between the nymphæ, limited in front by the clitoris, behind by the fourchette when that exists. It is not always used in this sense. Schäfer limits it behind "by a transverse line at the level of the urethra"; Gray, following the example of most French anatomists, by the entrance to the vagina. If this limitation were imposed, it would hardly be proper to speak of the "bulbs of the vestibule" or of the "vestibular glands," both of which structures are situated at the sides of or behind the vaginal opening.

Like the vagina, its walls are in contact when not stretched apart. When the thighs are separated it appears as an almond-shaped space, looking downward and a little forward, its broad, rounded end being posterior. It presents a roof, two ends and sides, the latter being the inner surfaces of the nymphæ.

The roof, which has in front a smooth, uniform surface, pinkish in color, presents, about the junction of its anterior and middle thirds, the *meatus urinarius* or external opening of the urethra. This is seated on a rounded eminence, the *urethral papilla*, which is not usually smooth, but covered with rugosities or small vegetations which may hinder the introduction of the catheter. The orifice is usually an antero-posterior slit 5-6 mm. in length, but may be of various shapes, semilunar, triangular, or puckered. While it is the smallest and least dilatable portion of the urethral canal, it may, if proper precautions are used, be gradually enlarged to 20-25 mm., or even to a greater size, without inducing incontinence of urine. Thus the finger may be introduced for exploration of the bladder, or stones and foreign bodies extracted. In some instances of absence or closure of the vagina, it is said that attempts at copulation have resulted in the introduction of the penis into the urethra. The orifice is almost vertically under the pubic arch and 25 mm. from it. Its distance from the glans of the clitoris is usually somewhat less.

Running forward from the meatus to the clitoris, there may be seen in young subjects two fine whitish lines, called by Waldeyer the *habenulæ urethrales* (Fig. 4242). They represent the vestiges of the anterior part of the corpus spongiosum which, in the female, remains rudimentary. They were first noted by Pozzi (1884), who called them the "bride masculine."

On either side of the urethral orifice there may be noted the openings of two ducts for tubular glands situated on either side of the urethra and apparently homologous with the prostatic glands of the male. These ducts are often called Skene's tubules, as they were especially

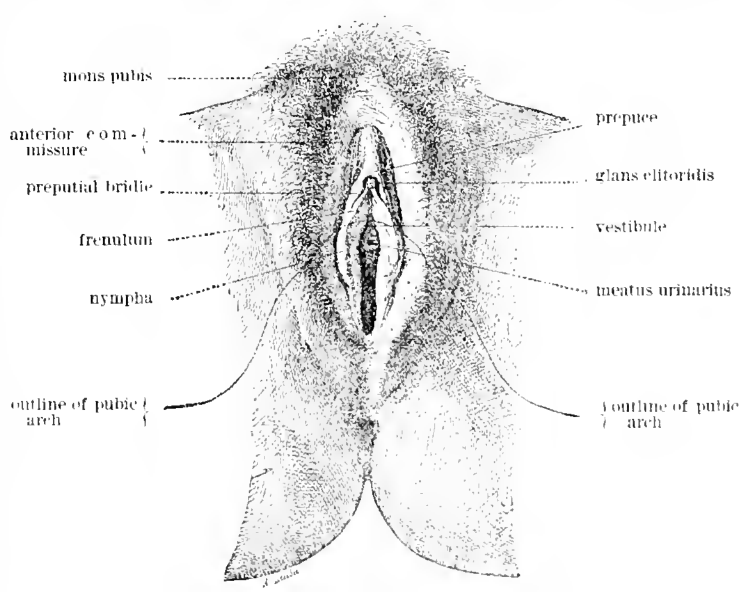

FIG. 4243.—External Genital Organs of a Multipara as seen after Slight Separation of the Labia. (Rieffel.)

studied by Skene in 1880. They were, however, known to Morgagni and De Graaf.

Behind the urethral opening is found the introitus vaginæ, closed more or less in the virgin by the hymen, and showing, in multiparæ, the carunculæ hymenales. The relation to the urethra borne by the anterior column of the vagina and the vaginal tubercle has been already mentioned. Since the hymen forms a membrane across the orifice of the vagina there is a slight groove formed between it and the nymphæ on either side, and this remains after the rupture of the structure. This is called the *nympho-hymeneal* or *nympho-caruncular sulcus.*

In this groove, opposite the lower and middle thirds of the introitus, are seen the openings of two ducts, one on either side, which belong to glands buried quite deeply in the fatty tissue between the vestibule and the ischium. These are the *greater vestibular glands* (*glandulæ vestibulares majores*, Fig. 4244), often called the glands of Bartholin, from Thomas Bartholin, who discovered them in the human subject in 1680. They had previously been seen in the cow by Duverney. Our most exact knowledge of them is due to Huguier (1849), who called them the vulvo-vaginal glands. He described them as situated, one on either side, about 1 cm. below the hymen, from 1 to 1.5 cm. from the ischium, 1 cm. from the bottom of the genito-crural fold of the integument. They are also about 3 cm. from the inferior edge of the labium. By compressing the posterior part of the labium between the thumb and forefinger, a gland can usually be felt. They are acinous glands, about as large as a pea or small bean, slightly oval in shape, and discharge by a duct 15–18 mm. long, and large enough to admit the cannula of an ordinary hypodermic syringe. They secrete a clear, viscid liquid that is discharged in considerable quantity during sexual excitement. This discharge was called by the older writers the female semen, and was long supposed to be the active generative product. It apparently serves as a lubricant to the passages during coitus. The glands attain their maximum development at puberty and atrophy during old age. They are homologous with the bulbo-urethral or Cowper's glands of the male. In normally developed virgins the nymphæ are united behind by a short transverse band, the *fourchette* or *frenulum labiorum.* This is ruptured at childbirth and sometimes by sexual approaches, and its relics may then be seen as a whitish scar. The shallow space between this band and the hymen, or the vaginal opening when the hymen is absent, is known as the *navicular fossa* (*fossa navicularis*). If the nymphæ are short the frenulum is absent. It should not be confounded with the artificial fold produced by widely separating the labia.

The Mons Pubis.—The genital cleft is bounded on either side by two pairs of tegumentary folds which unite in front below a rounded prominence situated directly over the symphysis pubis. This is the *mons pubis* or *mons veneris.* It is usually separated from the general surface of the abdomen by a shallow furrow, the *pubic sulcus,* and from the thighs by the *inguinal sulcus.* Smooth, or coated with a fine lanugo in the child, as puberty approaches it becomes covered with thick and somewhat stiff hairs that have a tendency to curl. The extent of this hairy covering varies very much in different individuals, being greatest in the races of Southern Europe. Usually it descends upon either side of the labia as far as the anus. Upward it may much exceed the limits of the mons pubis and extend upon the abdomen. The hairs usually agree in color with those of the armpits and head, but they have the general appearance of those of the male beard, though usually somewhat thinner. They are spirally twisted, have a medullary canal throughout, are stronger than the hairs of the head, and show on section a triangular, irregularly fluted outline (Waldeyer).

Beneath the integument of the mons pubis is a thick cushion of fat in which are found numerous elastic fibres continuous with those of the labia and the suspensory ligament of the clitoris. These cause a gaping of incised wounds made transversely in this region.

The Labia.—These tegumentary folds, often distinguished as the labia majora, correspond to the scrotum of the male and their external appearance is not unlike that organ when empty and considerably retracted. They are about 25–35 mm. long, 8–15 mm. in depth, and 3.5 mm. thick. They are limited on either side by a deep extension from the inguinal furrow known as the genito-femoral sulcus. Like the scrotum their outer surface is darkly colored, somewhat roughened, and covered with hair which is extended in a scattered manner to the marginal part of the inner surface. The deeper part of this surface has the appearance of the lips of the face, being smooth, reddish and humid. The groove between it and the nympha is called the nympho-labial furrow.

Immediately below the mons pubis the labia unite over the back of the clitoris (*torus clitoridis*) in an anterior commissure (commissura labiorum anterior). Behind they gradually narrow and are lost on the perineum.

Within their substance, the labia contain a layer of smooth muscular fibres analogous to the dartos of the scrotum, a considerable quantity of connective tissue, including many elastic fibres, and subcutaneous fat. A considerable mass, called the adipose body of the labium, almost wholly fills the middle portion of the lip, resembling somewhat the fat-ball found in the cheeks of the face. It is a derivation from the subperitoneal fat with which it is often continuous along the round ligament of the uterus, which, it will be remembered, passes through the inguinal canal and is inserted here. The canal of Nuck is sometimes continued down into the labium and may be the seat of a hydrocele.

The Nymphæ.—This name was introduced by Severinus Pinæus and Spigelius in the early part of the seventeenth century, "*ut enim nymphæ scaturientibus aquis præsunt,*" because, like nymphs, they control the gushing streams, it being supposed that they directed the course of the urinary jet. Though this view of their function is incorrect, the name lends itself well to combinations and ought to be retained. They are often called the labia minora or lesser lips, from their close association with the outer lips or labia proper. When the genital cleft is parted they appear as two cutaneous folds (Figs. 4242, 4243) running parallel with the labia, often more reddish in appearance, and not as smooth, being slightly roughened on their inner surfaces by small elevations, and often irregularly denticulated or incised on their free edges, an appearance which led Spigelius to compare them to a cock's comb. Their size varies much in different individuals. At birth they usually extrude beyond the labia, which are then but slightly developed. In the adults of European races they are ordinarily concealed, having a length of 25–35 mm., a breadth of 8–15 mm., and a thickness of 3–5 mm. They may, however, be large enough to extrude, and their exposed surfaces then take on a brown coloration like that of the areola of the nipple. In some African races they are enormously developed, being six to eight inches wide, extending upon the thighs to form what has been called the "Hottentot apron."

The outer surface of each nympha is separated by the nympho-labial furrow from the corresponding labium, from which it differs by its absolute freedom from hairs. The inner surface, more rough, is in contact with the opposite nympha when the genital cleft is closed. The attached surface is in contact with the bulb of the vestibule.

The anterior extremity is continued forward and embraces the clitoris by dividing into two branches (Fig. 4244), the anterior one of which unites with its fellow of its opposite side to form for the organ a small prepuce or foreskin, similar, on a diminished scale, to the prepuce of the penis of the male. It does not usually cover the glans, but may be sufficiently developed to admit of circumcision, which is said to be practised by the Abyssinians. The posterior branch is inserted, with its fellow, on the glans of the clitoris and forms a restraining band, the *frenulum* of the clitoris. Owing to the traction of the nymphæ through this band, the clitoris is bent downward toward the vaginal orifice.

The nymphæ are composed of a network of vascular, areolar tissue without fat, enclosing numerous large veins with associated, smooth, muscular fibres, which give the organ an erectile character. Its outer investment is stratified epithelium, which resembles a mucous membrane by its coloration, its smooth and humid character and its absence of hair; while, on the other hand, it resembles the skin by the character of its epithelium, which has scale-like cells that lose their nuclei, tactile corpuscles, and sebaceous glands in great numbers. In the lower animals these glands are especially active during rut, and doubtless entice the male by some characteristic odor. The epithelium becomes darker during pregnancy.

While the erectile tissue of the female genitalia is somewhat widely distributed, being found in the nymphæ and to some extent along the vagina, it is especially marked in two organs, which together are homologous with the penis of the male. These are the clitoris and the bulbs of the vestibule.

The Clitoris. — The name is neo-Latin, from the Greek κλειτορίς, said to be derived from κλείειν, to close or shut. Hyrtl thinks it is related to κλειτορίζειν, to titillate. This would be analogous to *Kitzler*, the German vernacular name for this organ.

It represents a small appendage, resembling a diminutive penis, suspended at the summit of the pubic arch (Figs. 4242, 4243, 4244, 4245, 4246) and enfolded by the anterior juncture of the nymphæ. Like the penis it possesses two corpora cavernosa, small rods of erectile tissue, united in front to form the *body* of the organ, diverging behind as its *crura*. The body is crowned with a small *glans*. Unlike the penis, the glans is not perforated by the urethra, and there is no corpus spongiosum attached to it. When lax the organ is so withdrawn within the folds of the nymphæ and labia that it is difficult to make out its form and dimensions.

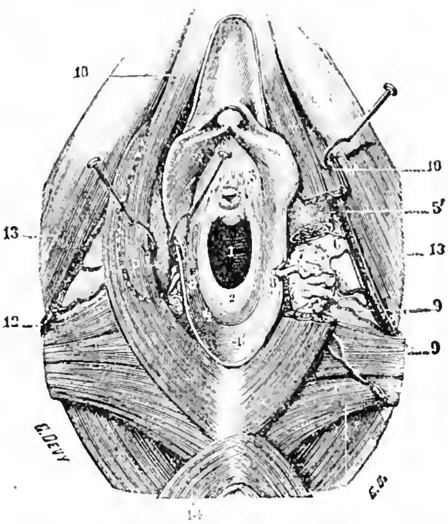

FIG. 4241.— Dissection of the Vulva, showing the Vestibular Glands. 1, Orifice of the vagina; 2, hymen; 3, meatus urinarius; 4, navicular fossa; 5, bulb of the vestibule; 6, vestibular or vulvo-vaginal glands; 7, 8, duct; 10, constrictor vaginæ; 11, transversus perinei muscle.

The crura are attached on either side to the inner aspect of the pelvic arch, half way between the tuberosity of the ischium and the symphysis. Wholly hidden within the folds of the labia, they pass forward, inward, and a little upward, along the external face of the triangular ligament, surrounded by the ischio-cavernosus muscle (*erector clitoridis*) and join each other below the symphysis to form the body, room being left between their junction and the arch to permit the passage of vessels and nerves.

Almost immediately the body is bent downward and backward, forming what is called the *angle* of the clitoris. Unlike the angle of the penis, this does not become obliterated when the organ is erect, and this doubtless subserves the function of the organ. Movements are prevented by the frenulum, which, as already mentioned, draws the glans down toward the vaginal orifice, and by the *suspensory ligament*, a fibrous band like the similar organ of the penis, that passes from the angle to the linea alba.

The body of this little organ is nearly cylindrical in shape, usually slightly grooved on its under surface because of its duplex structure. An imperfect division or *septum pectiniforme* separates the two lateral halves. Females of animal species in which the males possess a penis bone have sometimes a minute bone or

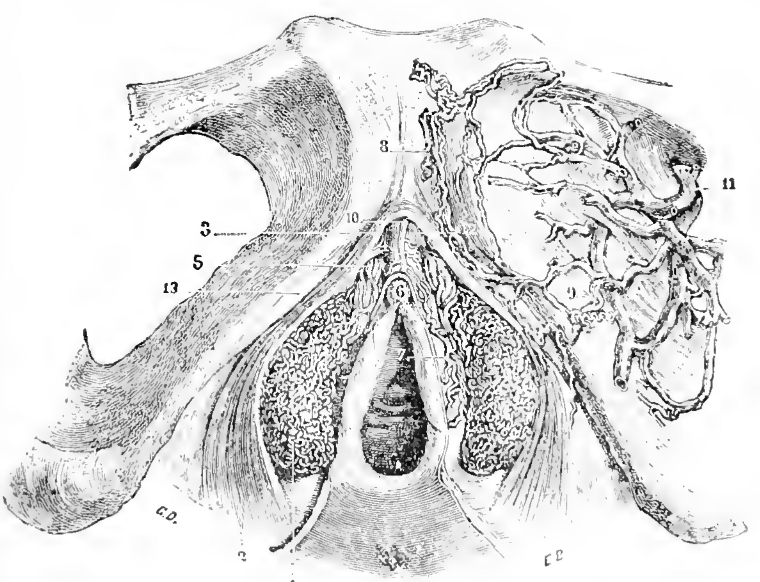

FIG. 4245.—The Bulb of the Vestibule and the Venous System of the Clitoris seen from the Front. (Kobelt.) 1, Bulb of the vestibule; 2, constrictor vulvæ muscle; 3, anterior portion of same; 4, portion that passes under the clitoris; 5, pars intermedia; 6, glans of clitoris; 7, veins from nymphæ; 8, veins passing to superficial veins of abdomen; 9, veins communicating with the obturator vein; 10, dorsal vein of clitoris; 11, obturator vein; 12, body of clitoris; 13, right crus of clitoris.

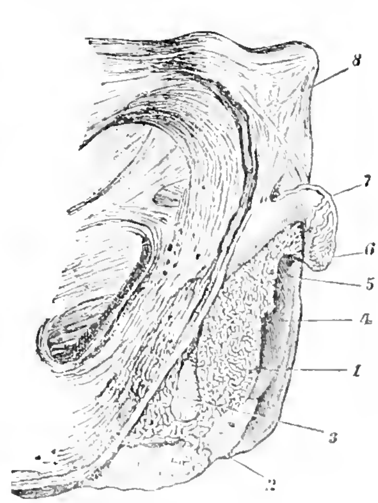

FIG. 4246. Bulb of the Vestibule and the Clitoris Seen from the Side. (Kobelt.) 1, Right bulb of the vestibule; 2, veins from its lower end that discharge into the internal pudic vein; 3, vestibular gland; 4, introitus vaginæ; 5, pars intermedia; 6, glans clitoridis (the clitoris is somewhat elevated); 7, dorsal vein of clitoris; 8, symphysis pubis.

cartilage in this septum. The greater part of the body is concealed under the anterior commissure of the labia, its swelling outline forming the *torus clitoridis.*

The glans, which terminates the organ, is a small, rounded, conoid tubercle. It is independent of the corpora cavernosa, capping over their fusiform ends as in the penis. It has a small prepuce derived from the nymphæ, and a preputial sac in which small collections of smegma may accumulate. To its under surface is attached the frenulum.

The following measurements of the clitoris are given by Krause:

	When relaxed.	When erect.
Length of body	18 mm.	29 mm.
Thickness of body	5 mm.	9 mm.
Length of crura	40 mm.	45 mm.
Thickness of crura	5 mm.	8 mm.
Diameter of glans	4–7 mm.	6–9 mm.
Total volume	2 c.c.	6 c.c.

Considerable individual variations are found. The organ may be of such size as to be mistaken for a small hypospadiate penis, and thus lead to mistake in determining the sex of a child.

The structure of the clitoris repeats, on a diminutive scale, that of the penis. Each corpus cavernosum is surrounded by a firm, elastic, fibrous envelope, the *tunica albuginea*, from whose deep surface are given off numerous bands or trabeculæ, along which run smooth, muscular fibres. These trabeculæ divide the substance of the organ into numerous small spaces, termed areolæ, which are really venous sinuses, as they are lined with endothelium and communicate widely with the veins. Into these areolæ empty arterioles (helicine arteries). Erection occurs from the rapid filling of the areolæ by the expansion of the arterial orifices through the action of vaso-dilator nerves, and the impeding of the venous discharge by the ischio-cavernosus muscle and the elastic envelope. This apparatus is by no means as well developed as in the corresponding organ of the male, consequently erection is less complete.

The glans has no albuginea, but under its epithelium is a considerable fibro-elastic network which performs a similar function. Areolæ occur and the vascular supply is similar to that of the corpora cavernosa. Its cutaneous investment is supplied with special nerve endings, which give it remarkable and special sensibility. According to Dogiel there are intra-epithelial plexuses with filaments ending in flattened platelets, tactile corpuscles within the papillæ, corpuscles of Pacini and the end bulbs of Krause in the subcutaneous tissue, while at the base of the papillæ are the special endings which Krause believes to be related to the peculiar sensibility of the organ and has named corpuscles of sexual pleasure (Wollustkörperchen). They are usually called genital corpuscles.

The Bulbs of the Vestibule.—The corpus spongiosum urethræ of the male, including the bulb of the urethra, is represented in the female by two oval masses of erectile tissue that lie beneath the nymphæ on either side of the vestibule and in front of the triangular ligament (Figs. 4245, 4246). Their lower ends are free, but they are united above over the lower end of the urethra, thus simulating the form of a horseshoe set astride of the vaginal opening. They were called by De Graaf *corpus clitoridis*, by Taylor *semi-bulbi corporis spongiosi*, and, since the time of Kobelt (1844), are generally known as the *bulbs of the vestibule* (*bulbi vestibuli*). They should be considered as the male organ separated into two portions by the intrusion of the vaginal opening in the median line.

Enlarged and rounded at their lower extremities, they are bulb-like in form. Their shape has also been compared to that of an almond, a fig, or, still more aptly, to that of an engorged leech, which they closely resemble because of their long, tapering, upper extremities which unite with each other and with the clitoris. Their dimensions vary in different individuals. Usually reaching as far back as the navicular fossa, they may not extend beyond the middle of the vaginal opening, or, on the other hand, they may be continued behind on to the perineum. When not turgid, each bulb is, in ordinary cases, about 30–40 mm. long, 10–15 mm. broad, and 5–10 mm. thick.

The bulbs are only about 8–10 mm. from the pubic arch, but are so situated with regard to the vaginal opening that they are pushed forward and away from the bones as the fœtal head descends. Rupture of one of them may, however, occur during labor, especially if instruments are used. This occasions a large hæmatoma in the corresponding labium, or, if the rupture extends through the entire integument, a serious hemorrhage.

The upper or deeper surface of the organ is applied to the ischio-vulvar or outer sheet of the triangular ligament, to which it is attached by some lax, areolar tissue. Its inferior or superficial surface is covered by the basis of the nymphæ. Like the bulb of the urethra in the male, it is invested externally by a sphincter muscle, the bulbo-cavernosus, which, by the separation of the two bulbs, becomes applied to the outer surface only, forming a constrictor of the vagina. Its internal surface embraces the vestibule, skirting the orifice of the urethra, the vagina, and the vestibular glands. Its anterior extremity, pointed and drawn out, communicates above the opening of the urethra with the glans of the clitoris and with the opposite bulb. The plexus thus formed was called by Kobelt the *pars intermedia.* It lies immediately under the habenulæ urethrales, and with them constitutes a vestige of the corpus cavernosum urethræ of the male.

In structure the bulbs resemble the corresponding organ of the male. They are invested by a thin tunica albuginea, within which is a plexus of large veins surrounded by muscular fibres sparsely distributed. The organ has the general structure of erectile tissue, but is much less perfect in that function than the clitoris, and very far below the male penis. When engorged with blood it assumes a swollen, doughy consistence rather than a complete rigidity. It is supplied by the artery of the bulb from the internal pudic. The blood, after leaving the plexus of veins found in the organ, passes into the pudic, perineal, and clitoridian veins.

Arteries.—The arterial supply of the vulva is shown in the following scheme:

Arteries.	Distribution.
From the common femoral artery	
Superior external pudic	Small branches to the mons pubis and anterior commissure of the labia.
Inferior external pudic	*Anterior labial* branches to anterior half of labia, some of which reach the nymphæ.
From the internal pudic artery	
Dorsal artery of the clitoris.	Glans clitoridis and anterior part of nymphæ, a few twigs extending upward to the mons pubis.
Artery of the corpus cavernosum.	Crura and body of clitoris, small branch to bulbs of the vestibule.
Artery of the bulb	Bulbs of the vestibule, meatus urinarius (*urethral artery*), vestibular glands.
Superficial perineal	*Posterior labial* branches to posterior half of labia and nymphæ, bulbs of the vestibule, vestibular glands.
Transverse perineal	Posterior end of labia, navicular fossa.
From the obturator artery	
Internal terminal branch.	*External labial*, to outer surface of labia.

Veins.—With one exception these have the same general arrangement as the arteries, discharging into the internal saphenous, the internal pudic, and the obturator trunks (Fig. 4245). The dorsal vein of the clitoris discharges into the vesical plexus (plexus of Santorini), whose efferent vessels terminate in the internal iliac vein. Numerous venous plexuses occur in the different organs. Thus the areolæ of the clitoris themselves constitute a plexus, the veins of the bulbs of the vestibule are arranged in a superficial large-meshed plexus and a deep, fine-meshed one, and a plexus also exists within the nymphæ.

These communicate freely with each other and with the vesical and vaginal plexuses.

Lymphatics.—The lymphatic vessels of the external genitals are very numerous, especially upon the nymphæ and the inner surface of the labia. They discharge, for the most part, into the superior internal or pubic group of superficial inguinal glands. This group lies internal to the saphenous opening and near the spine of the pubis. It includes two to four glands. Some vessels may discharge into the inferior internal group of superficial glands, or even, though rarely, reach some of the external group. In injecting the lymphatics on one side of the vulva, it is often found that the injection reaches the opposite side.

Cunéo and Marcille have recently shown that the lymphatics of the glans of the clitoris ascend by way of the mons pubis to the inguinal canal, through which they pass, to terminate in glands situated along the iliac vessels.

Nerves.—The nervous supply of the vulva is derived both from the cerebro-spinal and from the sympathetic systems. The cerebro-spinal nerves come from both the lumbar and the sacral plexuses, the sympathetic from extensions of the hypogastric plexus known as the cavernous and the utero-vaginal plexuses. From the first are given off two nerves, the greater cavernous nerves, and a number of small nerves, the lesser cavernous nerves that supply the crura, body, and glans of the clitoris. The nervous supply of the organ is far greater, in proportion to its size, than that of the penis. With the cavernous plexus are distributed the branches from the third and fourth sacral nerves that effect erection, the *nervi erigentes* of Eckhard. Other nerves from the cavernous plexus combine with the cerebro-spinal nerves, whose distribution is given in the following scheme:

Nerves.	Distribution.
From the lumbar plexus.	
Ilio hypogastric—	
Hypogastric branch....	Integument upon upper part of mons pubis.
Ilio-inguinal—	
Inguinal branch........	Integument upon lower part of mons pubis and upper part of labium.
Genito-crural—	
Genital branch.........	To labia (anterior labial nerves).
From the sacral plexus.	
Internal pudic—	
Perineal branch........	To labia (posterior labial nerves), nymphæ, prepuce and glans of clitoris, vestibule and meatus urinarius (nerve of vestibule), bulb of the vestibule.
Dorsal nerve of clitoris.	Glans, prepuce, body and crura of clitoris.
Small sciatic—	
Inferior pudendal branch.	To labia (posterior labial nerves).

SEXUAL ORGANS, MALE. See *Genital Organs, Male.*

SEXUAL ORGANS, MALE, INJURIES AND DISEASES OF.—I. CONGENITAL DEFECTS OF THE PENIS. —*Abnormalities in Shape and Size of the Penis.*—Abnormalities in the size of the penis are of relatively frequent occurrence, although they do not naturally come under the surgeon's observation. No two penes are alike in size, and the general rule that the length of the penis varies inversely to the girth of its possessor is commonly accepted. It is alleged that rudimentary development of the penis is often associated with intellectual deficiency. It is also alleged that men of great intelligence have undersized genitals. Cryptorchids and sufferers from epispadias and hypospadias habitually have small penes. That sexual exercise has any influence upon the size of the penis is not proven. The so-called penis congestor is a mere gauge of gullibility.

Absence of the Penis.—When the penis is so small as to be apparently or actually absent the testicles are usually retained in the groin or in the abdomen, and the scrotum is split. As a result the genital organs resemble those of the female, and the condition is that of complete male pseudohermaphroditism.

Apparent Absence of the Penis.—The penis may be congenitally adherent to the scrotum; very rarely it is concealed beneath the skin of the abdomen or of the scrotum. Thus Bouteiller reported a case in which the penis appeared to be absent, but could be felt beneath the skin of the scrotum, whence it was liberated by a T-shaped incision. Usually, however, the penis is curved and only partially adherent. Such a condition is commonly accompanied by hypospadias.

Double Penis.—Double penis is extremely rare. A number of cases have been recorded in which the penile abnormality was associated with other evidences of fœtal inclusion. Exceptionally, the reduplication of the genital organ is the only abnormality. How frequent such a condition is it is impossible to estimate, since patients so afflicted not only fail to apply for relief, but sedulously shun observation. Four cases have been recorded.*

Torsion of the Penis.—This is an unusual feature of hypospadias and epispadias (*q. v.*). Caddy † has reported a case of torsion unaccompanied by any other defect.

II. PHIMOSIS.—Phimosis is an abnormal tightness of the prepuce. There are two kinds of phimosis: the one consists in an adhesion of the prepuce to the glans penis, and this is a normal condition in every male child at birth. The relief of such a phimosis is accomplished by forcibly stripping back the foreskin until the glans is entirely uncovered, recurrence of the adhesions thus torn being prevented by the application of dusting powders and by repeated retraction of the skin. This minor operation is noteworthy chiefly because its omission is the commonest cause of permanent cicatricial phimosis.

The second variety of phimosis is an undue tightness of the prepuce caused by a chronic thickening at the preputial orifice, and resulting in an inability to retract the prepuce. Such phimosis is commonly spoken of as being either congenital or acquired; but, strictly speaking, it is probably always acquired, since the thickening at the preputial orifice which prevents retraction seems, in the cases called congenital, to be occasioned by the adhesive phimosis noticed above, and by the balanoposthitis to which it gives rise; acquired phimosis is caused by any inflammation of the prepuce, notably by chancroids occurring at the preputial orifice. During the course of any of these inflammations a temporary phimosis, known as inflammatory phimosis, may be caused by inflammatory œdema.

Results of Phimosis.—If the prepuce be unduly tight, or merely unduly long, it may cause two different sets of conditions, the one irritative, the other obstructive. Thus in infancy it encourages balanoposthitis, adhesions, premature sexual excitement, and masturbation; while, from retention, it may cause incontinence of urine, frequent and painful micturition so painful as to lead to the suspicion of stone; while the straining to overcome the obstacle may result in hernia and rectal prolapse. In later life the obstruction may give rise to hypertrophy of the bladder and dilatation of the ureters and kidneys; while chronic retention may result in the form of preputial calculi, in intensified venereal troubles, especially gonorrhœa and chancroid (*q. v.*), and epithelioma of the penis (*q. v.*). Finally, phimosis interferes with coitus, and violent retraction of the tight prepuce may result in paraphimosis.

Treatment.—The treatment of phimosis is circumcision. The operation of dilating the prepuce is not worthy of consideration (*cf. Circumcision*).

Sexual Organs.

III. Paraphimosis.—Paraphimosis is that condition in which the phimotic prepuce, having been forcibly retracted behind the corona glandis, cannot be replaced. The immediate result of such retraction is an acute œdema of the prepuce and the glans penis, which œdema persists and tends to grow larger and more leathery, and thus to form the chief obstruction to the surgeon's efforts at retraction. When the patient is seen the glans penis is greatly swollen and congested, while behind it rises a tense, shining œdematous collar of mucous membrane, behind which again lies a deep sulcus, most marked on the dorsum of the penis. This sulcus is the site of constriction; it is often ulcerated. Behind it usually arises a second collar. If the circulation is completely obstructed, spots of gangrene will be found upon the glans and the prepuce.

Fig. 4248.

Fig. 4249.

Figs. 4248 and 4249.—Simple Methods of Reducing Paraphimosis.

Treatment.—The treatment of paraphimosis depends upon the severity of the local reaction. If the obstruction is slight and there seems to be no danger of gangrene, palliative and mechanical treatment may be employed, in the hope of reducing the œdema sufficiently to permit reposition of the prepuce; but if gangrene threatens, the paraphimosis must be relieved at once lest the patient lose a portion of his penis.

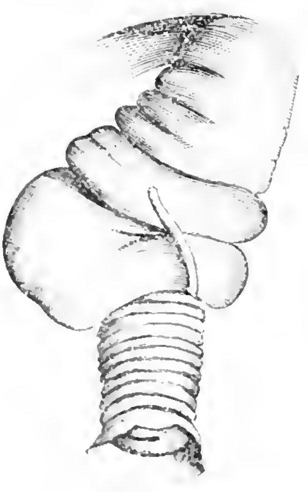

Fig. 4247. Method of Reducing Paraphimosis.

Mechanical Treatment.—The first aim of the surgeon must be to reduce the œdema as far as possible. This may be done by encircling the glans penis with tape or cotton string (Fig. 4247), or by applying over the whole penis a compressing wet dressing of boric-acid solution. Such a dressing should be applied as tightly as possible, and should be left in place not longer than an hour or two, after which reduction should be attempted. In reducing a paraphimosis the physician's efforts should be directed to slipping the constricting band over the glans penis, rather than to forcing the glans through the constriction. This may be accomplished in several ways, the simplest of which are shown in Figs. 4248 and 4249.

Surgical Treatment.—But mechanical treatment may fail, or the presence or imminence of gangrene may call for immediate relief, or the surgeon may very wisely conclude that his patient requires relief, not only from his present difficulty but also from the danger of its recurrence, a relief which can be obtained only by some sort of operation. The sole requirement is to relieve the penis from its constriction, and this is best accomplished as follows: The skin behind the constriction is rendered surgically clean, and a small area on the dorsum of the penis near its root is infiltrated with cocaine. In this area a longitudinal incision is carried through the skin to one side of the dorsal vein and just long enough to admit a small, blunt-pointed straight bistoury or tenotomy knife. This is burrowed forward through the loose, subcutaneous connective tissue until it arrives on the dorsum at the constricting band. Here some care is required to insert the knife blade beneath the constriction without puncturing it. When this is done the knife blade is turned outward and the constriction thoroughly divided, the knife immediately withdrawn, and the first incision protected with a collodion dressing. The prepuce may then be replaced, unless excessive œdema renders this impossible, and the penis is held erect and covered with a mild antiseptic wet dressing. The after-treatment requires no special comment, though circumcision may subsequently be necessary in order to obtain an æsthetic result.

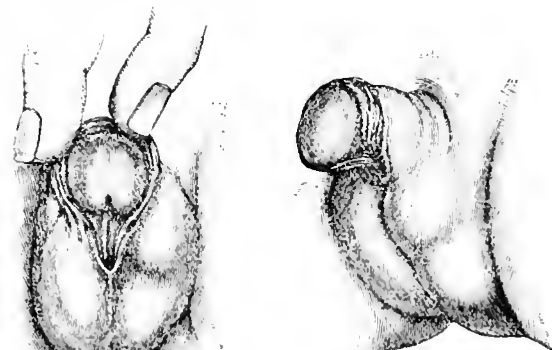

Fig. 4250. Penoscrotal Hypospadias. Front and side views.

IV. Hypospadias and Epispadias.—Hypospadias is a lack of union of the urethra upon its floor, while epispadias is a similar lack of union upon its roof. The canal may thus terminate at any point between the bladder

Sexual Organs.

and the normal meatus. Hence in hypospadias the canal may terminate (1) at the base of the glans (balanitic hypospadias), or (2) in the penile urethra (penile or penoscrotal hypospadias) (Fig. 4250), or (3) in the perineum (perineal hypospadias). Similarly epispadias may be balanitic or penile. The urethra may continue forward in front of the hypospadic or epispadic opening, or this remaining portion of the canal may exist only as a shallow gutter.

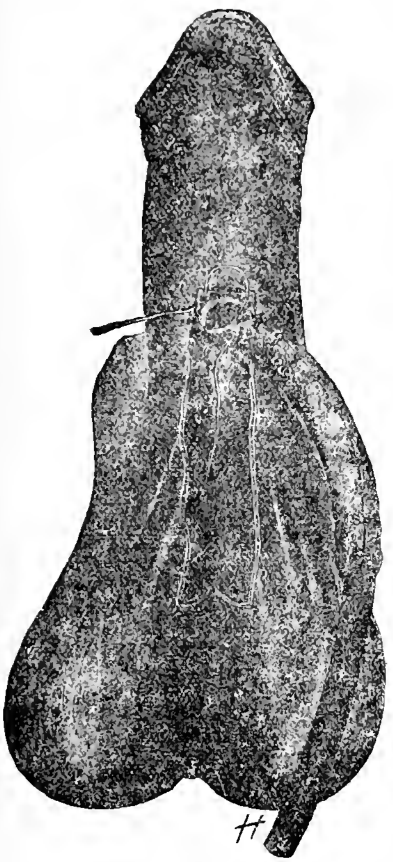

FIG. 4251.—Rochet's Modified Nové-Josserand Operation for Hypospadias. The flaps are cut, the catheter is introduced, and the scrotal flap sutured around it.

With urethral deformities of the graver sorts are often associated such deformities of the penis as incurvation, torsion, and scrotal adhesion; while with perineal hypospadias the scrotum is often split, and there may be other features of pseudohermaphroditism. Of these various deformities, balanitic hypospadias is by far the most common, while penile hypospadias stands next in order of frequency. Epispadias and perineal hypospadias are extremely rare. There seems to be a hereditary tendency to the occurrence of these urethral defects.

Symptoms.—The symptoms of hypospadias and epispadias are sexual and urinary. The sexual symptoms are incomplete erection and imperfect emission due to the urethral and penile defect, and varying in severity with the gravity of this defect. Though it is alleged that balanitic hypospadias may cause relative sterility by producing insufficient ejaculation, this theory is by no means proven; while the many known cases in which hypospadic individuals have had numerous children are at variance with the theory. The urinary symptoms of hypospadias consist in a deflection and a dribbling of the stream in all but the perineal cases; in these the patient cannot safely urinate excepting in a squatting posture. Yet the urethra always terminates in front of the triangular ligament, and, therefore, there is never incontinence of urine in hypospadias. In epispadias, however, the urethral orifice may be large and situated practically in the anterior wall of the bladder, there being little or no vesical sphincter. A patient suffering from this malformation has incontinence of urine, and is in almost as sorry a plight as he who suffers from exstrophy of the bladder. (*Cf. Bladder of the Male*—Malformations.)

Treatment.—The multiplicity of operations that have been suggested for the cure of hypospadias and epispadias attests the inefficiency of all of them. Time and again new procedures are advocated and new statistics compiled to prove the efficiency of one or the other operation. Yet it remains true to-day that no operation is ideal, that no operation can absolutely promise success, and that no operation should be attempted without the understanding that the best results can be obtained only by a succession of steps, the completion of which will certainly require several months, perhaps several years.

In general, the operation may be divided into two parts: (1) the relief of associated penile deformities, and (2) the relief of the urethral deformity.

Relief of Penile Deformities.—If there is incurvation of the penis or penoscrotal adhesion, this requires relief before the urethra is attacked. Adhesion is relieved by dividing the adhering skin transversely and suturing it longitudinally. Incurvation of the penis is relieved by carrying this transverse incision through the sheath of the corpora cavernosa and, if necessary, deeply into the intercavernous septum, and bandaging the organ in an overextended position until complete healing occurs. The urethral defect may now be attacked, the mode of attack depending upon the nature of this defect.

Relief of Balanitic Hypospadias.—While balanitic hypospadias cannot be said to demand relief, the patient may prefer that an attempt should be made to place his urethral orifice in the normal position at the end of the gland. This may best be done by Beck's operation, which is performed as follows: The prepuce is separated from the glans penis by a transverse incision running from side to side across the venter of the organ and skirting the orifice of the hypospadic urethra. The proximal flap of prepuce is then freely dissected up, exposing an inch or more of the urethra. This terminal part of the urethra is then dissected free from the surrounding tissues and carried forward until the meatus can be sutured in its proper position at the head of the glans penis, the glans having been prepared to receive the urethra by a simple incision or by puncture. The meatus is sutured in place, the preputial skin is brought forward over the urethra, and the suture and the wounds are sealed as far as possible with collodion.

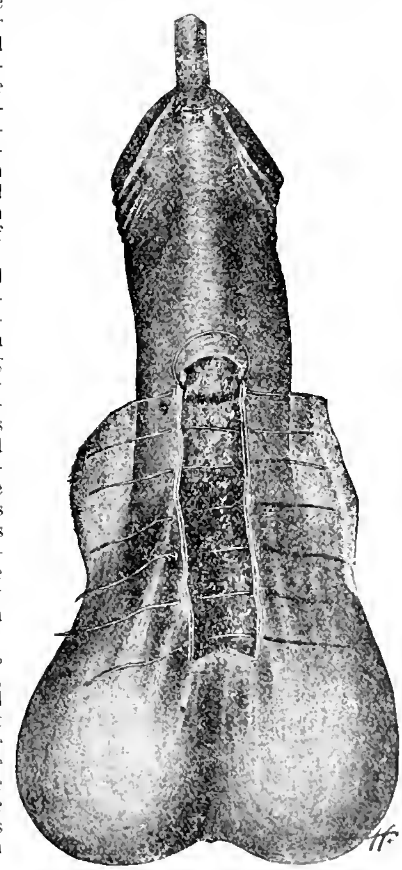

FIG. 4252.—Rochet's Modified Nové-Josserand Operation for Hypospadias. The final sutures.

Relief of Penile and Perineal Hypospadias.—Of the operations employed for the relief of penile and perineal hypospadias Duplay's is the most favored by text-books. This operation is performed as follows: A soft-rubber catheter is inserted through the urethra into the bladder and is carried forward along the groove on the under surface of the penis until it finally issues through a hole punched in the imperforate glans.

By means of a longitudinal incision, one third of an inch from the median line on each side, flaps are raised to surround this catheter, their epithelial surface inward. These are sutured with catgut, and the exposed raw surface is covered by flaps raised and carried inward from the sides of the penis.

Such operations as Duplay's have not been very successful, because the flaps do not unite well and the fistula left between the old hypospadic urethra and the new artificial one is very hard to close, both on account of the smallness of the parts—since these operations are habitually performed on children—and the befoulment by urine.

An operation which promises to avoid this difficulty is the Rochet-Nové-Josserand procedure. This is performed as follows: The hypospadic meatus having been incised in order that there may remain no stricture at this point, a transverse skin incision 2 cm. long is made just in front of it. Through this incision a stout probe is introduced and passed forward in the subcutaneous cellular tissue of the venter of the penis, thus burrowing a channel, the anterior orifice of which is formed by a slit or a puncture in the glans penis. A long rectangular flap is then cut from the perineum, its base surrounding the hypospadic orifice. It should be a little over 2 cm. wide and one-third as long as the new urethra is expected to be.

A small soft-rubber catheter is then introduced into the bladder, the flap is sutured around this with the finest catgut (Fig. 4251), and the distal end of catheter and graft is pushed through the subcutaneous canal and out at its anterior orifice, where the flap is sutured (Fig. 4252). A few skin sutures taken transversely close the perineal wound, and the child is then immobilized in a plaster-of-Paris dressing and put to bed with the penis in an erect position and the catheter leading into a urinal. This catheter should be left in place five or six days, after which spontaneous urination may be permitted.

The *after-treatment* consists in the passage of bougies every week or so in order to insure the patency of the canal. This operation reduces to a minimum the probability of fistula, and has been followed by admirable results.

Relief of Epispadias.—Epispadias is so rare that the surgery of this condition has not yet been satisfactorily developed. Duplay's operation may be applied to the epispadic urethra, while it is probable that Rochet's operation could be modified to give as good results here as in hypospadias.

The favorite operation of the text books is Thiersch's, in which the penile canal is formed by an inverted flap from one side of the penis covered by a longer direct flap carried across from the opposite, the inverted flap forming the roof of the urethra, the direct flap forming the skin covering. The fistula at the base of the penis is covered in by triangular flaps, one turned inside out and the other simply brought down and covering the raw surface, while the fistula at the base of the glans is covered by transferring the loose preputial skin from below the glans. Thiersch's original case was cured by this method after eighteen months. When epispadias is complicated by loss of the vesical sphincter, it may be regarded as a mild case of vesical exstrophy and should be treated accordingly.

It may be observed that none of these operations pretends to replace the corpus spongiosum, and the new urethra, bereft of its physiological coverings, may not be expected to perform its urinary and sexual functions in a perfect manner.

V. Injuries of the Penis.—*Contusion and Fracture.*—The flaccid penis may be expected to escape the buffets of adversity more readily than any other part of the body; injuries inflicted upon the erect penis are habitually in some manner sexual. Thus contusion may result from misguided efforts in coitus; strangulation is occasionally caused by encircling the penis with a metallic ring; and the so-called fracture, which is actually a rupture of the erectile bodies, is only a more severe injury due to like causes. Even though the contusion be but slight, hemorrhage into the loose subcutaneous tissue of the penis is likely to be free; while fracture of the erectile bodies is immediately followed by alarming subcutaneous hemorrhage, which may swell the organ to an incredible size.

The two therapeutic indications are control of hemorrhage and prevention of retention. The former is accomplished by the application of cold and pressure, or, if these fail, by incision; while the latter may require a retained catheter. In mild cases surrounding the penis with ice for a few hours is all that is required. But if the erectile bodies are fractured, it is wiser to incise immediately over the seat of the injury and to suture the torn fibrous sheath.

Open Wounds.—Open wounds require similar treatment, control of hemorrhage, and suture of the sheaths of the erectile bodies. If the injury to the erectile bodies has been severe the resultant scar may permanently impair erection.

Dislocation.—A few cases have been reported in which violent traction upon the skin of the flaccid penis has resulted in tearing this free at the balanopreputial junction and permitting the penis to slip under the integument of the thigh, the abdomen, or the scrotum. The immediate œdematous reaction conceals the absence of the penis from its cutaneous envelope, and it is not until catheterization is attempted or urination occurs that the abnormal position of the penis is discovered.

Nélaton was able in one case to replace the penis by means of an aneurism needle; but if this could not be done, it would always be possible to reach it by an incision. And in this connection it must be remembered that, even though the patient has urinated beneath his skin, unless the urine is infected it may be disregarded and will probably be absorbed.

Balanoposthitis. See *Balanitis.*

Venereal Ulceration. See *Chancroid, Syphilis.*

Herpes Progenitalis. See *Herpes.*

Lymphangitis and Cellulitis. See *Chancroid, Gonorrhœa.*

VI. Inflammation of the Erectile Bodies.—This condition, known variously as penitis or cavernitis, is extremely rare. Spontaneous inflammation is said to occur during acute exanthemata. The inflammation which occurs as a result of injury must be combated by the usual local antisepsis and drainage and irrigation, while the inflammation of the corpus spongiosum complicating gonorrhœa and stricture is a condition which meets consideration in the articles upon those subjects.

VII. Gangrene of the Penis.—The blood supply of the penis is so generous that gangrene of this organ is most exceptional. Yet it may occur from three causes: (1) strangulation, (2) virulent infection, (3) debility.

Strangulation is the commonest cause of penile gangrene. It occurs mechanically, as when the penis is encircled by a ring, or by a paraphimotic prepuce, and from inflammation, if the inflammatory reaction is severe enough to obstruct the lymph spaces. Virulent infection, a less frequent cause, is well exemplified by phagedena (see *Chancroid*), and by infiltration of urine (see *Urethra*, etc.). Debility, whether senile or diabetic, exceptionally causes gangrene, as do also thrombosis and embolism.

Treatment.—The treatment of these various forms of gangrene consists primarily in the removal of their cause. Thus a paraphimosis causing gangrene requires immediate reduction or incision. A ring around the penis must be cut away, or, if it be gold, amalgamated by the application of metallic mercury. Infiltration of urine calls for prompt incision and drainage (see *Urethra*, etc.). Severe cellulitis requires liberating incisions and wet dressings, while phagedena demands prompt and energetic antisepsis (see *Chancroid*). Senile and diabetic

Sexual Organs.

gangrene present here as elsewhere a most gloomy prognosis; yet much may be done by stimulating and dieting the patient and by cleansing and keeping clean the dead tissue.

A discussion of this part of the treatment will be found in the article on *Gangrene*.

VIII. TUBERCULOSIS.—Tuberculous ulceration of the glans and prepuce is very rare. It may be confounded with carcinoma or with venereal ulceration. The tuberculous ulcer is "shallow, rarely attaining a great size, with characteristic edge, is made up of a succession of small, jagged indentations, caused by the degeneration of miliary tubercles, so that the lesion has an appearance as if gnawed out. The floor of the ulcer is not, as a rule, crusted, but covered with a seropurulent fluid, and occasionally yellowish elevations, representing miliary nodules, may be seen scattered over its surface. At the periphery also these miliary nodules may sometimes be seen, and their presence is of course pathognomonic, although frequently they are absent" (Bowen).

A number of cases of tuberculous infection of the prepuce following ritual circumcision have been reported. This infection is attributed to inoculation from tubercle bacilli in the mouth of the rabbi who sucks the wound. Thus Lehmann found ten children infected by one man; three of them died marasmic.

IX. CIRCUMSCRIBED FIBROSIS OF THE ERECTILE BODIES.—Circumscribed fibrosis of the erectile bodies, otherwise known as chronic inflammation or induration of the corpora cavernosa, consists of a hard fibrous deposit in the sheath and the adjoining portions of the erectile tissue of one of the erectile bodies of the penis. This fibrous mass feels like a flat plate set in but not projecting from the surface of the erectile body. It is fairly common in the corpora cavernosa, of which it may affect one or both, but is very rare in the corpus spongiosum. The nature of this growth is disputed. The few specimens that have been examined have proven to be fibromata or enchondromata. Sometimes a single specimen is fibrous in one part, cartilaginous in another, and bony in another. Such a tumor has been excised by Dr. Chetwood.

Circumscribed fibrosis habitually appears upon one or other of the corpora cavernosa of a man between thirty-five and fifty-five years of age. The patient first notices that his penis when erect deviates toward the side affected. Less often the first symptom is a slight uneasiness in the region of the growth. But the patient does not habitually recognize the presence of any abnormal tissue before he presents himself for examination. This reveals a hard, flattened mass with sharply defined margins occupying the substance of one or both corpora cavernosa near the surface, and feeling like cartilage. The edges of the mass may be slightly elevated and slightly tender. The mass is usually irregularly oval in shape. The tendency of this growth is to change. It grows either larger or smaller and either toward or away from the root of the penis, involving new portions of the corpora cavernosa as it recedes in other directions.

Thus the *prognosis* of the condition is most uncertain. It is impossible to say where it will next shift to, and whether it will grow larger or smaller.

The two *symptoms* of the disease are the very slight pain and the bending on erection, the latter being often so great as to prevent intromission. As Verneuil first observed, this condition is apparently analogous to Dupuytren's contraction of the palmar and plantar fascia, and is habitually associated with gout. It has been suggested that diabetes plays some etiological rôle, but further experience has disproven this.

I know no *treatment* that can be depended upon to remove this growth satisfactorily. The application of ointments, of iodine, of electrolysis, and of blisters has uniformly failed. Alkaline and anti-gouty remedies seem to do some good in such cases. Cures have been reported after excision, but, inasmuch as this only replaces the new growth with scar tissue, it is not justifiable to promise a cure by the knife; although operation may be undertaken if the patient is willing to recognize that it is not a certain cure.

X. CALCIFICATION AND OSSIFICATION OF THE PENIS.—Calcification of portions of the corpora cavernosa is very rare and ossification is most unusual; only five cases of the latter condition have been reported. Apparently the cartilaginous or bony tumor develops secondarily in an area of fibrosis. The only treatment is excision.

XI. HORNS.—Soft warts of the glans or prepuce may become cornified and grow as horns. These horns seem peculiarly liable to epitheliomatous degeneration.

XII. MALIGNANT NEOPLASMS.—The primary neoplasms of the penis are epithelioma and sarcoma; secondary neoplasms are extremely rare.

Primary sarcoma begins in the cavernous tissue of one of the erectile bodies; it usually appears in early manhood and develops with characteristic rapidity, promptly involving the inguinal glands. As the tumor grows it causes priapism by closing the cavernous spaces, and may also obstruct the urethra, causing retention of urine. Early amputation is the only treatment (see below).

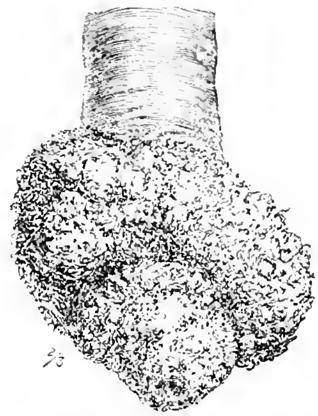

FIG. 4253.—Epithelioma of Penis.

Primary epithelioma occurs exceptionally in the urethra and fairly frequently in the prepuce and the glans (Fig. 4253). A few cases of epithelioma have been observed in early life, as, for instance, one of Freyer's at the age of seventeen. The growth may develop from scar tissue, as from urethral fistula or from the scars of injuries or of venereal sores; but the commonest sources of epithelioma are soft warts and chronic balanitis. Twenty-nine of the thirty-seven cases collected by Kaufmann began as apparently benign warts. Tight phimosis, by retaining the smegma and encouraging balanitis, seems to have a marked predisposing tendency. Thus Demarquay noted phimosis in forty-two out of fifty-nine cases, and it is claimed that the circumcised Jew does not suffer from this disease. There is no evidence that the penis may be inoculated from the carcinomatous cervix uteri.

Jacobson recognized four ways in which penile epithelioma may first show itself: 1. It usually begins as a wart, its malignancy being first recognized by the indurated and ulcerated base and the exuberant growth. 2. The first evidence may be a subepithelial lump or induration without warty excrescence or ulceration; this little, apparently innocent nodule is distinctly malignant. 3. A superficial excoriation may persist after a balanitis, comparable to the condition in the tongue when a leucoplakia becomes raw, and is the first evidence of malignant disease. 4. Very rarely the new growth begins as an ulcer, either proceeding from a venereal ulcer, arising from the scar of such an ulcer, or coming on after some injury.

Whatever be the origin of the tumor, it soon becomes frankly malignant, its base is indurated, elevated, and ulcerated; the discharge is thin, sanious, and foul, while there may or may not be exuberant warty overgrowth. The inguinal glands suffer a pyogenic as well as a cancerous infection, enlarge, become matted together, suppurate and ulcerate. The ulcers thus formed become new centres of epitheliomatous invasion. The primary disease spreads superficially, sparing the corpora cavernosa and the corpus spongiosum, although widely involving the skin and destroying the glans. If the urethra

Sexual Organs.

becomes obstructed the urine is passed through fistulous openings in the floor of the canal.

The foul discharge, the disgusting ulceration, and the liability to profuse hemorrhage are the symptoms of which the patient complains; pain is rarely troublesome until late in the disease. The ulceration spreads superficially quite as does epithelioma in other parts of the body, and the patient finally dies septic and cachectic. Lymphatic infection often gets no further than the inguinal glands, so that large visceral metastases are exceptional.

Diagnosis.—Penile epithelioma may be confused with chancre, chancroid, warts, tuberculous ulcers, and ulcers from chronic balanoposthitis. After the disease is well advanced there can be no possible doubt of its malignant nature; but in the early stages, when its character may still be doubtful, it is wiser to subject every growth of the penis which does not react promptly to treatment or which appears spontaneously or in an aged subject, to excision and microscopical examination for the purpose of determining its nature.

Treatment.—An epithelioma of the penis seen and recognized at its outset may usually be removed by circumcision if on the prepuce, or by cauterization with arsenious acid if on the glans; in this it resembles epithelioma of the other parts of the body. But if it has grown so widely as to destroy the greater part of the glans, or if the inguinal glands are already involved, the penis should be amputated close up to the pubes and the glands extirpated. Finally, if the greater part of the penis is covered by the ulcer, the treatment required is extirpation of the penis and simultaneous castration. Recurrence of the disease may be attacked by caustics or by the *x*-ray and thus controlled or even, exceptionally, cured.

XIII. Amputation of the Penis.—The patient should be prepared as for any aseptic operation; general anæsthesia is required. The operation is begun by tying a rubber catheter around the root of the penis; this may be held in place by harelip pins. Ample skin flaps are then elevated and dissected back fully an inch, after which the knife is inserted between the corpus spongiosum and the corpora cavernosa, and the latter are cut off three-fourths of an inch shorter than the former.

The elastic ligature is now removed and profuse hemorrhage immediately follows. The dorsal arteries must be caught and tied, and perhaps one or two arterial branches may require similar treatment; but after the first gush is conquered the oozing from the erectile bodies is controllable by pressure. The urethra is then split into two flaps and sutured to the skin flaps, which are then sutured in place and the whole dressed aseptically, with provision for the passage of urine through a retained catheter.

Flaps.—A circular skin incision may be employed, but neater apposition is obtained by employing skin flaps. Senn and Jacobson use long dorsal and short ventral flaps, Jacobson making the dorsal flaps so long that the urethra may be sutured into a perforation in its lower extremity. Other operators employ lateral flaps; while Dr. Davis, of Philadelphia, makes three urethral flaps each cut to a point and sutured to the skin, divided circularly. The urethra is split in order to avoid stricture at the new meatus.

After-Treatment.—The two things most to be feared are hemorrhage and tension on the flaps, both of which are due to erections. A light dressing and the free employment of bromides insure safety.

XIV. Extirpation of the Penis.—In order to remove the erectile bodies it is necessary to place the patient in the lithotomy position and to make a skin incision surrounding the base of the penis, thence splitting the scrotum from one end to the other of the raphé. Blunt dissection separates the two halves of the scrotum down to the corpus spongiosum. A sound is passed as far as the triangular ligament where the urethra is divided just in front of the bulb and thence freed back as far as the hole in the triangular ligament. The suspensory ligament is then divided, and each crus dissected out and separated from the pubic ramus by means of a stout periosteal elevator; this completes the removal of the organ. The edges of the scrotal incision are then united, the stump of the urethra being split and stitched to the lower end of the wound. Drainage is required, for there is likely to be some post-operative oozing as well as considerable hemorrhage during the operation. No retained catheter is needed.

Total Emasculation.—French surgeons seem generally agreed that it is wise, in extirpating the penis, to remove the testicles at the same time, since, as they allege, the removal of these glands lessens the hypochondriacal and maniacal tendency which this very operation has been said to cause when employed for the relief of prostatic hypertrophy. It is best in this matter to consult the wishes of the patient. The testicles are readily removed through the scrotal incision.

XV. Extirpation of the Inguinal Glands.—It is always wise to remove the inguinal glands as an accompaniment to any operation for penile epithelioma, since these glands may be infected even though they appear normal. If the glands are small they may readily be shelled out, if large or matted together there is danger of opening the femoral vein in the region of the saphenous opening in the fascia lata; hence, this should be sought for and worked away from in all difficult operations in this region.

XVI. Scrotal Injuries, Inflammations, and New Growths.—*Wounds.*—Scrotal wounds, whether surgical or accidental, bleed freely, and efficient hæmostasis of this bleeding is the most important feature of the treatment. Every bleeding vessel must be carefully caught and tied, for there is danger of the formation of an enormous hæmatoma, which may extend to the penis, thigh, and abdomen. Wounds of the scrotum, like those of the penis, heal readily and do not often suppurate.

Loss of Tissue.—Even though the greater part of the scrotum is destroyed by disease or by accident, the surgeon need not feel called upon to fill in the gap by a plastic operation. For such is the elasticity of the scrotal skin that cicatricial contraction will draw it over the exposed testicles and close the largest gaps within a few weeks, unless the patient is septic.

Contusion and Hæmatocele.—Scrotal contusions are manifested by great ecchymosis and œdema quite comparable to the familiar black eye. Compression (see Epididymitis, p. 181) and an ice-cap is the proper treatment if the case is seen early; later, absorption may be promoted by heat, while it is only in the most exceptional cases that incision is required. Extravaginal hæmatocele (blood cyst of the scrotum) is an encysted scrotal hæmatoma requiring incision (Fig. 4254).

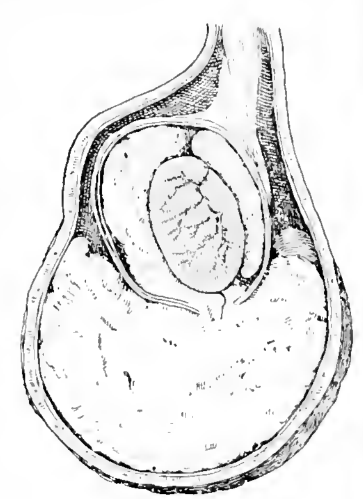

Fig. 4254.—Hæmatocele, Scrotal and Vaginal.

Scrotal Inflammations.—The inflammations of the scrotum closely resemble those of the penis in most of their characteristics. Gangrene of the scrotum following urinary infiltration in an aged or debilitated subject is often rapidly fatal, and must be combated by stimulants, free incisions, wet dressings, and excision of sloughs as fast as they form. Castration is never required.

Elephantiasis. See *Elephantiasis.*

Sexual Organs.

Cysts.—Small sebaceous cysts showing pearly white through the distended skin may occur anywhere on the penis and scrotum, but are usually found on the raphé; they may grow very large. Jacobson and Tilden Brown have recorded cases of so called cystic disease of the scrotum. Echinococcus cysts have also been found in this part of the body. Small subcutaneous capillary dilatations may occur in the skin of the scrotum; they show dark blue, and are totally harmless; but if the patient objects to them they may be cured by a minute incision and the application of nitrate of silver.

Solid Tumors.—Angioma, fibroma, lipoma, fibromyxoma, osteochondroma, and sarcoma occur in the scrotum; but the only neoplasm sufficiently common to merit notice is epithelioma, the so-called chimney-sweeps' cancer (see *Carcinoma of the Skin*).

XVII. Anomalies of the Testicle.—The accepted classification of anomalies of the testicle is that of Monod and Terrillon, as follows:

Anomalies in development	In number	In excess		Polyorchism.
		Deficient	Absence	Anorchism.
			Fusion	Synochism.
	In size	In excess		Hypertrophy.
		Deficient		Atrophy.
Anomalies in migration	Undescended	Incomplete migration		Retention.
		Abnormal migration		Ectopia.
	Descended			Inversion.

1. *Anomalies in Development.*—Polyorchism.—According to Jacobson, supernumerary testicles are sometimes found in certain animals, and the older literature contains many alleged instances of this condition in man. The only case in which the diagnosis was confirmed by microscopical examination is that reported by Arbuthnot Lane in *The British Medical Journal* of 1894. I have seen one case diagnosed by an able surgeon as polyorchism, in which the third testicle proved to be a large spermatocele.

Anorchism.—The absence of one or both testicles is rare. It is usually associated with absence of the epididymis and part of the vas. Exceptionally, the whole vas is wanting; still more rarely the testicle alone is absent. On the other hand, the testicle may be present and the seminal ducts absent. During life anorchism can be differentiated from abdominal cryptorchism only by operation.

Synorchism.—A fusion of the testicles has twice been observed, the glands being retained in the abdomen in each case.

2. *Anomalies in Migration.*—Cryptorchism.—In contrast with the rarity of the anomalies enumerated above is the familiar condition of cryptorchism, *i.e.*, absence of one or both testicles from the scrotum. The testicle may be either retained or ectopic; if retained it is arrested at some point in its normal descent; if ectopic it is lodged out of its normal path. Marshall records 11 cases of cryptorchism among 10,800 English recruits, while Rennes encountered 6 cases among 3,600 French recruits. Of these 17 cases only 1 was bilateral.

Retention of the testicle is caused by obstruction to its progress from the abdomen or by traction from behind. Thus some cases are attributed to peritoneal adhesions which close the inguinal canal at some point before the testicle has descended; in other cases there is an alleged congenital shortness of the vas.

The *etiology* of this condition, however, is very obscure, and has no direct bearing upon its clinical aspects. Suffice it to say that the commonest form of retention is the inguinal variety, the testicle lying in the inguinal canal (Fig. 4255), sometimes near the external sometimes near the internal abdominal ring. A certain freedom is usually enjoyed by the gland, so that in many young subjects a testicle in inguinal retention may be reduced either into the abdomen or into the scrotum. Puboscrotal retention, in which the testicle lies high up in the scrotum close under the pubes, is a less common condition; while abdominal retention—the testicle not having reached the inguinal canal at all—is most exceptional.

The ectopic testicle may be found in the perineum beneath the deep fascia just in front of the anus, or at the saphenous opening of the crural canal, or in the opposite side of the scrotum, or at the base of the penis in front of the pubes. These last two varieties have each been seen but twice; indeed, any form of ectopia is extremely rare.

Inversion of the testicle occurs when that organ is turned upside down in the scrotum or rotated so that its long axis is horizontal. The only clinical significance of this very rare anomaly is that, in hydrocele, the inverted testicle may lie above and in front of the sac, instead of below and behind it, and thus be punctured by the aspirating needle.

Fig. 4255.—Retained Testicle.

The pathological condition of the retained testicle is a subject of great interest, both because it is alleged that pressure of the abdominal muscles makes the gland especially liable to sarcomatous degeneration, and because it seems proved that this pressure habitually destroys the functionating power of the gland. Thus a double cryptorchid is habitually sterile. So general is this rule that Curling, after enumerating several cases of children born of women married to cryptorchids, felt compelled to doubt their paternity. Yet recent investigations have shown that retained testicles may acquire and retain, at least for a few years, the power of secreting spermatozoa. Thus Beigel found numerous spermatozoa in the semen of a double cryptorchid aged twenty-two, while Valette found a few in a retained testicle removed from a man in his twenty-first year. Yet Bellingham Smith alleges that cryptorchids never retain their virility for more than five or ten years. The question of the sterility of any given case may be determined by examination of the seminal fluid.

But apart from the atrophy and sterility of the retained testicle, this gland is subject to other dangers. Neuralgia is often the first evidence that the testicle is being affected by pressure of the surrounding muscle, and any inflammation, whether traumatic, gonorrhœal, or tuberculous, is sure to run a severe course and is habitually followed by atrophy. Finally, the great danger of these patients is that the testicle may become sarcomatous. It is difficult to estimate how frequent this sarcomatous degeneration may be, and yet, viewing it merely as a possibility taken in connection with the congenital hernia which habitually accompanies cryptorchism, it is enough to determine the surgeon always to remedy the congenital defect.

In infancy the proper *treatment* of retained testicle is the application of a truss, whereby the hernia may be reduced and the testicle forced down into the scrotum. I have succeeded in curing a number of cases in this manner, and have always preferred it as a preliminary to operation, although a cure may not be expected after the child is ten years of age. If mechanical treatment fails or if the patient has passed his tenth year herniotomy offers the only hope of cure. And this should be strongly urged upon the patient as calculated to cure his hernia, to insure him as far as possible against sterility, and to relieve him from the danger of sarcoma.

Broca has operated 138 times without a death; 79 of these cases were followed for a year or more. Of these, 31 had testicles normal both in size and position; 35 had testicles normal in size, but abnormal in position (near the external ring); while only 13 had undergone atrophy. These brilliant results were obtained on young children.

In order to reduce the testicle the usual operation of herniotomy is performed. The testicle is freed from all obstructing envelopes, and the cord is followed up as far as possible into the abdominal cavity and freed by the finger from all fascial bands. The further the cord is followed the further can the testicle be pulled out into the scrotum. Wood's device of freeing the vas from the globus major and then inverting the testicle may be mentioned as an ingenious way in which to gain an inch. If the testicle cannot be reduced it may be removed or replaced in the abdomen; but since the latter alternative leaves it subject to every danger and relieves only the hernia, it is my preference always to castrate if reduction is impossible.

Hypertrophy and Atrophy of the Testicle.—There is considerable variation in the normal size of the testicles as in that of the penis. When one testicle is defective or wanting its fellow seems to take on a certain compensatory hypertrophy. On the other hand, atrophy may occur in two ways: there may be arrest of development, or a testicle previously normal may atrophy from injury; *e.g.*, section or obstruction of the spermatic vessels; from pressure, *e.g.*, large hydrocele or varicocele; from inflammation, *e.g.*, orchitis, and rarely from injuries to the nerves, the spinal cord, or the brain. Atrophy is never due to sexual continence, to the use of the iodides, or to injury of the vas deferens alone. A microscopical atrophy is physiological in old age.

Atrophy of the testicle cannot be cured, but it may be prevented by the removal of a cause whose continued action favors atrophy.

XVIII. Injuries of the Testicles.—*Luxation and Contusion.*—Luxation of the testicle has been reported as the result of injury, the testicle being extruded under the skin of the adjoining parts or into the inguinal canal. Mild contusions of the testicle produce shock to the sympathetic system with nausea and faintness, and are followed by more or less prolonged tenderness of the parts. Severe injuries may produce ecchymosis, hæmatocele, or orchitis, and may result in atrophy, in abscess, or in gangrene. Kocher has recorded two deaths from the shock of contusion.

The *treatment* of contusion of the testicle consists in dorsal decubitus, elevation of the testicle, and application of ice. If orchitis ensues this must be combated.

Wounds.—Wounds of the testicle are very rare. Any incision of the tunica albuginea is likely to be followed by protrusion of the soft parts within (hernia testis). If the patient is seen immediately the wound should be cleaned and the tunica albuginea sutured in order to prevent hernia testis. If reduction is impossible, the hernia may be snipped off with scissors, but should not be pulled upon lest the whole testicle be eviscerated.

XIX. Torsion of the Spermatic Cord and Gangrene of the Testicle.—Gangrene of the testicle is usually caused by torsion of the spermatic cord. This occurs spontaneously and gives symptoms very closely resembling those of strangulated hernia. The groin and scrotum suddenly become swollen and sensitive; the patient vomits, feels faint, and has some fever; there may be chill and syncope. The onset of this condition is very sudden, and it may be distinguished from strangulated hernia by the mildness of the systemic disturbance after the first shock has passed. In doubtful cases immediate incision should be relied upon for an accurate diagnosis.

Dr. Charles Scudder has collected thirty-two cases, seventeen of which occurred on the right side and eleven on the left. Seventy-five per cent. of the cases occurred in patients under twenty-three years of age. In ten cases the testicle was retained in the inguinal canal, and in five others it was close under the pubes; in some the attacks were recurrent. Thus Dr. Van der Poel's patient learned to relieve his pain by untwisting the testicle.

The *treatment* of this condition consists in unrolling the testicle—if this be possible—or, if the swelling is great, as is usually the case, in incision. This operation has been performed twenty-nine times without a death; twenty-three times the testicle was removed; five times the cord was untwisted; this was followed twice by sloughing, thrice by atrophy. Once the testicle was allowed to slough away through a simple incision, and once the testicle was untwisted one hour and a half after the onset of symptoms, without incision. In this case the testicle subsequently atrophied.

Injury to the Spermatic Cord.—Tying off the veins of the cord—as is done in the operation for varicocele—has no effect upon the testicle; but if the spermatic artery is included in the ligature the testicle usually atrophies and sometimes sloughs. Similarly any injury to the cord destroying the continuity of the spermatic artery may be followed by gangrene of the testicle.

XX. Irritable and Neuralgic Testicle. — When there is pain in the testicle without disease of this organ it is said to be irritable or neuralgic. The terms are rather loosely used to cover a variety of conditions whose only obvious symptom is testicular pain; the testicle is said to be irritable if the pain is slight, neuralgic if the pain is severe.

The varieties of irritable and neuralgic testicle may be grouped under three heads:

1. Sexual excess, especially under the form of prolonged, ungratified sexual desire, is likely to be followed by what might be termed an acute neuralgia of the testicle, that gland being swollen, sore, and sometimes exquisitely tender. A single application of guaiacol and glycerin, equal parts, the wearing of a suspensory bandage, and the avoidance of the cause, are all that is required for a cure.

2. Reflex neuralgia from the prostate and seminal vesicles is the most common form of this condition. It may be due to any congestion or inflammation of the internal sexual organs, such as chronic inflammation or chronic sexual congestion. This form of the disease is both identified and treated by measures directed to the prostate and vesicles. These organs will be found sensitive, either to rectal touch or to the passage of a moderate-sized sound. The *treatment* consists of prostatic massage, with rectal douching, and perhaps the passage of a sound, or the instillation of a few drops of the nitrate of silver into the posterior urethra. Indeed, this condition is often concomitant with prostatic neuralgia and requires the same treatment, with mild counter-irritation on the scrotum as a temporary aid at the beginning of treatment.

3. Finally, there is a vague group of cases in which the testicular pain is due to causes neither sexual, nor prostatic, nor vesicular. Thus varicocele is often associated with neuralgia, although the cure of the varicocele by no means necessarily relieves the pain. Neuralgia of the testicle is sometimes due to renal or vesical calculus, and cases have been reported in which the pain was attributed to inflammations of the scrotum and of the tunica vaginalis.

If the local cause of such a neuralgia is ascertainable and can be removed a prompt cure may be expected. But in many cases this is impossible; or else the neuralgia has been started in a neurotic subject by some slight cause, which has ceased to act while the pain continues. Such is the nature of most varicocele neuralgias. These cases habitually improve under proper sexual hygiene—which is matrimony. Indeed, one never encounters them in men happily married. Cold-water applications often give great relief and may be all that is required if the pain is spasmodic; but if the agony is constant an endeavor may be made to relieve it by excising the nerves of the spermatic cord. This can be done by a careful dissection of the cord where it issues from the inguinal canal, the nerves being found close about the vas deferens. This operation, while not a sure cure, is sometimes the only hope that can be offered the patient, and should therefore not be denied him.

XXI. Inflammations of the Testicle. — The inflammations of the testicle may be divided into (1) those that pass along the seminal canals, *i.e.*, gonorrhœa, tuberculosis, and simple pyogenic infection from the pos-

Sexual Organs.

terior urethra; and (2) those inflammations that do not travel along the seminal canals, *i.e.*, traumatic inflammations, syphilis, and the inflammation of infectious diseases. In each class of cases the testicle and the epididymis may both be affected; but in the former class the epididymis is the prime point of attack, while in the latter the testicle is chiefly assailed. Therefore, while remembering that any given case may well be at once an orchitis and an epididymitis, we shall find it convenient to classify the simple and the tuberculous inflammations as epididymitis; the traumatic, the metastatic, and the syphilitic ones as orchitis. Our present concern is with gonorrhœal and simple pyogenic epididymitis.

XXII. Epididymitis.—Epididymitis is always secondary to an inflammation at the inner end of the seminal canals. It is always associated with inflammation of the seminal vesicles and usually with posterior urethritis. The inflammation reaches the epididymis by direct extension along the mucous membrane of the vas deferens, as is proven (1) by the constant presence of vesiculitis, (2) by the frequent prodromal symptoms of deferentitis, and (3) by the fact that ligation of the vas checks at once and forever the most virulent case of relapsing epididymitis.

Thus the underlying cause of epididymitis is an inflammation of the urethra, habitually an acute gonorrhœa, less frequently stricture, chronic prostatitis, or an inflamed hypertrophied prostate. The exciting cause may be anything which determines an exacerbation of the posterior urethritis or which weakens the resisting power of the individual. Thus one patient with acute gonorrhœa may acquire epididymitis in spite of every precaution, while another may escape it in spite of every dissipation. Yet, other things being equal, exposure to cold and dampness, sexual excitement, and the action of any severe strain or the possession of a lymphatic or debilitated constitution are the causes on the part of the patient to which the inflamed testicle may usually be attributed; while, on the part of the physician, epididymitis may be caused by the passage of instruments or by the employment of injections, the danger to the testicle increasing in proportion to the violence of the manipulation, to the size and roughness of the instrument, and to the strength of the injection employed.

With chronic posterior urethritis, with stricture, and with prostatic hypertrophy the infecting bacteria are not so virulent and secondary epididymitis is less frequent and occurs only as a result of considerable trauma or debility.

Epididymitis rarely occurs before the second week of a gonorrhœa, since grave inflammation of the posterior urethra is rare before that time. The exceptional instances in which epididymal swelling appears before urethral discharge are apparently attributable to previous chronic posterior urethritis, and are no evidence that the new gonorrhœal infection begins in the epididymis. Though both epididymes may be inflamed at the same time, it is most exceptional for the two inflammations to begin simultaneously.

The inflammation begins at one end of the epididymis, usually the tail. Here are felt the first swelling and pain, and here the hard lump of induration remains long after the acute attack has passed. The testicle and the remainder of the epididymis are intensely congested and œdematous during the acute attack, the tunica vaginalis being inflamed and acute hydrocele resulting. The vas is catarrhal, and this catarrh in the vas and in the epididymis may in the end cause cicatricial occlusion of the duct. It is not possible to determine in how great a proportion of cases this occlusion occurs; but it may be considered that relapse of the epididymitis is sufficient evidence that the vas is not occluded; whence the paradox that the more often the testicle is inflamed the less likely is its possessor to be sterile.

An attack of epididymitis may run an acute or a chronic course. An acute attack is preceded for perhaps twenty-four hours by a general soreness and tenderness along the course of the vas throughout the groin and often to the loin. Then a tender point appears in the epididymis, which swells so rapidly that within a few hours it is many times its normal size, and usually within twenty-four hours testis and epididymis are swollen to an ovoidal mass exquisitely sensitive to the touch and nearly as large as the closed fist. Excruciating pain accompanies the swelling and continues for two or three days, after which the pain rapidly grows less and the swelling more slowly follows suit; so that at the end of a week the pain has become bearable, the swelling has diminished considerably, and at the end of two or three weeks more the attack has completely passed, leaving behind only a nodular scar in one end of the epididymis. During the acute attack there are severe constitutional symptoms. The disease may be ushered in by chill, and there is high fever for a few days with the accompanying lassitude and want of appetite, while usually the urethral discharge is greatly diminished, sometimes even checked, during the course of the attack, only to reappear as the epididymal inflammation subsides.

A subacute or chronic epididymitis comes on very mildly as a tender swelling at one end of the epididymis, and does not spread throughout the organ with the intensity of the acute process. This tender epididymal lump may remain smouldering for months and years so long as it is fed by a focus of inflammation in the deep urethra, breaking out from time to time into subacute or acute attacks of inflammation, though generally quiescent. On the other hand, a subacute attack may last only a few days and then proceed to entire resolution.

From the frequency with which certain cases of epididymitis, whether acute or subacute, relapse, has arisen a clinical type of the disease known as *relapsing epididymitis*, the characteristic feature of which is the tendency to recurrence of the inflammation at the slightest provocation or at no provocation at all. Even though these attacks be but subacute, they may be sufficiently annoying to render the patient miserable and to merit drastic measures for their removal.

Complications.—The acute hydrocele which often accompanies acute epididymitis in some cases assumes importance as a cause of pain from tension within the tunica vaginalis during the attack and as a cause of swelling through lack of spontaneous absorption of the fluid after the attack. Suppuration occurs but rarely in gonorrhœal epididymitis; but if the inflammation occurs in an old and septic prostatic, it often suppurates, and this suppuration, by increasing the sepsis, may lead to the patient's death.

Diagnosis.—Nothing is more characteristic than an acute epididymitis. Acute orchitis is distinguished by its etiology and by the preponderance of general symptoms and the involvement of the testicle rather than the epididymis. Subacute epididymitis may closely simulate tuberculosis (see Diagnostic Table, on p. 185).

Prognosis.—Epididymitis does not endanger life or sexual potency or desire. As stated above, double epididymitis may be followed by occlusion of both vasa and sterility. It is impossible to say in what proportion of cases this occurs, but it is certainly less frequent than is commonly supposed. Benzler's investigations showed that ten per cent. of gonorrhœal cases without epididymitis, twenty per cent. of those which had had a single epididymitis, and forty-one per cent. of those which had had a double epididymitis were sterile. These figures suggest that chronic prostatitis and vesiculitis is an important cause of sterility and may be the active agent even in a case in which the sterility is attributed to double epididymitis.

Treatment.—Epididymitis may often be prevented by the wearing of a suspensory bandage by the patient during an acute gonorrhœa or while being treated for stricture. Observance of sexual hygiene and gentleness in urethral instrumentation work to the same end.

The treatment of an acute case consists in elevation of the testicle, local applications to it, brisk catharsis, rest, and a light diet. A patient with a sharp epididymitis is much better in bed than out of it. One may ordinarily promise that four days in bed will bring him nearer to a cure than eight days on his feet. But whether the patient will lie quiet or not, the testicle must be elevated as high as possible. With the patient in bed this is best accomplished by an adhesive plaster band across the two thighs with the testicles resting upon it (Fig. 4256), while, if the patient will be about, he can be made most comfortable by slinging his genitals up as high over his abdomen as possible in a T-bandage made with a towel, provision being made for the tenderness of the organ by a generous use of absorbent cotton padding.

Fig. 4256.—Strapping Testicle.

Curling's support consists of a bandage, a large silk handkerchief, and a piece of tape. The bandage is tied around the patient's waist, the tape is attached to the back of the bandage and to the centre of the handkerchief, which is folded once into a triangular shape, the tape being so arranged as to hold the central point opposite the perineum. The two long angles of the triangle are then tied snugly to the waistband in each groin, while the short right angle is carried up over the genitals supporting them high up on the abdomen.

Of local applications to the testicle guaiacol is much the best in the first forty eight hours of the inflammation. If applied pure before the swelling has reached its height it will often abort an attack. A mixture of equal parts of guaiacol and glycerin may be applied daily or twice a day during the first few days with marked benefit, and is far less irritating than the pure drug. If the patient is in bed it is advantageous to keep the testicle covered with hot poultices. The tobacco poultice is reputed an anæsthetic, but in this it falls far behind guaiacol, and, as the only real virtue of the poultice is its heat, the flaxseed poultice is adequate.

As the acute symptoms subside poultices may be replaced by a hot-water bag, and guaiacol is no longer useful.

As soon as it is bearable strapping is applied. The classic and dirty adhesive plaster strapping is obviously inferior to compression by a light rubber bandage held around the testicle by a single strap of adhesive plaster (Fig. 4256). This makes a light and comfortable dressing, the pressure of which can be varied at any moment without pain or discomfort to the patient. At first this dressing is changed every twenty four hours. As the testicle rapidly decreases in size and bears more and more pressure without irritation, the strap is reapplied at longer intervals. Finally, a suspensory bandage is all the patient needs, and this he may wear until the general swelling has entirely subsided.

The treatment for subacute cases need not be so energetic. Guaiacol may be applied in less strength and more frequently. A suspensory bandage is all the support required.

Relapsing epididymitis may often be relieved by attacking the prostatic or vesicular focus in which the disease centres, and every effort should be made to conquer this inflammation both by local treatment and by building up the patient's health before having recourse to any surgical procedure.

If these means fail—as they often do fail utterly—the patient is usually glad to submit to vasectomy, although this operation closes the canal forever; since by this means he can be absolutely assured against any further recurrence of the inflammation. Indeed, this operation performed in the midst of an attack will cut it short more quickly and more certainly than any other means I know.

The Operation of Vasectomy.—The operation of vasectomy may be performed under local anæsthesia. If the testicle is swollen the vas is most conveniently reached at the external inguinal ring. The technique of this operation is similar to that of the high, open operation for varicocele, which is described below. But if the testicle is not swollen, it is often a simpler matter to reach the duct through an incision in the back of the scrotum. The vas is identified as the thickest, most resisting member of the bundle of tissues making up the cord, and, as it is always behind and to the inner side of the large bundle of veins, it may be readily caught between two fingers and held close beneath the skin of the scrotum behind. The skin is infiltrated with cocaine; an incision through it and through the dartos permits the vas to be protruded. This is caught with a pair of forceps, freed from the surrounding fascial fibres, tied doubly and cut between the ligatures. If there is any suspicion of inflammation of the duct it is wiser to cauterize both ends before dropping them back into the scrotum. A single stitch closes the incision. The patient need remain in bed with his testicle supported for only three or four days.

XXIII. Orchitis.—The inflammations of the testicle to be described under this head are three: First, traumatic orchitis; second, subacute neuralgic or gouty orchitis; third, the orchitis of the exanthemata. The first two varieties may be dismissed with a word.

Traumatic Orchitis.—Traumatic orchitis, caused by a blow, a kick, a missile, or a fall, runs a course quite comparable to that of epididymitis; yet the excretory ducts are very rarely blocked, so that, even after a severe inflammation, sterility may not be anticipated; while, on the other hand, traumatic orchitis is far oftener followed by atrophy of the testicle than is the gonorrhœal inflammation. In the treatment of this form of orchitis poultices hold the first place.

Neuralgic or Gouty Orchitis.—Neuralgic or gouty orchitis is a mild inflammation with little swelling and tenderness, but with considerable neuralgia. It may result from sexual causes, or it may occur spontaneously in gouty or rheumatic individuals. The treatment is that of irritable or neuralgic testicle.

Orchitis of Infectious Diseases.—The orchitis of infectious diseases deserves more extended notice. It has been noted in the course of typhoid fever, influenza, smallpox, tonsillitis, and rheumatism, but it is commonly known as the orchitis of mumps on account of its frequency in this

Sexual Organs.

disease as compared with its great rarity in other infectious conditions.

Orchitis of Mumps.—The orchitis of mumps does not occur in children. In young adults orchitis complicates the parotid inflammation in at least five per cent. of all cases; indeed, Laveran encountered orchitis one hundred and fifty-six times in four hundred and thirty-two cases of mumps among soldiers. The inflammation of the testicle usually appears at the end of the first week of the parotitis; exceptionally, the testicle is inflamed before the parotid, and there are a few recorded cases of alleged mumps of the testicle without any inflammation of the parotid gland. The affection is habitually unilateral, runs a very acute course lasting but a week or ten days, and is followed by atrophy of the organ in one-half the cases; suppuration and gangrene are exceptional terminations, and, if the testis does not atrophy, its function is in no way impaired.

Symptoms.—The chief symptom of orchitis is pain. On account of the unyielding nature of the tunica vaginalis, the testicle swells but slowly, requiring several days to attain its full size. But the pain of the inflamed gland, tightly bound down by its fibrous envelope, is instant and excruciating. This pain has been compared to nephritic or hepatic colic. It cannot be relieved by position, and is greatly intensified by the slightest touch upon the inflamed organ. It is accompanied by marked general symptoms; chills, fever, vomiting, sleeplessness, etc. The testicle retains its ovoid shape, and the epididymis is not distinguishable from the rest of the tumor; the scrotum is often œdematous, swollen, and red.

The disease usually terminates by resolution, the pain subsiding gradually, the tumor disappearing more slowly, after which the testicle may or may not atrophy. Abscess may occur and may prolong the attack indefinitely, while the onset of gangrene is announced by sudden cessation of the pain without relief of the other symptoms.

Diagnosis.—Orchitis is distinguished from epididymitis by its cause, and by the great disparity between the severity of the general symptoms and the intensity of the pain on the one hand, and the slight degree of swelling on the other.

Treatment.—An adult with mumps should be kept in bed during the first days of the disease, with testicles well supported in order to prevent orchitis. When the attack is once on little can be done in the way of treatment, except to ameliorate symptoms and to prevent abscess or gangrene. For internal medication jaborandi is the only drug that bears any reputation. Locally, poultices and guaiacol should be employed as in epididymitis. If these fail to relieve pain the tunica albuginea should be divided subcutaneously. A sharp-pointed tenotome knife is introduced through the skin, and then made to cut the tense fibrous capsule, while the testicle is steadied in the other hand. From three to six short cuts should be made at different points in the tunic. This relieves the pain almost instantaneously. If abscess forms it should be incised and drained, while gangrene demands castration.

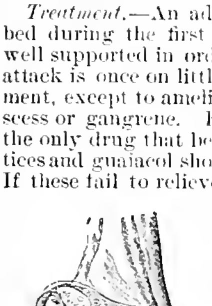

Fig. 4257.—Tuberculous Epididymitis.

XXIV. Tuberculosis of the Testicle.—Tuberculosis of the testicle occurs under two forms: diffuse, miliary tuberculosis, part of a general miliary tuberculosis, and circumscribed tuberculosis; only this latter concerns us here (Fig. 4257). It occurs as one or more tuberculous deposits, appearing usually in the epididymis and affecting the testicle only secondarily. It may or may not be accompanied by pyogenic infection.

Etiology.—The recognized causes of epididymal tuberculosis are the tuberculous predisposition, the existence of a tuberculous focus elsewhere in the body, and a local trauma or inflammation, precedent or persistent. Of these causes the first is ascertainable almost always, the second sometimes, and the third rarely. The efficient cause of the disease is the tubercle bacillus. The belief is gradually gaining ground that tuberculosis of the genital organs habitually begins in the epididymis, and thence extends in one direction to the testicle, in the other to the vesicle and prostate. The opposite view, that the inflammation begins in the prostate or in the vesicles, has the authority of Kocher, of Lancereaux, and of Guyon, and to this view I am inclined to adhere. For I have often seen tuberculous prostatitis and vesiculitis without tuberculous epididymitis, and yet, having examined the urine of every case of tuberculous epididymitis that has come under my observation, I have never failed to find urinary evidences of prostatic congestion. Moreover, I have often found manifestly tuberculous nodules in the internal genitals and sometimes tubercle bacilli in the urine; while, finally, the affection of the opposite testicle which so often follows not long after the primary inflammation, is explicable only on the theory of transmission through the internal seminal tract. Thus, while it is patent that in many cases tuberculous epididymitis is the only striking evidence of tuberculosis in the individual, the disease is none the less systemic, and patient investigation will usually disclose some lesion of the prostate and sometimes an unsuspected disease in the kidneys or in the lungs.

I do not believe that genital tuberculosis can be acquired in coitus. The inflammation is most common in the third decade of life, and very rare before the fifteenth and after the fiftieth year.

Morbid Anatomy.—The discrepancy of opinions as to whether the tuberculous deposit begins in the tubules of the epididymis or in the intertubular tissue apparently has some connection with the views of the pathologist as to the primary or the secondary nature of the epididymal lesion. However this may be, the disease, as seen by the clinician, appears in an acute and a chronic form.

Acute tuberculosis is manifested by general swelling of the testis and epididymis with an accompanying hydrocele, considerable tenderness, and the fever and night sweats that go with acute tuberculosis. These cases of so called galloping or fulminating tuberculosis of the testicle are apparently attributable to a mixed infection; they appear and extend rapidly and reach the stage of suppuration within a few weeks.

The chronic form of the disease may appear as such or may follow upon the subsidence of an acute tuberculosis. In this condition there is little or no hydrocele or inflammation of the testicle; while in the epididymis and in the vas are found rounded nodules of tuberculous inflammation, small, hard, and caseous, or fluctuating and purulent.

The urinary organs are often infected either primarily or secondarily, although the lungs are frequently spared. Thus even on autopsy Kocher found only ninety-five cases of pulmonary tuberculosis among four hundred and fifty-one autopsies on cases of urogenital tuberculosis.

Symptoms.—The patient, a young man with tuberculous antecedents, usually comes complaining of a spontaneous enlargement of one testicle. Exceptionally, the enlargement may be a persistence of an acute gonorrhœal epididymitis; more frequently it has appeared during the course of a chronic gleet of long duration, though often enough there is no obvious cause for the swelling.

The history may be acute, in which case the testicle will be found considerably enlarged, with much fluid in the tunica vaginalis, aspiration of which reveals an enlarged testicle surrounded by a lumpy, œdematous epididymis, the vas deferens of which is enlarged and perhaps nodular. All of the inflamed areas are rather tender to the touch.

On the other hand, if the attack is a chronic one, the general aspect of the organ is normal while in one or more parts of the epididymis or of the vas tuberculous

Sexual Organs.

nodules may be seen and felt. Further questioning usually reveals a history of rather frequent calls to urinate; while examination of urine, prostate, vesicles, and kidneys will often reveal some congestion or inflammation of the internal sexual organs and perhaps an inflammation of the kidneys as well.

Diagnosis.—See Diagnostic Table, on p. 185.

Prognosis.—The usual course of the disease is that of a local tuberculous trouble advancing slowly to a fatal termination. Innumerable castrations are performed in the hope of eradicating the disease while still confined to one testicle; but its recrudescence on the opposite side affords bitter confirmation of the belief that tuberculosis here as elsewhere is not a local but a systemic disorder. In fact, it has seemed to me that removal of one testis hastens the appearance of tuberculous nodules in its fellow.

The prognosis of the disease is quite as indefinite as is the prognosis of tuberculosis elsewhere in the body. If the testicular lesion is circumscribed and chronic, if there is no evidence of grave internal disease, and if the patient can and will put himself for a long period of time in proper hygienic surroundings, the prognosis is good. The sexual potency of the testicle is lost, but the potency of the individual is unimpaired, and probably the testicle will not atrophy. If the local foci go on to suppurate they may be drained, and climatic and tonic treatment may be expected to control the disease and to prolong the patient's life indefinitely, even in many cases to effect a cure.

On the other hand, the prognosis of fulminating tuberculosis is bad. If seen early and treated intelligently this condition may subside and become chronic; but the very occurrence of the hyperacute form of the disease is evidence that the patient's tissues form a good soil for the growth of the tubercle bacillus, and is a warning that the greatest care will be required to prevent generalization of the disease, if indeed this has not already occurred.

Treatment.—From what has been said in the preceding paragraphs it is evident that not much need be expected from the surgical treatment of testicular tuberculosis. A recent discussion of this subject before the Paris Surgical Society (*Annales des Maladies Génito-urinaires*, 1900, xviii., 961, 1066) is brilliantly expressive of the change of opinion upon this subject which has occurred in France during the past quarter of a century. The consensus of opinion now favors conservatism and the belief that, in most cases, castration is harmful. My own experience with acute tuberculosis of the testicle is that treatment by hygiene, cod-liver oil, creosote, and perhaps local applications of guaiacol, will sometimes cause resolution and will oftentimes be followed by localized suppuration and subsidence of the general acute inflammation; while any surgery, beyond drainage of the suppurating foci, will only start up new trouble in the testicle or, if this is removed, in other parts of the body.

In the more chronic forms of the disease incision and drainage of suppurating foci is always indicated, and, when the whole epididymis is involved in a suppurating indurated mass, it is undoubtedly advantageous to perform the operation of epididymectomy; but it is questionable whether any benefit is obtained by removal of discrete, uninflamed caseous lumps.

Castration is never indicated unless the whole organ is reduced to a suppurating cavity. Many surgeons prefer to castrate for fulminating tuberculosis, but my experience is against this.

XXV. Epididymectomy.—The operation of epididymectomy resembles orchidectomy, except that, instead of removing the whole testicle, the inflamed epididymis is shelled off from the gland and removed with the extrapelvic portion of the vas deferens. If the upper end of the vas is found inflamed or exuding pus, it should be stitched into the wound; otherwise it will cause deep suppuration. The removal of the whole vas and of the vesicle along with the epididymis is an operation required only in the most exceptional cases in which there is considerable inflammation of the vesicle itself. It will not give good results as a routine procedure. (See Tuberculosis of the Seminal Vesicle.)

XXVI. Syphilis of the Testicle.—The testicle may be involved by syphilis in its secondary and in its tertiary stages.

Secondary Epididymitis.—Secondary syphilis sometimes causes a slight painless enlargement of the epididymis. This occurs at the time of the secondary skin manifestations, and is insignificant.

Tertiary Lesions.—Tertiary syphilis attacks the testicle and the epididymis. The disease may show itself by the deposition of gummata or by a diffuse infiltration of the organ. In the former case the testicle is enlarged, painless, and nodular, and in the latter—a more common form—the testicle is enlarged, painless, and smooth. The most characteristic changes are found in the epididymis, which may be affected throughout or at one or the other extremity; the part involved is evenly enlarged in such a way as to cap the testicle, forming a sharp-edged, hard mass like a clam-shell in which the testicle lies. As hydrocele is a very common accompaniment of this inflammation, the clam-shell characteristics of the epididymis are often obscured by the vaginal effusion; but aspiration of the hydrocele will in fully seventy-five per cent. of all cases of syphilitic orchitis reveal the pathognomonic, insensitive clam-shell epididymis. The cord is habitually normal. I have never seen double syphilitic testicle.

Syphilitic testis rarely appears before the second year of the disease. The gland enlarges gradually and painlessly; it is never tender unless there is some complicating gonorrhœal inflammation. The progress of the disease is very slow. The sexual function is little impaired. Syphilitic testicle occurs as a hereditary manifestation.

For *diagnosis*, see Diagnostic Table.

The *prognosis* is good. The disease is sometimes quite rebellious to treatment; but, inasmuch as the seminal tubules are not immediately involved and perish only by atrophy from pressure, a testicle may be syphilitic for a long time without losing its function.

Local *treatment* is useless. Mixed treatment will generally conquer the lesion, and, if this fails, hypodermic injections once or twice a week of 1 gm. of a ten-per-cent. solution of mercuric salicylate in benzoinol will often effect a cure.

XXVII. Tumors of the Testicle. — Testicular tumors are so rare and so diverse and mixed in character that an entirely satisfactory classification of them has yet to be made. They may be roughly divided into benign tumors, cystic tumors, and malignant tumors.

Benign Tumors.—Enchondroma, fibroma, osteoma, and myoma have been observed, and in the tunica vaginalis, lipoma and fibroma. These if small are not discovered ante mortem; if large it is usually impossible to distinguish them from beginning malignant disease.

Cystic Tumors.—Teratoma, benign cystic disease, and malignant cystic disease (Fig. 4258) are recognized by the pathologist; but clinically they are often indistinguishable from one another. Dermoid cysts and teratoma both have a tendency to malignant degeneration, and it is impossible—given a cystic tumor of the testicle —to be sure that it is benign and will so remain. Therefore, from a therapeutic point of view, all such cystic growths must be classified as at least potentially malignant.

Malignant Tumors.—Kober has recently collected the records of one hundred and fourteen cases of sarcoma of the testicle. Seventy-one per cent. occurred between the ages of twenty and fifty with a history of trauma in forty-three per cent. The tumors were usually round-celled or spindle-celled, less frequently cystic and alveolar. Carcinoma, usually medullary, is rarer than sarcoma; cystic and chondrocarcinoma have been described. The occurrence of lymphadenoma is affirmed by the French and denied by the Germans. Jacobson has seen three

Sexual Organs.

cases of myxoma. Four cases of sarcoma of the tunica vaginalis have been reported.

The only symptom of testicular tumor is the presence of a growth. The patient comes complaining of an en-

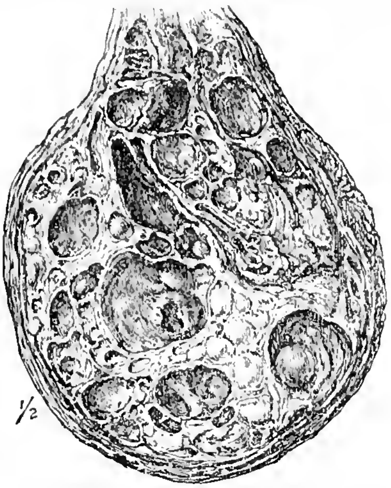

FIG. 4258.—Cystic Disease of the Testicle.

largement of the testicle which may have been present for many years without varying notably in size; or it may have suddenly taken on a more rapid enlargement after many years of quiescence; or it may have grown rapidly from the outset. In any event the tumor is usually found to be an irregular enlargement of the whole testicle, perhaps cystic in places, perhaps complicated by hydrocele. The pain is not severe and the general shape of the testicle is preserved, while testicular sensation is lost. If the disease has been present for some time enlarged iliac and lumbar glands may be felt by deep abdominal palpation. The inguinal glands are not involved until very late in the disease when the neoplasm has burst through the tunica albuginea and reached the scrotal tissue. The patient is usually seen before he has reached this stage, and, in the present surgical days, malignant fungus of the testicle (ulcerating neoplasm) is practically unheard of.

Diagnosis.—While it may be possible to state clinically that a tumor of the testicle shows no evidence of malignancy, one can never feel sure that it will not at some time undergo malignant degeneration. Therefore it is only necessary to be sure that the growth is a tumor in order to have recourse to immediate orchidectomy. To be sure, it is always necessary to employ mixed treatment and the aspirator; the one to rule out syphilis, the other to exclude hydrocele, spermatocele, and hæmatocele.

XXVIII. ORCHIDECTOMY.—Preparation.—The usual preparations for an aseptic operation are required. I prefer general to local anæsthesia.

The Incision.—Dr. White removes both testicles through an incision in the median raphé of the scrotum, but, since it is usually necessary to remove only one of these organs, the best incision is in the upper part of the scrotum just below the groin, an extension downward, as it were, of the ordinary incision for hernia.

The Actual Operation.—The cord is laid bare as in the operation for hernia and is divided between ligatures. The testicle is then drawn upward and out through the incision, and excised. If the skin is adherent the incision must be carried down far enough to remove the portion of skin involved.

Treatment of the Cord.—If the operation is performed for tubercle the end of the vas should be sutured to the skin in order to avoid deep suppuration. It is always safer to use one ligature for the vas and one for the bundle of veins in order to prevent hemorrhage.

Termination of the Operation.—The surface of the wound must be carefully scrutinized and every bleeding point caught and tied, for in the loose cellular tissue of the scrotum the slightest oozing may cause enormous hæmatoma. To guard against this still further it is convenient to apply an adhesive plaster dressing supporting the scrotum upon one strap running from thigh to thigh, and compressing it under a light aseptic dressing between other straps running criss-cross from the thighs to the abdomen. Weir and others have replaced testicles by celluloid and paraffine substitutes.

Complications.—Hemorrhage is the only complication to be feared; it may require reopening and repacking of the wound. The post-operative insanity alleged to result from castration for hypertrophy of the prostate has not been proven peculiar to this operation.

XXIX. SYMPTOMATIC HYDROCELE.—The hydrocele that so frequently complicates inflammatory diseases of the testicle is called symptomatic. The inflammation of the tunica vaginalis is secondary to the testicular disease, and, while the patient's comfort may be increased by the occasional tapping of such a hydrocele, no permanent relief may be expected in most cases unless the prime cause—the disease of the testicle—is removed.

XXX. IDIOPATHIC HYDROCELE.—An accumulation of serum in the tunica vaginalis occurring without any recognizable disease of the testicle is called idiopathic hydrocele. This disease is more common in the tropics than in temperate climes. It usually affects men who

DIAGNOSTIC TABLE.

	Simple chronic epididymitis.	Tuberculosis.	Syphilis.	Tumor.
History	Gonorrhœa, stricture, or hypertrophy of the prostate.	Tuberculosis, family or personal.	Syphilis, inherited or acquired.	Perhaps trauma.
Frequency	Uncommon	Frequent	Frequent	Rare.
Size	Small between attacks	Does not reach any great size.	Does not reach any great size.	May reach any size.
Sensitive	Yes	Yes	No	No.
Shape	Between attacks testis normal, epididymis nodular.	Epididymis nodular. Testis not involved unless acute or ancient.	Testis evenly enlarged, slightly nodular. "Clam-shell" epididymis as a rule.	Testis considerably enlarged; no characteristic involvement of epididymis.
Cord	May be slightly thickened	Usually enlarged and nodular	Free	Free; veins dilate in later stages.
Seminal vesicles	Usually distended	Tuberculous	Uninfluenced	Uninfluenced.
Prostate	Posterior urethra congested or inflamed.	Congested; may be tuberculous.	Uninfluenced	Uninfluenced.
Urine	Cloudy	Cloudy; may contain bacilli.	Clear	Clear.

Onset	Usually acute	Usually chronic	Chronic	Chronic.
Course	Recurrent acute attacks	Usually chronic	Chronic	Fairly rapid.
Opposite testicle	Often involved simultaneously.	Usually involved subsequently.	Free	Free.
Abscess	Unusual	Common	Rare	None.
Potency	Unimpaired	Somewhat impaired	Somewhat impaired	Unimpaired.
Atrophy of testis	Rare	Rare	Common	Never.

At the end, as at the beginning, the iodides with mercury, and the aspirator.

have reached middle age, but may occur in youth and in infancy.

Varieties.—The commonest form of hydrocele as seen in the adult is confined to the tunica vaginalis (Fig. 4259). In infancy and less frequently in later life the fluid may be found to fill not only the tunica vaginalis but also the unobliterated processus funicularis up to and into the inguinal canal. This is *infantile hydrocele*. Another form of hydrocele met with in infants is called *congenital hydrocele*. In this condition the funicular process of peritoneum has never been closed off at all, and the hydrocele sac communicates directly with the abdominal cavity and is habitually complicated by congenital hernia.

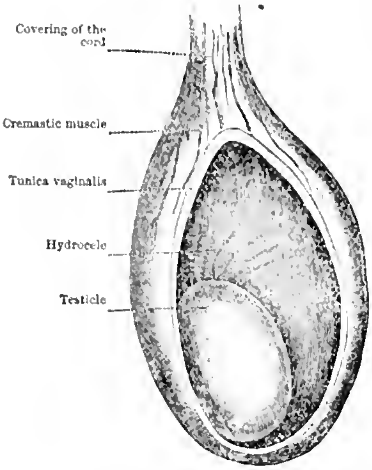

FIG. 4259. Hydrocele.

A fourth variety is *hydrocele of the cord* in which the funicular process, closed off from the abdominal cavity above and from the cavity of the tunica vaginalis below, is affected by hydrocele. Exceptionally, hydrocele occurs in the tunica vaginalis of a retained testicle; this is *inguinal hydrocele*. And again, hydrocele may occur in an old hernial sac the neck of which has been shut off by adhesions. These varieties are extremely rare. There are also certain cysts that develop in connection with the testicle, *i.e.*, *spermatocele* and multilocular hydrocele of the cord. Neglecting for the present all these more or less unusual varieties in intrascrotal cysts, we may consider at length idiopathic hydrocele of the tunica vaginalis.

Symptoms.—This condition presents itself as a fluctuating or elastic ovoid swelling somewhat pear-shaped, being larger below than above. Its surface is smooth, it is irreducible into the inguinal canal; indeed, the spermatic cord, normal in size and sensibility, can usually be grasped above the top of the tumor. There are almost no subjective symptoms; the patient complains only of the large tumor and of some dragging and pain due to its position and weight. The history is always chronic, the fluid accumulating by slow degrees.

Diagnosis.—In examining a hydrocele the two points to be determined are the fluid nature of the tumor and the position of the testicle in reference to the fluid. If the normal cord can be felt above the tumor, if fluctuation can be obtained in it, and if palpation reveals the testicle as a slight nodosity with testicular sensation, both of these questions are answered without further investigation. But the testicle may be impalpable, fluctuation may be unobtainable; and a large hydrocele extending into the inguinal canal exhibits a slight impulse on coughing, and so requires some test to distinguish it from irreducible hernia. For this purpose the so called light test is commonly employed.

The room is darkened and a tube is made by rolling a sheet of paper upon itself, and, while one end of this is applied to one side of the tumor, a match or a candle is lighted and held at the opposite side. If the tumor is fluid light will be transmitted through it, and a dull red glow may be seen by looking into the paper tube. The same effect may be more brilliantly obtained by the use of an electric light, by which means the whole tumor may often be made luminous without darkening the room and without the use of the paper tube. It is alleged that this reaction may be obtained in small hernias in infants; but with this possible exception its positive result is absolute evidence of the presence of hydrocele.

If there is no question of hernia in the diagnosis hydrocele may be distinguished from solid tumors of the testicle by aspiration. When this test is applied, the surgeon should be ready in the event of its success to attempt a radical cure by injection.

Complications.—Exceptional complications of hydrocele which may interfere with the diagnosis and treatment are great thickening of its walls, which may proceed even to calcification (and so frustrate the light test), multilocular hydrocele (resulting either from an adhesive inflammation or from the simultaneous existence of several varieties of hydrocele), fibrous bodies in the hydrocele sac (doubtless the result of previous attacks of inflammation), and, very exceptionally, suppuration of or hemorrhage into the hydrocele.

Treatment.—It is so easy to cure idiopathic hydrocele in children that a great number of palliative treatments have been devised by those whose chief experience is with young patients. Thus the application of various counter-irritants to the skin, multiple puncture with a sharp needle, and simple evacuation of the fluid will often prove curative in the young. But in adults such treatments are purely palliative, as is instanced by Curling's case, who had ruptured his hydrocele thirty times only to see it return within a few months. I have seen a similar case, the patient returning for tapping every six months for many years, but refusing to have any more radical procedure attempted, although the fluid reaccumulated with unvarying regularity.

Of the radical cures of hydrocele the one which I prefer is aspiration followed by the injection of pure carbolic acid. All simple hydroceles which are translucent, no matter how old or how large, are amenable to this treatment; and in such simple cases injection can boast a percentage of cures equal to that of any other operation. Injection will not cure symptomatic hydrocele, nor will it cure suppurating, hemorrhagic, or fibrotic hydrocele.

A great number of substances have been employed for injection into the tunica vaginalis, but for safety and comfort and assurance of success none equals pure carbolic acid. The method of operating is as follows: If the hydrocele contains more than six ounces of fluid it should be tapped and the patient told to return for the cure a week or two weeks later, when partial reaccumulation shall have occurred; otherwise the aspiration and injection may be performed at once. The instruments required are a large hypodermic syringe and an aspirator. The solutions are a bottle of carbolic-acid crystals deliquesced by heat, some pure alcohol, and some green soap to cleanse the skin. The needles are boiled; the surgeon cleanses his hands and the skin of the patient with green soap and alcohol. A hypodermic syringe is then filled with the pure carbolic acid, and its needle, unattached, is plunged into the front of the tumor, the drop of serum issuing through it proving that its point is in the cavity. The needle of the aspirator is then plunged into another point on the surface of the tumor (the position of the testicle having been previously ascertained by the light test), and immediately serum gushes from this. The aspirator is now set in action and the contents of the sac are drawn off, every effort being made to withdraw the fluid even to the last drop.

Only two precautions need be taken: (1) not to allow the hypodermic needle to slip from the sac; (2) not to wound the testicle. The sac being dry, the hypodermic syringe is attached to its needle and from five to thirty drops of the pure carbolic acid are injected. I have injected two drachms of pure carbolic acid without any serious reaction; but the use of such large quantities, while it does not cause carbolic-acid poisoning, may produce a good deal of inflammation, and is, I believe, quite unnecessary. Indeed, Dr. Coley has had excellent

Sexual Organs.

results from the injection of a single minim of the acid; but, inasmuch as it is impossible entirely to empty the sac, I always prefer to inject enough fluid to cover its surface thoroughly. Immediately after injection the needle is withdrawn, some alcohol poured over the skin to protect it from the carbolic acid, and the scrotum briskly rubbed in order to diffuse the fluid throughout the tunica vaginalis.

After this little operation the patient may often continue to go about, but as the reaction for the first forty-eight hours is often considerable, it is better that he should lie in bed during this time.

During the first week the sac usually refills, but thereafter this fluid is gradually absorbed, and at the end of six weeks the patient should be practically well, except for the presence of the hardened, thickened tunica vaginalis which gradually softens and disappears during the succeeding months. If the reaccumulated fluid does not disappear within a few weeks aspiration should again be performed, and a few drops more of carbolic acid may be injected at this time, although this is usually unnecessary.

Failure of the injection treatment may be attributed to three causes, namely:

1. Application of injection to cases incurable by this method—*i.e.*: (*a*) Most symptomatic hydroceles. (*b*) Some spermatoceles. (*c*) Hydroceles with inflamed, indurated, or calcareous walls. (*d*) Hæmatoceles and chyloceles.

2. Errors of technique, notably: (*a*) Endeavoring to cure too large a hydrocele. If the sac contains more than six ounces its contents must be reduced by one or more preliminary tappings. (*b*) Incomplete evacuation. This I believe to be the most frequent cause of failure; to insure success the last drop must be squeezed from the vaginalis. (*c*) Injection of the carbolic acid into the cellular tissue. I need scarcely insist upon this point. (*d*) Failure to perform the secondary aspiration which is sometimes part of the cure.

3. The use of iodine instead of carbolic acid. Iodine injection is painful and uncertain, while carbolic acid, being a local anæsthetic, produces only a momentary tingling and, at my hands, has been a certain cure.

The Open Operation.—For cases in which the diagnosis is not certain or in which, for one of the reasons stated above, the injection treatment is inapplicable or has failed, the open operation should be performed. This operation may be done in one of three ways:

FIG. 4260.—Hydrocele of the Cord Complicated by Hernia.

1. Volkmann's operation consists of simple incision and drainage. The sac is opened by one sweeping cut, its edges are sutured to the skin, its surface swabbed with pure carbolic, and a wick of gauze inserted into the wound. The convalescence from this operation is so prolonged that it has been generally discarded in favor of—

2. Von Bergmann's operation. Here an attempt is made to excise the sac; skin and fascia are divided down to the tunica vaginalis, and this is shelled out, opened and cut away up to the testicle. That part of the tunica which is adherent to the testicle is then swabbed with pure carbolic acid, and the skin incision is closed over a drainage-tube which is removed in a few days.

3. Eversion of the sac is an operation recently proposed to take the place of von Bergmann's operation, the advantages claimed for it being that it is more rapidly performed and that it requires no drainage. The sac is dissected out roughly and the greater part of its parietal layer cut away. The testicle is then extruded through the wound, and the remainder of the sac is inverted and sutured behind the testicle by a few strands of catgut. Testicle and sac are then replaced and the skin wound sutured.

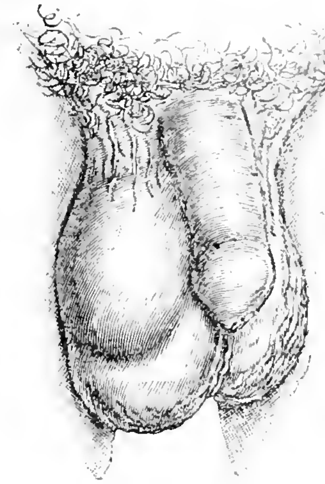

FIG. 4261.—Spermatocele.

I prefer this operation to any other open procedure, and expect to cure by it within ten days; yet there have been recurrences after this as after every one of the various operations advised for hydrocele.

Congenital Hydrocele.—Congenital hydrocele, in which the hydrocele sac communicates with the abdominal cavity, occurs in infancy.

Congenital hydrocele is often confused with hernia, since the tumor is continuous into the inguinal gland and is reducible into the abdomen. The distinction between the two conditions is not important, since with congenital hydrocele there is habitually hernia, and the treatment of the two conditions is the same—namely, a well-fitting truss, and if this fail, the operation for radical cure of hernia. Congenital hydrocele should never be injected.

Infantile Hydrocele.—Infantile hydrocele is far more common than the congenital variety. Thus Horwitz records one hundred and ten cases of hydrocele, of which twenty-two were infantile and only one congenital.

The diagnosis and treatment of this condition present no peculiarities.

Abdominal Hydrocele (Bilocular Hydrocele).—This is a very rare variety of infantile hydrocele, in which the sac fills the scrotum and also extends into the abdominal cavity, pushing the peritoneum before it, sometimes forming an enormous cyst in the latter. Some twenty cases have been recorded, cure having been accomplished by simple drainage and by injection.

XXXI. HYDROCELE OF THE SPERMATIC CORD.—Hydrocele of the cord (Fig. 4260) may be multilocular (diffuse) or encysted. Kocher classifies multilocular hydrocele under the following heads: (1) Echinococcus cysts, (2) spermatocele, (3) encysted hydrocele of the cord subdivided into loculi by adhesive inflammation, (4) cysts of Müller's duct of the Wolffian body or of the organ of Giraldes, (5) cystic lymphangioma.

The three conditions commonly classified as encysted hydrocele of the cord are: (1) Hydrocele of the processus funicularis, (2) spermatocele, and (3) hydrocele of an old hernial sac.

Whatever the true nature of the hydrocele, it is in appearance either a single cyst or a number of small cysts occupying the region of the spermatic cord. Habitually the cyst is either a hydrocele of the processus funicularis (the serous peritoneal prolongation surrounding the cord, which normally disappears during infancy, but which sometimes persists and is then liable to hydrocele) or spermatocele.

The treatment of hydrocele of the processus funicularis is by injection.

XXXII. SPERMATOCELE.—Spermatocele (Fig. 4261) (encysted hydrocele of the testicle, epididymal cyst) is a collection of fluid "contained in a cyst or in cysts distinct from but close to the cavity of the tunica vaginalis" (Jacobson).

Clinically, two classes of spermatocele may be recognized

1. Small cysts are very common about the head of the epididymis in old men They do not attain any notable size; they rarely contain spermatozoa, they produce no symptoms, and are usually discovered by accident.

2. Large cysts develop in the epididymis before the fiftieth year, as a rule; they are often multiple and usually contain spermatozoa. They form irregular fluid tumors about the top of the gland, the smaller tumors having a notch in the upper end, giving them a shape comparable to that of a heart. This heart shape is so common as to be considered a pathognomonic sign. These cysts rarely contain more than an ounce or two of fluid, although Curling drew thirty-two ounces from one individual and forty from another; while Jacobson mentions a case from whose right side forty nine ounces were drawn and fifty-eight from the left. Such large cysts as these are habitually mistaken for hydroceles, their true nature being disclosed by the milky fluid which, on examination, proves to be full of spermatozoa.

Hydrocele and spermatocele may coexist. Spermatocele is commonly attributed to dilatation and sacculation of the spermatic ducts behind a partial obstacle, just as the kidney dilates behind a partial obstruction but is not dilated by complete obstruction. The earlier authors held that spermatocele is due to cystic growth in various fœtal remains, and attributed the presence of spermatozoa to the bursting of the cyst into the epididymal canal. The communication between the cyst and the epididymis has several times been demonstrated.

Diagnosis.—The heart shape, though pathognomonic, is not always present. The diagnosis may usually be made upon the discovery of a small uninflamed tumor above the testicle. Large tumors can be diagnosed only by aspiration, without which they are commonly mistaken for hydrocele of the tunica vaginalis, hydrocele of the cord, or neoplasm.

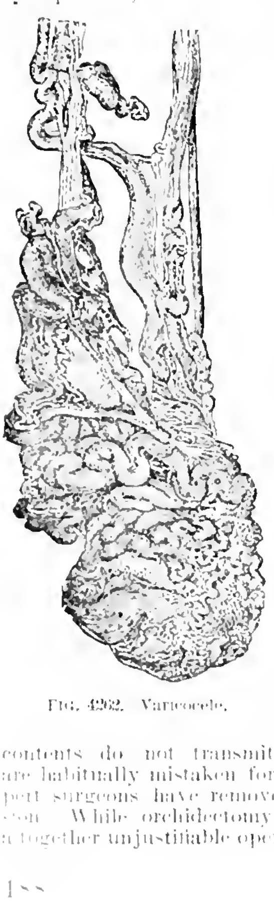

FIG. 4262. Varicocele.

Treatment.—The small spermatoceles of later life require no treatment. The larger growths may sometimes be cured by aspiration and injection of carbolic acid; a more certain method is excision of the entire sac.

XXXIII. HÆMATOCELE.—If a hæmatoma, whether of the testicle, of the tunica vaginalis, or of the scrotum, becomes encysted instead of being absorbed, the cyst is denominated hæmatocele (Fig. 4254). Scrotal hæmatocele and testicular hæmatocele are always traumatic in origin. Hæmatocele of the tunica vaginalis is sometimes spontaneous. I have seen a case of spontaneous hæmatospermatocele

The diagnosis of hæmatocele presents no difficulties, unless it be spontaneous or of such long duration that its traumatic cause has been forgotten. The tumor usually retains the pyriform shape of a hydrocele, but its thickened walls and dense contents do not transmit light. Such hæmatoceles are habitually mistaken for neoplasms and the most expert surgeons have removed them under this impression While orchidectomy in this condition is not an altogether unjustifiable operation, it is more satisfactory to the surgeon to make a correct diagnosis before operating and more pleasant to the patient to retain his testicle, if that be possible. The only sure means of diagnosis in these cases is aspiration or incision.

The treatment is incision and drainage, or, if the testicle is disintegrated, orchidectomy.

XXXIV. CHYLOCELE.—Chylocele (fatty, milky, chylous hydrocele, galactocele) is an accumulation of chyle or fatty lymph in the tunica vaginalis. It occurs in connection with elephantiasis; exceptionally it is due to the traumatic rupture of a lymphatic vessel into the tunica vaginalis. False chylocele is due to a fatty or cholesterin-producing degeneration in a hydrocele. The treatment is incision and drainage.

XXXV. SYMPTOMATIC VARICOCELE.—Symptomatic varicocele is rare. It is caused by obstruction of the spermatic veins. I have seen one case due to prolonged use of a truss. It is usually caused by the pressure of enlarged retroperitoneal glands upon the spermatic veins. This generally occurs in connection with malignant disease of the kidney and is an evil omen, since it indicates glandular involvement.

Diagnosis.—Symptomatic varicocele develops very rapidly, late in life, on either side. It is painless, attains a large size, and is always associated with an abdominal tumor or some other cause of obstruction.

XXXVI. SPONTANEOUS VARICOCELE.—The left testicle habitually hangs lower than its fellow, and the veins of the left spermatic cord are habitually somewhat more prominent than those upon the right side. Idiopathic varicocele is a spontaneous varicose enlargement of these veins (Fig. 4262). The proportion of adult males suffering from this disease is estimated as between seven per cent. (Bennett) and twenty-five per cent. (Senn), the discrepancy in these figures being evidence of how common are small varicoceles and how slight is their importance.

Varicocele always occurs on the left side; very rarely a large varicocele on the left side is associated with a small one on the right side. The disease occurs only in young adults. The cause of varicocele has been bitterly debated. It occurs in young adults on account of the sexual congestion to which they are so peculiarly liable. It is not known why it should always occur on the left side, although this has been attributed to the anatomical position of the left spermatic vein, which is longer than the right and enters the left renal vein at right angles, so that it is not so much affected by the venous suction as is the right vein, which enters the vena cava at an acute angle. Exceptionally, varicocele results from a sudden strain.

Symptoms.—The symptoms paraded by advertising charlatans as those of varicocele cover every neuralgic manifestation, and to this notoriety is attributable a large proportion of the symptoms complained of by these patients. Three sets of symptoms may be distinguished:

1. Neurotic symptoms, such as the failure of sexual desire and potency, and all kinds of reflex pain and weakness.

2. Neuralgic symptoms, of which the most notable is a continuous soreness or pain running from the testicle up through the groin into the loin, most marked in some one of these localities.

3. The only symptom may be the presence of venous tumor.

In a general way it will be found that patients with the smallest varicoceles, those in whom the enlargement of the veins is scarcely more than a fancy, encouraged by the weighty opinion of some quack, suffer most from the purely neurotic symptoms; while it is the medium-sized varicoceles that present the most marked neuralgic symptoms, leaving the largest growths to cause the least pain.

Diagnosis.—The sufferer habitually diagnoses his case by the fact that the left testicle hangs lower than the right, and that he has some real or imaginary sexual neurosis. The surgeon must not be misled into this opinion. The perverted sexual appetite, the morbid broodings over sexual matters, the swindling methods of the quack, are causes quite adequate to explain the neurotic symptoms of these patients, whose varicocele is only one evidence of general morbid sexuality. Cure of the varicocele can affect the neurotic symptoms only by its hypnotic influence upon the patient's mind.

The actual varicocele tumor manifests itself as a general swelling of the scrotum which, when palpated, is felt to be made up of a mass of varicose veins, which feel like earthworms, soft and convoluted. Veins of this description can almost always be felt in the left side of the scrotum, and it is fair to make the diagnosis of varicocele only when these veins make a considerable tumor and drag the testicle well below its fellow. Palpation may also reveal atrophy of the testicle from pressure. No other scrotal tumor is mistakable for varicocele.

Treatment.—The mild cases in whom sexual symptoms predominate are best treated by the application of a suspensory bandage, rigid sexual hygiene, and medication of the prostate, as for neuralgia of that organ. The patient may be reassured that his varicocele cannot influence life or potency, and that, with the lapse of years or by the sexual hygiene of matrimony, he may expect to be relieved from all his symptoms. Larger varicoceles require operation for their removal, in order to relieve the patient of his discomfort and to prevent atrophy of the testicle from pressure. When neuralgia is the prominent symptom, operation may be performed to relieve the disfigurement and with some prospect of relief to the neuralgia; but it is never possible to assure the patient absolutely that any operation for varicocele will relieve sexual or neuralgic symptoms. The constant failure of surgery to live up to its promises in this matter is an example of the futility of attempting to cure a reflex phenomenon without absolute assurance of the nature of the reflex. If operation is decided upon, whether for the purpose of relieving the patient's mind, or of attempting to cure his painful symptoms, or of removing a large mass of varicose veins, two methods of approach are open to the surgeon. Without stopping to consider the applicability of coagulating injections and of electricity to this condition, we may briefly describe the operations of subcutaneous ligature and of excision.

Subcutaneous Ligature.—The instruments required for this operation are the Keyes-Reverdin needle (Fig. 4263), a sufficient length of stout silk, and a pair of scissors. These are sterilized by boiling, the patient's skin is prepared as for any aseptic operation, and the surgeon cleanses himself with proper care. The operation may be performed with or without general anæsthesia. If the patient prefers he may take chloroform during the whole operation, or he can avoid this and at the same time have the pain greatly mitigated by the injection of cocaine into the points of puncture and the administration of a whiff of chloroform at the time the ligatures are tied. Under these circumstances he is made to stand during the insertion of the ligature, in order that the veins may be as full of blood as possible; while, if general anæsthesia is employed throughout, the operation must be performed with the patient recumbent.

To perform the operation the first and almost the only technical requisite is to separate the bundle of varicose veins from the vas deferens. In order to do this the contents of the left half of the scrotum are squeezed repeatedly between the thumb and index finger of the left hand and allowed to roll piecemeal from this grasp until the surgeon can be sure of distinguishing (1) the large, tortuous varicose pampiniform plexus; (2) the vas itself which stands out separately as the largest, hardest single cord in the whole mass; and (3) a few veins running to the inner side of the vas. These three sections having been distinguished, the thumb and finger are pressed between the vas deferens and the varicose veins at a point just below the junction of the scrotum with the trunk. Pressure is made until the surgeon feels sure that no vascular tissues lie between his fingers, all the while being careful not to allow the vas to slip outward or the veins to slip inward.

Now taking the needle threaded with a piece of silk fourteen inches long, the surgeon quickly plunges this into the space made by his pressure between the vas and the veins. Needle and thread enter the front of the scrotum, issuing behind. The eye of the needle is then opened, the silk loop extracted from it, the eye tightly closed, and the needle slowly withdrawn until its point is only just within the anterior puncture. One end of the silk loop is then pulled through to the back of the scrotum, the veins are allowed to slip back toward the vas, and the needle is reintroduced externally between the veins of the skin and made to issue accurately through the original posterior puncture. At this stage the varicose veins are encircled by a strand of silk to the inner side and the needle to the outer side. All that remains to be done is to open the eye of the needle once again, to insert in it the end of the piece of silk and to withdraw the needle, carrying the silk around the veins and out through the original anterior puncture. The veins are now held in a sling formed by the silk loop. The dartos at the point of posterior puncture is caught in the loop, and this must be freed by a sharp tug. The loop is now tied tightly. This operation squeezes certain nerve filaments, and is the only intensely painful part of the whole procedure. A second and a third knot are then tied for safety, the ends of the silk are cut off short, and another jerk frees the dartos at the point of anterior puncture, permitting the knot to slip out of sight into the scrotum.

FIG. 4263.—Keyes Varicocele Needle.

This little operation may be repeated just above the testicle and again just below it; while, in very exceptional instances, it may seem necessary to tie a few veins running to the inner side of the vas. I have never put more than three ligatures in any one case, and it is my routine custom to place one ligature high up in the scrotum and one just above the testicle. If general anæsthesia is not employed it is convenient to insert all the ligatures, then to give the chloroform and then to tie.

After the operation the points of puncture are sealed with collodion, the scrotum is slung up with a T-bandage, and an ice-cap is placed against it to minimize the painful and œdematous reaction. The patient remains in bed some three or four days, though this period may be cut short, and then goes about his business wearing a suspensory bandage. For a few months the points of ligature remain surrounded by hard nodes of induration, after which this gradually disappears. Thereafter the suture may be readily detected grasping the atrophied veins.

The Open Operation.—Excision of varicocele may be most conveniently done through an oblique incision over the spermatic cord at its point of exit from the inguinal canal. The tissues of the cord are laid bare and the veins separated from the vas and pulled out, drawing the testicle up to the lower end of the incision. When the whole pampiniform plexus has thus been extruded it is tied off by two stout ligatures, and excised between them; the ends of the ligatures are then tied together, thus supporting the testicle. A few stitches close the incision; the patient lies in bed for from four to six days.

In choosing the operation appropriate to a given individual case, it must be remembered that: (1) ligature avoids incision, while excision postulates it; the temperament of the patient may require one or other operation to be chosen on this account; (2) ligature in unskilful hands may injure the vas and the potency of the testicle, while the open operation in unskilful hands is commonly followed by prolonged suppuration. Suppuration is extremely rare with ligature, and either operation if skilfully and carefully done should avoid either complication; (3) atrophy of the testicle is as likely to occur after either operation. I have never seen it, nor have I seen relapse of the varicocele in any case upon which I have performed subcutaneous ligature; (4) subcutaneous ligature is a neater operation requiring shorter convalescence and involving less shock to the patient; therefore it is habitually to be preferred.

One other operation is frequently performed for the relief of varicocele—viz., *ablation of the scrotum*. If a large varicocele have stretched the scrotal skin, it is the custom of many operators to excise a portion of this, partly to obtain an æsthetic result, partly to support the testicle. This second hope is vain. The distensible scrotal skin cannot be employed to support anything, and for the same reason, if the pressure of the varicocele is removed, the skin may be left to contract of itself, unless it has been enormously stretched.

XXXVII. Tumors of the Cord.—The various hydroceles of the spermatic cord have already been dwelt upon. Of solid tumors the only one of any significance is the so-called fibrolipoma, a tumor which sometimes grows to enormous size simulating malignant disease of the testicle. In fact, so many of these tumors which have been pathologically passed upon as fibroma, fibrolipoma, or, fibromyoma, prove by their prompt recurrence to be malignant that it is more correct to group the whole class as sarcoma, the pathologist to the contrary notwithstanding.

XXXVIII. Diseases and Injuries of the Seminal Vesicles.—*Malformations.*—The malformations of the seminal vesicles are unimportant. There are never more than two vesicles, and if one is missing the testicle on that side is missing as well. The ejaculatory ducts may empty into the ureters or into the urethra at some point anterior to the triangular ligament, instead of on the edge of the prostatic utricle.

Wounds.—Guelliot recognizes only one case of undoubted accidental wound of the vesicle due to fracture of the ischium. Operative wounds of the ejaculatory ducts are doubtless frequent as the result of various perineal cystotomies, prostatotomies, and prostatectomies. Incision of one or both of the ducts is doubtless usually followed by obstruction which, if partial, causes dyspermia; if total and bilateral, sterility. Another result of such a wound is inflammation, showing itself as an acute vesiculitis and epididymitis. It is for these reasons that cystotomy performed upon a young adult should be suprapubic rather than perineal. Spermatic fistula has resulted from the old-fashioned lateral lithotomy operation. It heals kindly unless the parts are cancerous or tuberculous.

Acute Seminal Vesiculitis.—Acute inflammation of the seminal vesicle is a common complication of acute prostatitis. But the acutely inflamed vesicle gives no characteristic symptoms, and is not observed clinically except under three conditions: (1) acute epididymitis, with which there is always an inflammation of the vesicle; (2) chronic vesiculitis, the result of an acute attack; and (3) abscess of the vesicle.

Abscess of the Seminal Vesicle.—If the vesicular inflammation is so intense as to produce suppuration, the symptoms of prostatitis (for these patients always suffer first from an inflammation of the prostate) are intensified. The temperature is high, there may be chills, increased vesical irritability, and a sense of burning and discomfort deep in the perineum, oftentimes sufficiently irritating to cause sympathetic rectal tenesmus.

The pus accumulates either within or alongside of the vesicle and habitually points toward the rectum. Examination of such a case in its early stages reveals a hot, boggy, pulsating swelling above and to one side of the prostate, or perhaps extending down over that organ. Later, as the pus focalizes, the tenderness and heat are less, while fluctuation becomes apparent.

If the inflammation is discovered before abscess has developed, an attempt may be made to abort it by placing the patient in bed and irrigating the rectum twice a day with water as hot as he can bear. But after fluctuation becomes apparent, the only appropriate treatment is incision and drainage, preferably through the rectum (see below).

Chronic Seminal Vesiculitis.—Chronic inflammation of the vesicle may result from an acute inflammation, or may come on insidiously as a result of sexual intemperance or with no obvious cause. Many cases show no symptoms to distinguish them from chronic prostatitis. The surface prostatitis causes pyuria and chronic gleet, and there may well be no subjective elements of any deeper trouble; but the vesicular focus can be felt by rectal touch as a hard, irregular mass just above one horn of the prostate, and, unless this vesicular mass is dissipated by local treatment, it is impossible to cure the gleet. In other cases, however, there are subjective evidences of the inflammation of the vesicle, and all cases of chronic seminal vesiculitis may be classified as follows:

1. Cases (as noted above) in which there are no subjective symptoms of the vesicular inflammation, but only chronic gleet.
2. Cases of relapsing urethritis, the recurrence being occasioned by sexual excitement and due to a smouldering focus in the vesicle.
3. Cases of gleet complicated by painful or hemorrhagic emissions.
4. Cases of relapsing pyuria. These cases differ pathologically from all the others, in that the vesicle is a dilated pus sac, filling up and emptying at more or less regular intervals, so that the urine is at one time entirely free from pus and at another loaded down with it.
5. Neuralgic cases. These may be subdivided into cases of neuralgia about the perineum and along the urethra, and cases of neuralgia of the back and of the testicles. In the former class the indurated vesicle is usually very tender and local treatment immediately efficacious; while in the latter class there may be only a little enlargement of the vesicle with scarcely any tenderness, although the reflex neuralgia in the testicle, the rectum, or the loin be intense. Such cases are slower to improve under treatment.

Diagnosis.—The diagnosis of chronic seminal vesiculitis is made by rectal touch. The prostate may or may not be inflamed; it may be large and congested, or it may contain foci of induration; but above and at the outer angle of the prostate is always felt a lumpy mass; this is the inflamed vesicle. In some cases it is soft and massage upon it for a few minutes will greatly decrease its size, while drops of pus exude from the meatus, and the urine next passed will be extremely purulent. In other cases the mass is harder and less affected by massage.

Treatment.—The treatment of chronic seminal vesiculitis may be local or hygienic. Hygienic treatment consists in abstention from excessive sexual intercourse, and, in severe cases, from all sexual matters whatever. An improvement in the surroundings of the patient, a vacation in the country, will often entirely relieve the mild neuralgic and gleety cases. But in the majority of instances hygiene should be employed only as an accessory to local treatment in order to keep the patient in a condition in which local measures can effect a cure.

The local methods of treatment are: (1) Mechanical, (2) thermic, (3) chemical, (4) electric.

1. The mechanical treatment consists in massage, a manipulation which is performed by the finger introduced into the rectum. The vesicular induration is palpated and then gently rubbed in all directions with a to-and-fro and spiral motion, and the pressure is gradually increased until it is quite firm; but severe manipulation is to be avoided for fear of lighting up an epididymitis.

Various metal implements have been devised for massage but it is so difficult to employ them with sufficient

Sexual Organs.

gentleness that the surgeon's finger is the instrument to be preferred.

2. Thermic treatment is applied by means of the double-current rectal tube. The tube I prefer is that devised by Dr. Chetwood (Fig. 4264). This is inserted into the patient's rectum, as shown in Fig. 4265, and two quarts of water at the temperature of 105° F. are run

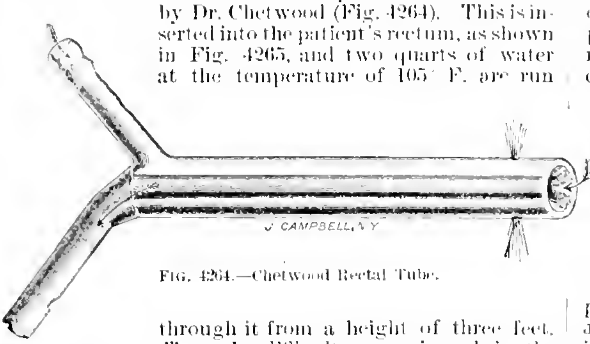

FIG. 4264.—Chetwood Rectal Tube.

through it from a height of three feet. The only difficulty experienced in the use of such a tube is in getting the water out. It runs in easily enough, but some experience is required before it can be made to flow out through the tube without running up the bowel and causing colic and an evacuation.

3 and 4. Chemical and electrical applications to the prostate have been generally employed without any great success. Ichthyol suppositories are well spoken of.

In choosing the treatment appropriate to a given case it is best to place one's chief reliance upon the hot-water irrigations. These may be used once or twice a day, and it is my custom to employ them for two weeks out of three. Except in hyperacute cases the patient experiences little or no immediate relief from this treatment, but under it the indurations slowly disappear. In some neuralgic cases cold water is more efficacious than hot. At the same time it is well to massage the vesicle once or, in severe cases, twice a week. Rectal irrigation must be kept up for from eight to twelve weeks, as a rule, though it is not necessary to employ massage during the latter part of this time.

Tuberculosis.—Genital tuberculosis often begins in the seminal vesicles (see above). It seems always to begin as a unilateral disease; indeed, it often involves the vesicle, the epididymis, and even the kidney of one side, with one-half of the prostate, before making any incursion upon the other side. But it is apparently through tuberculosis of the vesicle and of the prostate that the disease passes from one testicle to the other.

There are commonly no symptoms directly referable to the vesicle. Hæmosperm, abscess, fistula, and irritation or apathy of the sexual appetite are very exceptional manifestations. In most cases the disease is discovered only by rectal examination and manifested only by symptoms of the associated inflammation in the prostate and in the epididymis.

Diagnosis.—The diagnosis depends upon the discovery in a patient with prostatic or epididymal tuberculosis of hard nodules, boggy, inflamed areas, or large fluctuating masses in the region of one or both vesicles. Primary vesicular tuberculosis without prostatic or epididymal disease is not diagnosed.

Treatment.—The treatment appropriate to most cases is systemic. Local applications or massage can only do harm by increasing the epididymal inflammation. The tuberculous vesicle should rarely be examined, never massaged.

Operations.—A suppurating vesicle, whether tuberculous or simply inflamed, may require incision. This for simple inflammation may be carried through the anterior rectal wall where the abscess points. Such incision, though theoretically subjecting the patient to grave danger from sepsis, is practically followed by the happiest results. It may be performed without anæsthesia by means of a thin bladed knife introduced on the finger, and it results in evacuation of the abscess without untoward complications.

Incision of the tuberculous vesicle is always followed by fistula, and must therefore be carried from the perineum. It is convenient to make a circular incision beginning at one ischial tuberosity and encircling the front of the anus about one inch from it, carried past the opposite tuberosity and back to the median line, thus surrounding the anus by three-fourths of a circle. This incision is carried upward through the deep fascia and the levator ani muscle; blunt dissection and retraction of the rectum then expose the prostate and the vesicle. Through this incision the vesicle may be incised, scraped, or excised. Excision of the organ is a difficult and tedious operation on account of the depth at which one must work. Although the apex of the vesicle rests against the peritoneum, it is usually easy to shell it away, and rupture of the peritoneum is a complication of this operation which has not been recorded. The real dangers of the operation are puncture of the urethra or of the rectum. These are avoided by introducing a sound into the former, a finger into the latter.

The vesicle may also be excised by a Kraske or Rydgier excision of the sacrum and lateral displacement of the bowel; while Young, of Baltimore, has reintroduced Villeneuve's operation of excising the vesicle as a complement to castration, employin. the oblique inguinal incision.

Vesicular Cysts.—Prolonged inflammation of the vesicle may leave it greatly dilated. Such cysts are not uncommon in the aged. Occlusion of the ejaculatory duct

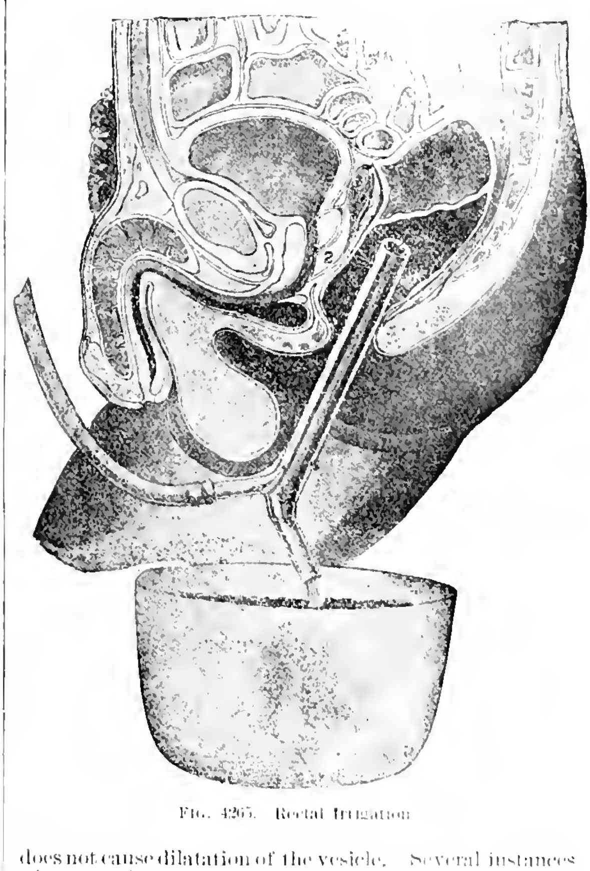

FIG. 4265. Rectal Irrigation

does not cause dilatation of the vesicle. Several instances of retrovesical echinococcus cysts have been attributed without convincing proof to the vesicle.

Concretions and Calculi.—Vesicular concretions formed of starchy matter, epithelia, and phosphatic salts are common in the aged; exceptionally they give rise to *spermatic colic.* This pain occurs spontaneously or at the moment of ejaculation, and is sharp, colicky, and nauseating. It is most intense at a point about an inch up the anterior rectal wall or at the neck of the bladder; thence radiating to the testicle and the loin. The pain is caused by the impaction of a concretion in the ejaculatory duct. It may cause painful or deficient emission or hæmosperm. It may be long-continued or of brief duration.

The treatment of a mild case consists in introducing a finger into the rectum and gently massaging the painful spot. This usually dislodges the concretion and relieves the patient. Recurrent colic seems to be relieved by the hot rectal douche. If the attack is severe, prostate and vesicle may be massaged against a full-sized sound introduced into the urethra; this failing, incision may be considered.

Malignant Growths.—Guelliot records one case of primary carcinoma of the vesicle; secondary involvement occurs from the prostate, the bladder, or the rectum.

XXXIX. Seminal Incontinence or Spermatorrhœa.—Seminal incontinence or spermatorrhœa may be defined as the involuntary and unconscious loss of seminal fluid. It may show itself in one of two ways: either the semen leaks away quite continuously, in which case a few spermatozoa may be found in the centrifuged urine, or else the semen is squeezed out by muscular exertion or by defecation, in which case it appears as a pearly drop at the meatus. Both conditions are fairly common, and neither involves any symptoms or threatens impotence. The lesion to which the seminal leakage is attributable is a weakness of the prostatic muscle encircling the orifices of the ejaculatory ducts. This weakness may be due to antecedent gonorrhœa or to perineal section, or it may result from sexual causes (habitual masturbation).

Thus the condition of spermatorrhœa presents itself clinically in three types:

1. Spermatorrhœa without Symptoms. This I am confident is a large if not the largest class of cases.

2. Spermatorrhœa without any Symptom except Exudation from the Meatus. The pearly drop of mucus which is so commonly extruded by a constipated movement of the bowels habitually contains no spermatozoa and has no connection with the seminal vesicles or their contents. In most cases it consists entirely of prostatic secretion and is evidence of a prostatic congestion. It is quite exceptional to find spermatozoa in this discharge.

3. Spermatorrhœa with Neurotic Symptoms. Lallemand's huge tome upon spermatorrhœa is the text-book from which modern charlatanism draws the elements of the lurid pictures with which it deludes and depraves young men suffering from sexual weakness. Lallemand attributed practically every urinary and genital disorder to the loss of seminal fluid, and inasmuch as any man who is worried about his sexual capacity rates that fluid as his most valuable possession, it is an easy matter to persuade him that its loss entails many and dire evils.

As a matter of fact, spermatozoa are elaborated in the testicle and are merely stored in the seminal vesicle, and there is no evidence to show that leakage of the seminal elements from the vesicle has any more effect upon the potency or nervous tone of a man than has sexual intercourse or the nocturnal emissions which take its place. On the contrary, the frequency with which spermatozoa are found in the urine of men sexually normal proves that this dribbling is entirely harmless. The only connection which can be established between spermatorrhœa and sexual incapacity is that of a common cause. For the sexual debility which causes impotence may equally well cause spermatorrhœa, and the lymphatic, neurotic individuals who are most subject to sexual weakness are equally subject to the muscular weakness and the gonorrhœal inflammations which cause spermatorrhœa.

The treatment of spermatorrhœa is a matter of hygiene, local, general, and mental. The tone of the urethra and of the prostatic muscles should be strengthened by counter irritation with sounds, with the cold water rectal douche, or with mild electrical currents. The general health may be built up by muscular outdoor exercise to replace the lounging, smoking, and drinking with which these men are prone to occupy their leisure hours. While above all and most difficult of all it is the physician's duty to elevate the patient's moral tone, to discourage his pruriency, and to set his mind upon a clean, decent basis. It is not always possible to insist that the loss of seminal fluid has no connection with the sexual disorder, since the conviction of these patients that such is the case is often absolute. It is better to try to lessen the symptoms while paying little attention to the theory of their cause, though, as a matter of fact, probably seventy-five per cent. of those who complain of sexual weakness due to seminal incontinence possess the sexual weakness, but have not and never have had any spermatorrhœa.

XL. Impotence.—Impotence is inability to perform the sexual act. It is not to be confounded with sterility, which is inability to beget children. Impotence may exist without sterility and sterility without impotence. Three varieties of impotence may be recognized: the organic, the symptomatic, and the neurotic.

Organic Impotence.—This may be caused in six ways:

1. Abnormal size of the penis. If the penis is absent or so small as to make intromission impossible, the patient is relatively impotent. The same is true of an overdeveloped penis.

2. Hypospadias and epispadias involve impotence, inasmuch as the semen is not thrown into the vagina; thus the more marked the urethral deformity the more likely the impotence. In the same way tight stricture causes impotence, whether by forcing the ejaculated semen back into the bladder or by permitting it to flow out through fistulous openings in the perineum.

3. Imperfect, irregular, or bent erections, whether due to congenital deformity, to injury, or to inflammation, may prevent direct ejaculation.

4. Various external agencies may have the same effect; among these may be mentioned tumors about the genitals, ankylosis of the hip, excessive abdominal fat, etc.

5. Eunuchs and persons with atrophy of both testicles are always sterile and usually impotent.

6. Faulty erection or ejaculation from disease of the brain or of the spinal cord is an exceptional cause of impotence.

Symptomatic Impotence.—Impotence is symptomatic of youth and of old age, as also of many acute and chronic diseases, of debility from sexual excess, from drugs or alcohol, or from any other cause that lowers the patient's tone. Chief among the troubles of which impotence is a symptom may be placed congestion, neuralgia, and inflammation about the prostate and the seminal vesicles.

Nervous Impotence.—Nervous impotence is a state of mind rather than a state of body, and a person with entirely adequate sexual capacity and no organic disease may become temporarily or permanently impotent through some purely functional cause. As subsidiary causes of impotence are ranged chronic prostatitis and vesiculitis and various forms of sexual excess, in particular the solitary vice. That these causes are secondary is obvious from the fact that, of the great number of men who have chronic prostatitis and vesiculitis, and of the still larger number who masturbate habitually, only a very small proportion fall victims to nervous impotence. Such being the case and the essentially neurotic nature of the sexual act being obvious, it is evident that when a patient complains of lost manhood his trouble is mental, although it may have some underlying physical basis. In passing it is to be noted that neither obstruction of both vasa deferentia, nor prostatectomy, nor castration in adult life, necessarily results in impotence.

The nervously impotent may be divided into three classes: (1) Those whose potency, whether normal or congenitally slight, is not up to the mark they would set for it; (2) those who having been adequately potent have lost their powers through sexual excess or other cause; (3) those who have suddenly become impotent as the result of shock or fright.

1. If it can be determined that the patient is setting

himself a sexual pace of which he is incapable relief obviously consists in making him recognize his own sexual coefficient and in impressing upon him that, if he persists in trying to put a quart into a pint measure, he will inevitably reach the far more grave condition of permanently debilitated potency.

2. When the patient, as the result of excessive sexual indulgence, of prolonged gonorrhœa, or of quack doctoring, complains of loss of manhood, and tells the routine sad story of a debauched youth, it is necessary not only to discover his sexual coefficient, as in the first class of cases, but also to encourage him to look for a return of his sexual powers and to make him recognize that this return will come only as a result of total abstinence from all sexual excitement. For in these cases, even though there be no history of overworked passions, the long months and years during which the patient has moped over his sexual incapacity have had a like effect. All this must be dropped as far as the patient can drop it, and to assist him in this it is necessary to ply him with drugs of which damiana, strychnine, belladonna, and monobromated camphor are among the best, as much for the reason of making him feel that he is being treated, as for the rather dubious end of actually stimulating the sexual nerve centres. Yohimbin has been recently advocated for the treatment of these cases, but I cannot say that I have seen any good results from its use. Finally, it is often a great help if some physical cause can be found for the disorder. The cure of a chronic vesiculitis is of all things the most likely to set such a patient sexually straight. And if this can be once accomplished, if the physician recognizes that his patient has reached about as high a plane of sexual capacity as can be expected, he should immediately insist that this can be retained only by absolute sexual regularity. Celibacy is quite beyond the aspirations of such a patient; matrimony is an ideal state for him if he can muster the courage to attempt it and can develop sufficient moral sense to look upon the marriage state from a decent point of view. But sexual relations outside of marriage are inevitably harmful and, in the end, pull him down to his lowest plane, both morally and physically.

3. Of the cases coming under this head by far the greatest number occur among the newly wed. For one reason or another the young husband fails in his first attempt at sexual intercourse, and the result is so deep a discouragement that subsequent success is temporarily impossible. To handle such a case successfully it is only necessary to separate the couple at night, to administer some light stimulant to the man, and to bid him make no attempt whatever at sexual intercourse until a morning erection, which will sooner or later occur, gives him the opportunity of hurriedly proving his capacity, and this once done the disease is cured.

XLI. Sterility in the Male.—*Definition.*—Sterility in the male is inability to produce healthy spermatozoa or to discharge them from the urethra; conversely, in order to be fertile, a man must be able to discharge semen containing healthy spermatozoa.

Etiology.—Thus the causes of sterility are interference with the production of spermatozoa, interference with their health, and interference with their discharge. These causes may be tabulated as follows:

Interference with production. (Azoöspermia.)	Physiological—youth and extreme age. Local—atrophy, or disease of testes. General—Systemic disease. Excess of any kind. Congenital deficiency.
Interference with health. (Oligozoöspermia or azoöspermia.)	Testicular—excess of any kind especially sexual. Prostatic and vesicular / Urethral or deferential } inflammation.
Interference with discharge.	Organic { Stricture of vas (azoöspermia). Stricture of urethra (aspermia). Functional—(oligospermia or aspermia).

The seminal fluid is made up of the spermatozoa, which are the transformed epithelial cells of the testicular seminal tubules, combined with the secretions of the prostate and the seminal vesicles. The production of spermatozoa by the testicle begins at puberty and continues until old age is reached; and the sexual age of a man depends primarily upon heredity, secondarily upon surroundings. Recorded instances of fertility at the age of eighty and of ninety contrast with the accepted sterility after the seventieth year.

Of the causes interfering with the production of spermatozoa, the local ones require no comment. Of the general causes systemic disease is the most common. Such wasting diseases as tuberculosis and diabetes commonly check testicular activity, the system withdrawing this function in favor of more vital ones. Similarly, excess of any kind, be it excessive debauchery, alcoholism, even excessive exercise, worry, and nervous tension, equally result in azoöspermia (absence of spermatozoa from the semen). Thus a finely trained athlete often keeps himself in a condition of temporary sterility, while the overworked business man, the drunkard, and the victim of sexual excess suffer in the same way. Finally, there are a certain few who suffer what is apparently a congenital absence of spermatozoa; in all respects healthy, except that they are usually the neurotic products of over-civilization, their seminal fluid never contains any spermatozoa.

The health of the spermatozoa may be interfered with in their production, and this is the common result of sexual excess. Repeated ejaculations empty the seminal vesicles and call upon the testicles for renewed supplies, which are elaborated hurriedly and imperfectly; yet this condition is commonly an ephemeral one. An exceptional cause of interference with the health of the spermatozoa is inflammation of the canals through which the semen passes—*i.e.*, the vas deferens and the urethra, whose acrid discharges interfere with the vitality of the organisms. But prostatitis and vesiculitis are the usual causes of reduced spermatic vitality; for the vitality of the spermatozoa depends primarily upon the normal alkalinity and consistence of the prostatic and vesicular secretion in which they abide. It has been frequently observed that acidulation of the semen promptly kills the spermatozoa, and concentration seems temporarily to paralyze them; while the addition of a drop of warm water to a specimen of such concentrated semen under the microscope has the immediate effect of reviving the still organisms.

Gonorrhœal occlusion of the epididymis, following acute epididymitis, is probably the commonest cause of sterility in the male. Urethral stricture causes sterility but rarely. Functional derangements of ejaculation are most uncommon. Certain neurotic individuals are unable to effect ejaculation in sexual intercourse no matter how long this be continued, although they may have frequent and copious nocturnal emissions.

According to the estimates of good authorities, one-third of matrimonial sterility is due to the male.

Symptoms and Diagnosis.—The evidence of sterility is absence of ejaculation, lessened vitality of the spermatozoa, or absence of spermatozoa from the semen. Absence of ejaculation and absence of spermatozoa are readily determined. Malformation of the spermatozoa shows itself as oligozoöspermia, in which condition the spermatozoa, instead of swarming throughout the microscopic field, are very few, generally immobile and frequently deformed. Such a condition suggests either malproduction of the semen or interference with their health by prostatitis or vesiculitis. The diagnosis of sterility is therefore not difficult, though the diagnosis of its cause is not so easy. The usual causes of sterility are gonorrhœal epididymitis (double), vesiculitis, and prostatitis; most other cases are due to dissipation, to overwork, etc., or to a congenital weak sexuality.

Treatment.—The treatment of sterility consists in the removal of its cause. Many cases tend to spontaneous cure. Others are by their nature incurable; but in a large proportion of cases, whether due to prostato vesiculitis or to a run-down general condition, a cure may be expected to result from intelligent treatment. One of the latest triumphs of surgery is the operation of Dr. Edward Martin, of Philadelphia, of suturing the vas deferens into the globus major of an epididymis having an obstructed globus minor. The result of this operation was the appearance of spermatozoa in the expressed secretion of the seminal vesicles, from which they had previously been absent. *Edward L. Keyes, Jr.*

SHADOW TEST.*—"Keratoscopy," "Retinoscopy," "Retinoskiascopy," "Korescopy," and other names. An objective method of determining the refraction of the eye.

When, from a certain distance, an observer throws light into an eye by means of a perforated mirror, on looking through the hole in the mirror he sees the entire pupil illuminated with a reddish light. If, now, the mirror is slightly rotated, a dark segment ("shadow") comes into view and, increasing as the mirror is rotated, presently extends over and darkens the entire pupil. The direction in which the "shadow" grows—*i.e.*, the direction in which the border of the shadow moves, whether in the same or in the opposite direction to that in which the mirror is rotated—depends, with certain limitations, on the refraction (hypermetropia, emmetropia, or myopia) of the observed eye, and affords a means, when the necessary conditions are fulfilled, of measuring its refraction.

The perforated mirror used in the shadow test may be either plane or concave.

1. We will assume that a plane mirror is used, and that the observer's eye, which is immediately behind the perforation, is stationed at a distance of one metre from the observed eye. The mirror is now adjusted to reflect light, preferably from an Argand burner, directly upon the observed eye, whose pupil is seen filled with a uniform red light. On rotating the mirror to the right (*i.e.*, turning the left side of the mirror forward) a dark "shadow" appears at the left side (*i.e.*, to the observer's left) of the pupil and passes over it, increasing from left to right, until the entire pupil is darkened. Similarly, on rotating the mirror to the left, the shadow appears at the right side of the pupil and passes over it from right to left.

This movement of the border of the shadow in the direction of the rotation of the mirror occurs whenever the focus of the observed eye for pencils originating at its fundus (*i.e.*, the far-point of the observed eye) falls elsewhere than between the observer's and the observed eye. When, as we have assumed, the observer's eye is stationed at a distance of one metre, the observed eye may be either hypermetropic, emmetropic, or myopic in any degree less than 1 D.

2. On rotating the (plane) mirror to the right the "shadow" appears at the right side of the pupil and passes over it from right to left; or, on rotating the mirror to the left, the shadow appears at the left side of the pupil and passes over it from left to right.

This movement of the border of the shadow in a direction opposite to that of the rotation of the mirror occurs when the focus of the observed eye for pencils originating at its fundus (*i.e.*, the far-point of the observed eye) falls within the distance at which the observer's eye is stationed. In our assumed case this distance is taken equal to one metre; the observed eye is therefore myopic in some degree greater than 1 D.

3. On rotating the (plane) mirror in any direction, no "shadow" is seen, but the illumination of the pupil fades gradually into darkness. This fading out of the illumination of the pupil in its totality, without any appearance of a moving shadow, occurs only in the case in which the focus of the observed eye for pencils originating at its fundus (*i.e.*, the far point of the observed eye) falls at the exact distance at which the observer's eye is stationed, which in our assumed case has been taken equal to one metre; the observed eye is therefore myopic, and its myopia is equal to 1 D.

4. If a concave mirror of short focus is substituted for the plane mirror, in which case a real image of the flame is formed between the observer's and the observed eye, the "shadow" is seen to move in a direction opposite to that in which it moves when the plane mirror is used.

These facts have been utilized for the practical determination of the refraction in several different ways, two of which have been especially cultivated.

I. The observer, stationed at a distance of one metre, and using a concave mirror preferably of about 20 cm. focus, throws light from an Argand burner placed beside or above the patient's head, into the eye whose refraction is to be investigated. If on rotating the (concave) mirror in any direction, he sees the "shadow" moving in the opposite direction, he concludes that the eye is either hypermetropic, emmetropic, or myopic in some degree less than 1 D. Convex glasses, of progressively increasing strength, are then placed, one after another, in a trial frame before the observed eye, until a glass is found through which no shadow movement is discernible in the transition from the illuminated to the darkened state of the pupil. The combination of the observed eye and this convex glass represents myopia of 1 D., and the subtraction of 1 D. from the value of the glass gives the refraction of the eye. For example, if the convex glass measures 3.5 D., the refraction is H = 2.5 D.; if the convex glass measures just 1 D., the eye is emmetropic; if without a glass no moving shadow is seen, the refraction is M = 1 D.

If, on rotating the (concave) mirror, the shadow is seen moving in the same direction, the presence of myopia of a higher grade than 1 D. is established; concave glasses, of progressively increasing strength, are then placed, one after another, in front of the observed eye, until a glass is found through which no shadow movement is seen. The combination of the observed eye and this concave glass represents myopia of 1 D., and the addition of 1 D. to the value of the glass gives the actual myopia.

This is the method advocated by Cuignet, Parent, and others.

II. The observer uses a plain mirror, and does not keep at a fixed distance from the observed eye. We will suppose that he first stations himself at a distance of one-half metre, and sees the "shadow" moving in the same direction as that in which the mirror is rotated, thus establishing the fact that the eye is either hypermetropic, emmetropic, or myopic in some degree less than 2 D. A convex glass of sufficient strength to render the observed eye myopic in excess of 2 D. is then placed before it in a trial frame, thus causing an image of its fundus to be formed in front of the eye of the observer. The observer next approaches the observed eye until he reaches a point at which no moving shadow is discernible—*point of reversal*. The observer's eye is now at the far-point of the observed eye as modified by the convex glass, and the distance from eye to eye is measured by means of a rule or a tape measure. The reciprocal of the fractional part of a metre thus measured represents, in dioptries, the refraction of the observed eye plus the convex glass, and the subtraction of the value of this glass gives the refraction of the eye.

When the observed eye is myopic in excess of 2 D., so that its far-point lies within the distance of one-half metre at which the eye of the observer is stationed, the movement of the shadow is in the direction opposite to that in which the mirror is rotated, and the distance of the point of reversal from the observed eye gives the measure of the myopia.

When the myopia of the observed eye is in excess of 4 D. or 5 D., the point of reversal falls too near the eye for an entirely trustworthy measurement of its distance. In such a case a concave glass, of sufficient strength to carry the far point back to a distance of from one-quarter metre to one-half metre, is placed before the observed eye, and the value of this (concave) glass must be added to that obtained by measuring the distance of the point of reversal

This is the method advocated by Chibret, Schweigger, and others.

* The writer desires again to acknowledge his indebtedness to Dr. John Green, of St. Louis, for assistance most kindly rendered in revising the present article for the press.

Shadow Test.

In emmetropia, and in simple ametropia (hypermetropia and myopia), the movement of the mirrored image of the flame, whether virtual or real, and that of the "shadow" are always in one and the same plane passing through the observer's and the observed eye. The same is true also in astigmatism whenever the plane in which the image moves, as determined by the direction in which the mirror is rotated, passes through either of the two principal meridians of the observed eye. The shadow test is, therefore, perfectly adapted to the measurement of the refraction of an astigmatic eye in each of its two principal meridians. If, however, the shadow is seen to move in a plane other than that determined by the direction of the rotation of the mirror (see Fig. 4266), it is certain both that the observed eye is astigmatic, and that the plane in which the mirrored image moves does not pass through either of its principal meridians. To find a principal meridian, whether of greatest or least refraction, it is then only necessary to vary the direction in which the mirror is rotated, until the shadow is seen to move in the same or in the opposite direction. The statement made by different writers, that the direction of the obliquely moving shadow corresponds to that of one or the other of the two principal meridians, is erroneous.

The idea of utilizing the direction of the movement of the "shadow" in the pupil for the practical determination of the refraction originated with Cuignet (1873), but he gave a wrong explanation of the phenomenon and so was led to give to the procedure the very unsuitable name "keratoscopy." Landolt (1878) was the first to propose a nearly correct theory, and his and Parent's descriptions have contributed largely to the popularization of the method. Credit must also be given to Chibret (1882) for the important modification of the procedure in which the plane mirror is used at a varying distance. Leroy and Monoyer have further developed the theory, which, strange to say, had been erroneously, or at best inadequately, stated during a number of years.

The theory of the shadow test will be best understood if we consider a few special cases:

I. We will assume that the observed eye is emmetropic, and that the test is made with a plane mirror at a distance of one-half metre. An image of the source of light (Argand burner) is formed at the fundus of the observed eye, which, within the limits of this image, is strongly illuminated so that every point gives out rays of light as if it were self-luminous. The details of this illuminated area at the fundus are, however, indistinguishable, or at best imperfectly distinguishable, inasmuch as, by the conditions of the test, the observer's eye is accommodated, not for the fundus, but for the pupil of the observed eye. The illuminated area is seen, therefore, in circles of confusion, consequently as a more or less diffuse red light shining through the pupil.

How much of the illuminated area is, in any case, visible to the observer, is determined in part by the diameter of the pupil of the observed eye, and in part also by the size of the hole in the mirror, or, if this is rather large, by the diameter of the pupil of the observer's eye. Let $a\,a'$ (Fig. 4267, *I*) represent a portion of the illuminated area (image of the flame) at the fundus of the observed eye, which we assume to be directed upon the hole in the mirror, consequently upon the pupil of the eye of the observer. Let $a\ P\ p\ \pi$ represent a limiting ray passing out of the pupil of the observed eye to enter the pupil of the observer's eye; similarly, let a' represent the origin of another limiting ray, as determined by the points P' and p', meeting the retina of the observer's eye at π'. Now $P\ P'$ and $p'\ p$ represent, respectively, the diameters of the two (circular) pupils, consequently $a\ a'$ and $\pi\ \pi'$ must also represent diameters of circles. We will call the circular area $a\ a'$ the *visible circle*. Inasmuch as the illuminated area (image of an Argand burner when the distance of the mirror is taken anywhere between the limits of one metre and one-quarter metre) is considerably larger than that of the visible circle, the entire pupil $P\ P'$ will be lighted up, and the visible circle $a\ a'$ will coincide throughout with the two pupils, $P\ P'$ and $p p'$, and with the circle $\pi\ \pi'$ at the fundus of the eye of the observer. But we have already seen that the visible circle $a\ a'$ is pictured at $\pi\ \pi'$ in circles of confusion; hence the impression made on the observer is rather that of the illuminated pupil $P\ P'$ than of the circle $a\ a'$.

To explain the phenomenon of the moving "shadow" we will suppose that the observer, whose attention is

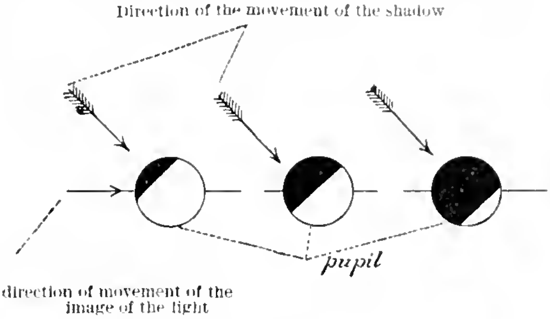

Fig. 4266.

fixed on the illuminating pupil $P\ P'$ of the observed eye, now rotates the mirror a little to the right (see Fig. 4268), thus displacing the mirrored (virtual) image of the flame to the left, consequently displacing the real image of the flame at the fundus of the observed eye to the right. The displaced image of the flame, as it passes over the visible circle, presently leaves a segment of the latter without illumination, consequently a segment of the pupil $P\ P'$ darkened (see Fig. 4269). As already explained, the border of this dark segment is seen somewhat imperfectly defined, thus suggesting a shadow with its penumbra, and accounting, in a way, for the name "shadow test."

It will be observed that in this case (emmetropia of the observed eye) the growth of the darkened segment of the pupil (movement of the shadow) is in the same direction as that in which the (plane) mirror is rotated, the reversed movement at π, or at π', being perceived as a direct movement at a or at a', consequently at P or at P'.

II. We will now assume that the observed eye is hypermetropic, the other conditions remaining as before (see Fig. 4267, *II*). Comparing *I* and *II*, Fig. 4267, it is evident that nothing essential has been changed, as regards either the formation of the "shadow" or the direction of its movement. The illuminated area (image of the flame) is, however, smaller, and the visible circle larger, than in the case of emmetropia of the observed eye. The dark border of the illuminated area will therefore pass the limit of the visible circle more quickly (the rate of rotation of the mirror being assumed to be unchanged), but more time will be required for its transit. We have seen that the apparent diameter of the visible circle is the same as that of the pupil; the rate of passage of the shadow across the pupil is therefore slower in hypermetropia than in emmetropia.

In hypermetropia of the observed eye the conditions for obtaining a clearer view of the details of the fundus, when the eye of the observer is accommodated for its pupil, are more favorable than in emmetropia, and the higher the grade of the hypermetropia (*i.e.*, the less the distance at which the virtual image, $h\ h'$, of the visible circle lies behind the plane of the pupil) the more clearly will the retinal vessels, etc., be seen. On the other hand, hypermetropia of the observed eye is unfavorable for the accurate focusing of the image of the flame on its retina, and for this reason the outlines of this image are less sharply defined than in emmetropia. The advantage, to the observer, of the clearer view which he obtains of the image of the flame is, however, greater than the disadvantage resulting from its less perfect definition; hence the free border of the shadow, as it traverses the pupil, appears more sharply defined in hypermetropia than in emmetropia, and the higher the grade of the hypermetropia, the more distinct, on the whole, does the shadow appear.

III. The observed eye is assumed to be myopic in some degree less than 2 D., the observer being stationed, as

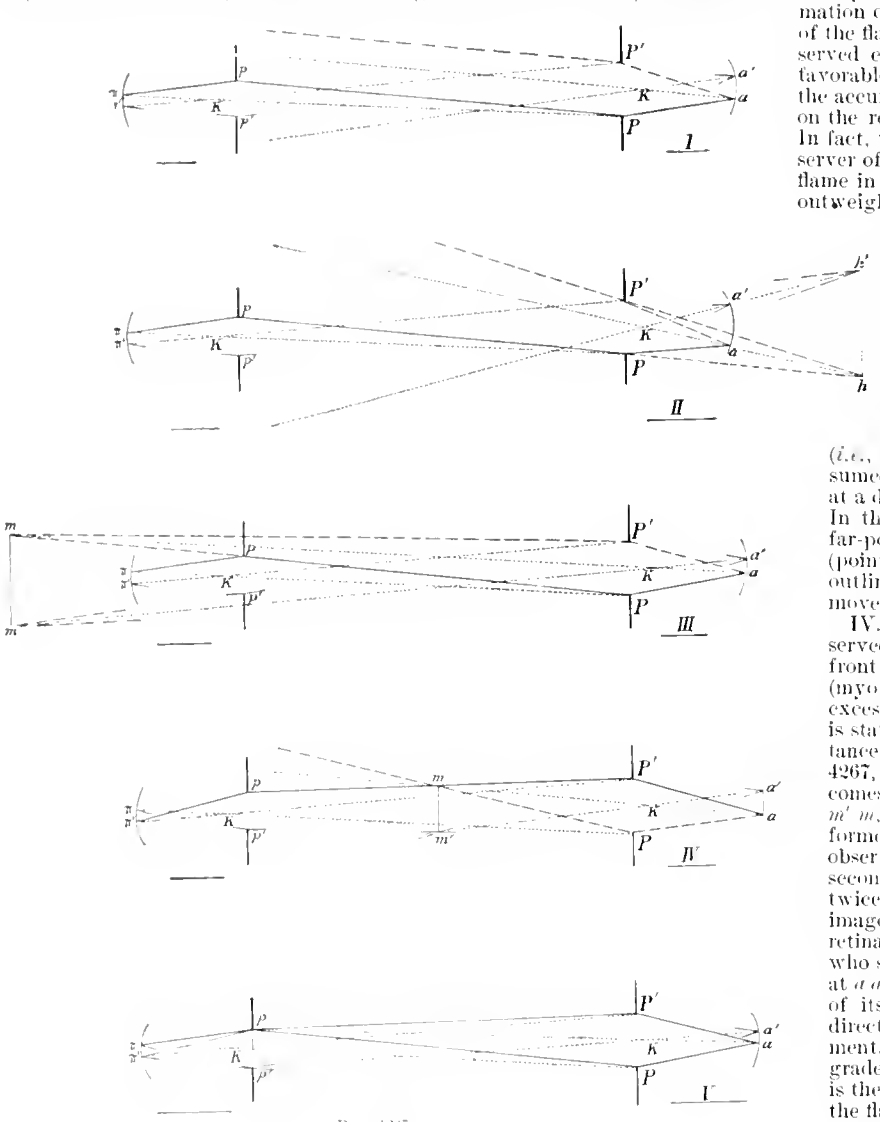

FIG. 4267.

before, at a distance of one-half metre (see Fig. 4267, *III*). Comparing *III* with *I* and *II*, Fig. 4267, we see by inspection that the conditions which determine the forma-

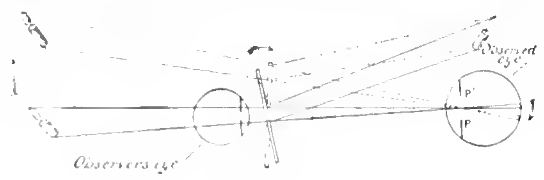

FIG. 4268.

tion and the direction of movement of the "shadow" still remain unchanged. The illuminated area (image of the flame) is, however, somewhat larger, and the visible circle smaller than in emmetropia. The appearance of the shadow will therefore be somewhat retarded, but its transit across the pupil will be accomplished in less time, consequently at a more rapid rate of movement.

In the case under consideration (myopia of less than 2 D.) the conditions are especially favorable for the formation of a sharply defined image of the flame on the retina of the observed eye, but they are even less favorable than in emmetropia for the accurate picturing of this image on the retina of the observer's eye. In fact, the disadvantage to the observer of viewing the image of the flame in larger circles of confusion outweighs any advantage accruing from the more perfect definition of this image, and this preponderance of disadvantage increases, in a progressively augmenting ratio, as the grade of myopia approaches the limit in which the far-point of the observed eye lies exactly at the distance of the pupil of the observer's eye (*i.e.*, 2 D., when, as we have assumed, the observer is stationed at a distance of one-half metre). In this limiting position of the far-point of the observed eye (point of reversal) no shadow outline, consequently no shadow movement, is discernible.

IV. The far-point of the observed eye is assumed to lie in front of the eye of the observer (myopia of the observed eye in excess of 2 D., when the observer is stationed at the assumed distance of one-half metre—see Fig. 4267, *IV*). A new condition now comes into play. A real image, m' m, of the visible circle a a' is formed at the far-point of the observed eye. Of this image a second image π π' (which is a twice inverted, therefore an erect image of a a') is pictured on the retina of the eye of the observer, who sees the image of the flame at a a inverted, and the direction of its motion, consequently the direction of the shadow movement, reversed. The higher the grade of the myopia, the larger is the illuminated area (image of the flame), and the larger also is the visible circle, the latter increasing, however, at a greater rate than the former. Conversely, the lower the grade of the myopia within the assumed limit of 2 D. (*i.e.*, the nearer to the plane p' p of the pupil of the observer's eye the real image m' m falls), the smaller is the portion

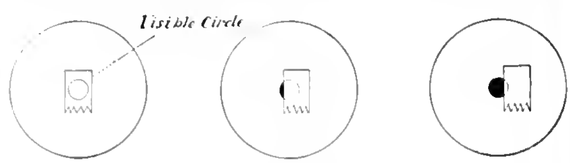

FIG. 4269.

of the fundus at a a'—*i.e.*, the visible circle—from which rays of light can enter the eye of the observer. Again, the higher the grade of the myopia (*i.e.*, the nearer to the plane P P of the pupil of the observed eye the real image $m' m$ falls), the sharper will be the definition of the shadow outline. Conversely, the lower the grade of the myopia (*i.e.*, the nearer to $p' p$ the real image $m' m$ falls), the less advantageous will be the conditions for seeing it distinctly; consequently the more imperfect will be the definition of the shadow outline, until, in the assumed limit of 2 D., no shadow outline, consequently no shadow movement, will be seen.

V. The far-point of the observed eye is assumed to lie at the exact distance of the pupil of the observer's eye (myopia of 2 D., when the observer is stationed at the assumed distance of one-half metre—see Fig. 4267, *V*). In this case the real image of the visible circle (*cf. V.*, with *III* and *IV*, Fig. 4267) is formed at and fills the pupil, $p\ p'$, of the eye of the observer, the point p corresponding to a, and p' to a'. Now the outermost rays, $a\ P\ p$ and $a\ P'\ p$, of the limiting pencil originating at a to pass out of the pupil of the observed eye and enter the pupil of the observer's eye, are refracted to π and π', respectively, at the retina of the observer; and, in like manner, all intermediate rays belonging to the same pencil are refracted each to its own point intermediate between π and π'; hence every point in the circle $\pi\ \pi'$ is faintly illuminated by rays emanating from a. Similarly, the limiting pencil originating at a', likewise all pencils originating at points lying between a and a', contribute each its own share to the general illumination of the circle $\pi\ \pi'$, consequently to the illumination of $P\ P$, the pupil of the observed eye, in its totality. The effect of the rotation of the mirror is manifested, therefore, by a gradual fading out of the light in the pupil, and not, as in Cases I. to IV, by the appearance of a moving "shadow." It will be further observed (*cf. I, II, III, IV*, and *V*, Fig. 4267) that in this case the diameter of the visible circle (*i.e.*, of the area at the fundus of the observed eye from which rays of light can pass out through its pupil to enter the pupil of the observer's eye) is as its minimum.

Comparing these several cases, we draw the following deductions:

(*a*) Appearance and direction of movement of the shadow. Whenever a "shadow," appearing at the side of the pupil of the observed eye, is seen to move in the same direction as that in which the (plane) mirror is rotated, the eye is either hypermetropic, emmetropic, or myopic in such (lower) degree that its far-point lies behind the eye of the observer—Cases I. to III.

When the "shadow" is seen to move in the direction opposite to that in which the (plane) mirror is rotated, the eye is myopic in such (higher) degree that its far-point lies in front of the eye of the observer—Case IV.

When no shadow outline is discernible, the illumination of the entire pupil fading gradually into darkness whatever may be the direction in which the mirror is rotated, the eye is myopic in such degree that its far-point lies at the distance of the eye of the observer—Case V.

(*b*) Distinctness of the shadow outline. The definition of the shadow outline is always less perfect than that of the image of the flame at the fundus of the observed eye, for the reason that the (virtual or real) image of this image, which we may regard as the object actually viewed by the observer, is formed either at an infinite distance from the pupil of the observed eye (in emmetropia), at a finite and always considerable distance behind the pupil (in hypermetropia), or at a finite and always considerable distance in front of the pupil (in myopia). In no case, therefore, can this image be perfectly focused by the eye of the observer, when, in accordance with the requirements of the test, the latter is accommodated for the pupil of the observed eye. Nevertheless, in high grades both of hypermetropia and of myopia, the difference in the distance (from the observer) of the pupil and the image is not so great as to prevent a fairly distinct view of both at the same time. In hypermetropia (Case II.) of decreasing grade, passing through emmetropia (Case I.) and myopia of relatively low grade (Case III.), to the limiting grade of myopia (Case V.), in which the image of the visible circle at the fundus of the observed eye lies at and fills the pupil of the eye of the observer; likewise in myopia of relatively high grade (Case IV.), decreasing to approach the same limit (Case V.), the distinctness of the shadow outline diminishes at a rapidly increasing rate, until, in the limiting case (Case V.), the shadow outline and the shadow movement vanish together.

Again, the image of the flame at the fundus of the observed eye is itself imperfectly defined, except in the particular case in which the far-point of the observed eye lies exactly at the distance of the (virtual or real) image of the flame as formed by the mirror. When the test is made with a plane mirror (see Fig. 4268) this particular case implies myopia of low grade, which, as already stated, is a condition unfavorable for obtaining a distinct view of the image of the flame at the fundus of the observed eye. When, on the other hand, the test is made with a concave mirror, the higher grades of myopia offer the most favorable conditions both for the sharp definition of the image of the flame at the fundus and for seeing the outlines of the real image of this image, consequently for good definition of the shadow outline.

Narrowness of the pupil, whether of the observed eye or of the eye of the observer, is favorable to the definition both of the image of the flame, at the fundus of the former, and of the image of this image, as pictured on the retina of the latter. But narrowness of either pupil, and still more of both pupils, involves a notable limitation of the area of the visible circle (see Fig. 4267) and narrowness of the pupil of the observed eye involves also a diminution (in the ratio of the square of its diameter) of the brightness of the image of the flame at its fundus. Furthermore, a narrow pupil is unfavorable for observing the passage of the shadow. For these reasons, it will readily be comprehended that the preponderance of advantage may be greatly on the side of a large and well-lighted pupil, and this is in practice found to be the case. To this end the diameter of the hole in the mirror should be somewhat greater than that of the pupil of the observer's eye, and the pupil of the observed eye, unless naturally rather wide, should be dilated by instilling a solution of one of the weaker-acting mydriatics.

(*c*) Brightness of the pupil. We have given the name "visible circle" to the circular area, at the fundus, from which alone any ray of light can both pass out of the observed eye and enter the eye of the observer. Under the conditions of the shadow test the visible circle is simply that portion of a larger illuminated area (image of the flame) which, seen always in circles of confusion, is visible through the pupil of the observed eye. The image formed on the retina of the observer's eye is, therefore, an indistinct image of the visible circle, but by reason of its indistinctness, together with the fact that its outline is the same as that of the pupil of the observed eye, the impression made on the observer is rather that of an illuminated pupil than of the portion of the fundus behind it. As the size of the image on the observer's retina is independent of the actual size of the visible circle it follows that the larger the visible circle (its brightness being assumed to be constant), or the brighter the image of the flame (the size of the visible circle being assumed to be constant), the stronger will be the illumination of the pupil.

The area of the visible circle is larger, (α) the wider the pupil of the observed eye, (β) the wider the pupil of the observer's eye, (γ) the greater the myopia of the observed eye in excess of the critical grade (Case V.), in which the far-point of the eye lies at the distance of the pupil of the observer's eye, (δ) the less the refraction of the observed eye measured from the same critical grade of myopia, and (ε) the less the distance of the observer's from the observed eye.

The brightness of the image of the flame at the fundus of the observed eye is greater (α) the wider the pupil of the observed eye; and, when the test is made with the concave mirror, the greater the apparent area of the mirror, that is, (ε) the less the distance of the observer's eye (looking through the hole in the mirror) from the observed eye, or (ζ) the larger the concave mirror.

The conditions favorable to a strong illumination of the pupil of the observed eye are then, (α) wideness of its pupil, (β) a fairly large pupil on the part of the observer, (γ) a high grade of myopia of the observed eye, (δ) a high grade of hypermetropia of the observed eye, (ε) a short observing distance, and (ζ) the use of a large concave mirror. Of these conditions, the first (α) may be secured when necessary by resorting to artificial mydriasis; the second (β) is best attained by observing with relaxed accommodation, the observer correcting the far-point of his own eye for the distance of the pupil of the observed eye by means of a suitable lens mounted behind the hole in the mirror. A short observing distance (ε) may be tried whenever the condition of the observed eye (*e.g.*, exceptionally dark pigmentation of the fundus, narrowness of the pupil from extensive synechiæ, imperfect transparency of the media, etc.) is unfavorable to good illumination of its pupil. The use of a concave mirror of large diameter (ζ) is also a possible resource in cases of exceptional difficulty.

(*d*) The rapidity of the shadow movement (other things being equal) varies inversely with the diameter of the visible circle, over which the image of the flame passes as the mirror is rotated; the smaller the visible circle, the less will be the time occupied in this passage, consequently the more rapid will be the movement of the shadow across the pupil. The darkening of the pupil occurs most quickly in myopia of the particular grade in which the far-point of the observed eye lies at the distance of the pupil of the observer's eye—Case V.; the passage of the "shadow" is progressively slower in higher grades of myopia, also in lower grades of myopia passing through emmetropia and the lower and medium grades of hypermetropia to hypermetropia of high grade.

(*e*) The form of the "shadow" is determined by the form of the image of the source of light. If this is approximately circular the shadow outline will be correspondingly curvilinear, and the shadow will have the form of a crescent. When an Argand burner is used the shadow outline appears as a somewhat ill defined straight line (see Fig. 4269.)

When the shadow test is made with the concave mirror, the direction of the shadow movement is in every case the opposite of that observed when the plane mirror is used. But with this exception there is no essential change in the reactions. When the observer is stationed at a fixed distance, of say one metre, the concave mirror has the advantage of affording a stronger illumination; when the test is made at a shorter and varying distauce, the plane mirror is to be preferred.

The complete theory of the shadow test as applied to the investigation of astigmatism is too complicated to be adequately presented in an elementary paper.

The shadow test is, on the whole, the most exact method which we possess for the objective determination of the refraction of the eye. As compared with the determination of the refraction with the ophthalmoscope by the direct method, it is both more accurate and easier of execution; and this is especially true in the higher grades of myopia, in which measurements made with the ophthalmoscope are always very unsatisfactory. In the measurement of astigmatism it has an advantage over the ophthalmometer of Javal Schiötz, in that it reveals the total astigmatism of the eye and not merely the corneal asymmetry. On the other hand, the shadow test affords almost no information regarding the condition of the fundus of the eye under examination, and none as regards its acuteness of vision. The true value of the shadow test is therefore as supplementing, not as superseding, other methods of examination.

The technique of the shadow test is comparatively easy to acquire, and it calls for almost no special apparatus; an ophthalmoscope furnished with a concave and a plane mirror and a Rekoss disc, or a clip for holding a correcting glass, and a short tape measure graduated to fractional parts ($\frac{1}{5}$, $\frac{1}{4}$, $\frac{1}{2}$, etc.) of a metre, make up the list of essentials.
Carl Koller.

SHANNONDALE SPRINGS.—Jefferson County, West Virginia.

Post-Office.—Charlestown. Hotel.

Access.—Viâ Baltimore and Ohio or Norfolk and Western Railroad to Charlestown, thence five miles by carriage to springs.

This delightful old summer resort is situated in the bend of the Shenandoah River, at the foot of the Blue Ridge Mountains. Shannondale was formerly one of the most noted of the Virginia watering-places. The large hotel was burned during the war, and no other was built for a number of years. The present hotel has accommodations for upward of one hundred guests. It is pleasantly located and overlooks the Shenandoah River, where excellent boating and fishing may be had. The place is much frequented during the summer by visitors from Washington, Baltimore, Philadelphia, and other localities. It is highly esteemed for its fine scenery and for the beneficial character of the mineral waters. The springs are three in number. An analysis by Dr. Stewart showed the presence of two hundred and forty grains of solid ingredients to the United States gallon. They consisted chiefly of the sulphate and carbonate of calcium and the sulphate of magnesium. There is also a small proportion of the sulphate and the carbonate of iron, and an undetermined quantity of carbonic acid and sulphureted hydrogen gas. The water has laxative, diuretic, and tonic effects. It may be classed as a saline-calcic-chalybeate. There are several bath-houses at the resort.
James K. Crook.

SHARON SPRINGS.—Schoharie County, New York.

Post-Office.—Sharon Springs. Hotels, boarding-houses, and cottages.

Access.—Viâ Albany and Susquehanna Railroad direct to the springs; also viâ New York Central Railroad to Palatine Bridge, and thence by stage nine miles to springs.

The village of Sharon Springs is situated in a valley about eleven hundred feet above the sea-level; the streets are provided with good sidewalks, and are well shaded with maple-trees. The air is pure and bracing and free from malarial influences. Even in the warmest of summer weather the nights are cool and pleasant for sleeping. The springs are easy of access within the village limits on the edge of a natural forest abounding in pleasant walks. The surrounding country is hilly and affords interesting drives and pleasant scenery. Excellent accommodations, conformable to any taste or grade of expenditure, may be obtained in the village. Sharon is one of the well-established old resorts of New York State, its waters having been used for medicinal purposes since early in the last century. The old bathing buildings were destroyed by fire a few years ago and have been replaced by the present spacious establishment, believed to be unexcelled for its purposes anywhere in the country. There are several valuable springs at Sharon, the most important being the White Sulphur, the Magnesia, and the so-called Eye-water Spring. The waters of the White Sulphur Spring are used both internally and for bathing purposes. The water is clear and bright as it issues from the spring, of an agreeable temperature for drinking (48° F.), and free of the roughness and acerbity which so often characterize sulphur waters. It is conducted to the bath-house and heated to any desired temperature for bathing. This spring yields fourteen hundred or fifteen hundred gallons of water per hour, so that the supply is always fresh and abundant. The Magnesia Spring is also valuable for drinking purposes. The third spring is used extensively as a lotion for inflammatory conditions of the eye, which fact has led to the designation of the Eye-water Spring. A chalybeate spring is also found within the village limits. The following analyses of three of the springs were made a number of years ago:

One United States Gallon Contains:

Solids.	White Sulphur Spring. (Lawrence Reid.) Grains.	Gardner Magnesia Spring. (J. G. Pohll.) Grains.	Eye-water Spring. (Lawrence Reid.) Grains.
Sodium bicarbonate	......	0.54	......
Calcium bicarbonate	......	9.70	......
Magnesium bicarbonate	24.00	1.36	32.00
Calcium sulphate	85.40	93.50	77.50
Magnesium sulphate	34.00	19.68	7.50
Sodium chloride } Magnesium chloride }	2.70	1.23 / .41	2.50
Calcium chloride	......	.16	......
Calcium sulphide } Magnesium sulphide }	3.00	.63	......
Silica	.....	.40	......
Total	149.10	127.61	119.50
Gases.	**Cu. in.**	**Cu. in.**	**Cu. in.**
Sulphureted hydrogen	20.50	6.00	......
Carbonic acid	......	2.22	......
Atmospheric air	......	3.00	......

The sulphur baths here have a wide reputation in the treatment of gout, rheumatism, and certain forms of paralysis. They are also serviceable in cases in which exudations are to be absorbed, *e.g.*, in old gunshot wounds, stiff joints, glandular enlargements, etc. It is said that many of the consequences of high living, such as congestion of the liver, abdominal plethora, and hemorrhoids, are quite certain to be benefited by a course of the Sharon waters. They are useful also in metallic poisoning and in ridding the system of chronic syphilitic infection, etc. The methods of employing sulphur waters at the well-known French spas, Aix-les-Bains, Challes, and Allevard, were adopted at Sharon Springs in 1884, and have been in successful operation since that time. The sulphur water of Sharon is also used commercially.

James K. Crook.

SHEBOYGAN MINERAL WELL.—Sheboygan County, Wisconsin.

Post-Office.—Sheboygan. Hotels.

Access.—Viâ the Ashland division and also the Fond du Lac division of the Chicago and Northwestern Railroad; also viâ steamers on Lake Michigan. The city of Sheboygan is beautifully located at the entrance of the Sheboygan River into Lake Michigan, at an elevation of about 650 feet above the level of the Atlantic Ocean. The mineral well is located in Fountain Park, and is 1,475 feet in depth. It was bored in 1875, and extends down to the granite bed-rock. Abundant water was discovered, the pressure, as indicated by the gauge, being 52.5 pounds to the square inch, or sufficient to raise a column of water to the height of 115 feet. The well was carefully tubed. The water is pure, bright, and sparkling, and entirely free from all surface contamination. The following analysis was made by Prof. Charles F. Chandler, of New York, in 1876:

One United States gallon contains (solids): Sodium chloride, gr. 306.94; potassium chloride, gr. 14.48; lithium chloride, gr. 0.11; magnesium chloride, gr. 54.91; calcium chloride, gr. 27.82; sodium bromide, gr. 0.19; calcium sulphate, gr. 16.98; calcium bicarbonate, gr. 13.66; iron bicarbonate, gr. 0.59; manganese bicarbonate, gr. 0.17; calcium phosphate, gr. 0.04; alumina, gr. 0.13; silica, gr. 0.47; organic matter, sodium iodide, baryta sulphate, and sodium biborate, traces. Total, 436.49 grains.

This water is seen to be very highly mineralized, and is closely allied to those of Kissingen and Kreutznach, in Germany. It contains, however, in addition to all the mineral constituents of those waters (except the nitrate of soda in Kissingen), traces of sulphate of baryta and biborate of soda, and a small quantity of bicarbonate of manganese. It has practically the same therapeutic properties as those waters, and is applicable to the same conditions. The most pronounced effects are laxative, diuretic, and tonic. It seems to act as a stimulant to the mucous membrane generally, and promotes the secretions. It is highly recommended as a remedy in chronic constipation. It is further applicable to a large class of morbid conditions depending upon a deranged circulation and defective secretion, such as dyspepsia, functional disturbances of the liver, hemorrhoids, anæmia and chlorosis, rheumatism, etc. The water is bottled and sold all over the country.

James K. Crook.

SHELDON SPRINGS.—Franklin County, Vermont.

Post-Office.—Sheldon. Hotels.

Access.—Viâ Vermont Central Railroad to St. Albans; thence viâ Missisquoi Valley Railroad to Sheldon.

Persons going to Sheldon Spring, one of the group, should buy tickets for Congress Hall Station, eight miles east of St. Albans. These springs are charmingly situated along the banks of the Missisquoi River, at an elevation of about two thousand feet above the sea-level. Within sight are Mount Mansfield and others of the Green Mountains. The springs are four in number—the "Central," within the village; the "Vermont," half a mile from the village; the "Missisquoi," one mile and a half northward; and the "Sheldon," two miles from the village. So far as I have been able to ascertain, the "Sheldon" is the only spring of which the water has been analyzed; and this analysis shows it to be very feebly mineralized. Notwithstanding this fact, the "Sheldon" water has been found to possess a very useful action in uric-acid gravel, gout, and catarrhal states of the bladder. The waters of the Missisquoi Spring are found on the market.

James K. Crook.

SHOCK. (SURGICAL.)—Shock may be defined as a condition of general vital depression or a state of general exhaustion of the nervous system coupled with a dilatation of the peripheral arterioles and a loss of the normal blood pressure.

Shock may be the result of an accidental injury, an operation, a profound emotion, or an overpowering fear. It is a condition in which the motor, sensory, and sympathetic nervous systems as well as the cerebral cortex are profoundly affected, and their action, for the time being at least, more or less arrested or destroyed.

Shock the result of an injury, an emotion, or of fear, follows very closely upon the action of its cause. When the result of an operation it may become manifest during any of its stages or only at its close. Shock may make its appearance suddenly, or it may come on gradually and be slowly progressive in character.

Symptoms.—The symptoms of shock will depend upon its severity. There may be as the result of some trivial injury a slight faintness, a pallor of the face, and a feeling of nausea which pass off in a moment, or the traumatism may be so severe and so sudden that the heart's action is arrested and the patient succumbs at once. In a well developed case of shock the patient's sensibilities are lessened and his mental faculties held more or less in abeyance. The pulse will be quickened, feeble, thready, and perhaps irregular. The respirations are increased in frequency, labored, and often irregular. The face and visible mucous membranes are pale, the eyes sunken and listless. The face, hands, and often the entire body are bedewed with a cold, clammy perspiration. The patient is usually torpid and indifferent to his surroundings, the mental faculties are depressed, and occasionally there is complete unconsciousness. The tone of the muscular system is so lessened that it is capable of only feeble contraction, the patient manifesting little disposition to move hand or foot. The sphincter muscles are at times completely relaxed. The temperature of the body may be reduced one, two, or even three degrees. Nausea and vomiting occur in many cases. In the so-called erethistic form the patients are excitable, restless, often incoherent, and even delirious.

DIAGNOSIS.—Shock must be differentiated from fat embolism, from hemorrhage, and from the effects of ether or chloroform. With each or all of these it may, however, be associated. Fat embolism most frequently occurs in injuries to the skeleton, and makes its appearance as a rule about thirty-six to seventy-two hours after the injury, while shock occurs at once. In fat embolism there are restlessness, anxiety, dyspnœa, accelerated respiration, and a quickened heart action with fat globules upon the surface of the urine. Hemorrhage is very frequently an associated factor with shock and aggravates the latter condition, but the two may be, and often are, entirely separate. Shock presupposes an injury. A patient may die from hemorrhage without suffering in any degree whatsoever from shock, while, on the other hand, a patient may receive a blow on the epigastrium, upon the head, or have his limbs crushed off and suffer the loss of scarcely a drop of blood and still die almost instantly or within a few hours from shock. Loss of blood when external is readily to be seen. When it occurs within closed cavities, as the abdomen, thorax, or skull, it will have to be diagnosed by the symptoms produced. These will be accompanied by those characteristic of the sudden or more or less gradual loss of blood. The symptoms of hemorrhage are not always those which are most typical of shock, in that in the former there is more of restlessness and nervous excitement, more acuteness of intellect, far greater pallor of the skin and visible mucous membranes, greater dilatation of the pupils and alæ nasi, and often a decided rise in temperature. There will also be a lowering of the hæmoglobin. It will be impossible, at least as a rule, to separate the effects of chloroform and ether from those of shock. Either of these substances when given incautiously or to excess interferes with respiration, lowers blood pressure, and materially aggravates the condition of shock.

PROGNOSIS.—This will depend upon the degree of shock, upon the organ or organs injured, and also upon the presence or absence of sources of irritation which will maintain or aggravate the existing condition. The prognosis will also depend very largely upon the treatment. It may be said that if shock be not immediately fatal, if the traumatism has not produced irreparable injury to vital organs or exhausted the vaso-motor nervous system, and the conditions are such that shock is not constantly added to, the prognosis will be good. The injury may be to the brain, heart, or some other organ of vital importance, and be of such a character or produce such an exhaustion of the nervous system that recovery is an impossibility.

Reaction from Shock.—With proper treatment and under ordinary conditions reaction will become manifest in a few hours. The patient then becomes restless and changes his position. The cold perspiration disappears, slight color comes to the lips and cheeks, the eyes seem less sunken and the face less pinched. The pulse gains in volume and loses something in its frequency, the respiration is deeper, more regular, and less frequent. The patient now seems to realize his injuries. He is less drowsy and perhaps asks questions concerning his condition. This state may progress uniformly until the temperature has reached a point above normal, when the pulse becomes full and strong, a flush comes to the cheeks, restlessness is increased, and reaction is fully established. If the injury has been such that the irritation is maintained for a time reaction may be delayed or prevented, or the condition may oscillate between reaction with improvement and an aggravation of the condition or shock.

The Pathology of Shock; the Mechanism of Blood Pressure.—The condition of vital depression known as shock seems inseparably connected with three pronounced conditions. One of these, and perhaps the most important, is the decrease of blood pressure, the second is the loss of muscular force, and the third a lessening of the mental phenomena of the patient, including the intellectual, emotional, and volitional. For the proper circulation of the blood, a condition which is essential in the maintenance of the functions and health of the individual, a certain degree of blood pressure must be maintained. If this fall to any considerable degree the capillary lake and venous system are flushed, the pulse becomes weak and thready, the arterial system is depleted, the venous system congested, and the functions of the body disturbed or even arrested. The blood pressure is maintained in part by the vaso-motor system of nerves whose centre is in the gray matter of the floor of the fourth ventricle. There are also certain subsidiary centres in the spinal cord. In health these nerves acting upon the muscular tissue in the walls of the blood-vessels and especially upon that in the arterioles, maintains an equable and constant tonic contraction, in consequence of which the heart is able to maintain the blood pressure throughout the general arterial system at a certain definite standard. A stimulus imparted to the vaso-motor system, either directly through the splanchnic area or indirectly through a sensory nerve, increases the action of the vaso-motor system, the contraction of the peripheral arterioles, and augments the blood pressure. If this stimulus is continued for an indefinite period or is excessive in character, then and in that case the vaso-motor system becomes exhausted, the peripheral arterioles dilate, and the blood pressure is lowered. There are three factors, however, which are responsible for the maintenance of a normal blood pressure. One of these is the forceful rhythmic action of the heart, another a suitable quantity of fluid in the vascular system, and a third a proper tonic contraction of the peripheral arterioles. If any one of these three conditions is disturbed the blood pressure will be effected. A diminution in the force, with an increased frequency of the heart's action, a lessening in the amount of circulating fluid within the vessels or a dilatation of the arterioles, each and all will lessen the blood pressure. That the blood pressure is very markedly lessened in cases of serious shock is the testimony of all observers.

The mechanism of the lessening of blood pressure in shock is the following: An injury to a peripheral sensitive nerve, if of mild degree, acts as a stimulus which is conveyed to the brain and transmitted reflexly to the bulb in the floor of the fourth ventricle, the centre for the vaso-motor nerves. Acting upon this centre this impulse is transmitted through the vaso-motor system, producing contraction of the arterioles and consequently increasing the blood pressure. After the abdomen has been opened slight handling of the intestines or stomach causes, in consequence of the stimulus being applied directly to the splanchnic area, a rise in blood pressure. If the stimulus be excessive or often repeated the vaso-motor centre becomes partially or totally exhausted, the peripheral arterioles dilate, and a great lessening in the blood pressure occurs. That a severe traumatism, whether it be peripheral, intraabdominal, intrathoracic, or intracranial, exhausts or paralyzes the vaso-motor system of nerves, is well established by experimental research.

By kymographic and sphygmographic tracings it has been shown in every case of long-continued operation and in cases of severe injury that there is a lessening of the blood pressure. This is due, in operations or injuries without the loss of blood, to the exhaustion of the vaso-motor system and a loss of tone in the heart's muscular contractions. In cases in which there has been hemorrhage it is also due to the diminution of the volume of fluid in the vascular system. It is well to inquire if in shock there is not something more than a weakened heart's action, a lessening of the peripheral resistance by the dilatation of the arterioles, and consequently a lowering in the blood pressure. In every case of severe shock there is a decided lessening or weakening of the mental phenomena. The intellect is inactive, the emotions are suppressed, and volition is at a standstill. There is also a muscular powerlessness. The patient is not only unable to exert his mind, but his muscles have also gone out of action. In severe shock there has been such an injury or stimulus to the nerves as practically to put out of action the mental faculties, the motor and sensory nerves, and the sympathetic system. It seems to me that this condition is scarcely due in its entirety to the loss of blood pressure, but that the same crushing force which overstimulated the vaso-motor centres and produced their practical paralysis has overstimulated the cortex of the brain, suspending in a large measure the action of the intellect, the force of the will, the play of the emotions, and the function of the motor nerves. It is often stated, following the teaching of Goltz, that patients dying of shock bleed to death in their own veins. This is supposed to occur in the splanchnic areas, but the condition is simply one of vaso-motor paralysis in which the peripheral vessels have lost their tone, and in consequence of which the blood rushes through the arterioles into the capillary lake and venous channels. While this condition perhaps occurs with greater force in the abdominal region than elsewhere, it does occur wherever there are arterioles and vaso-motor nerves which may be acted upon by overstimulation.

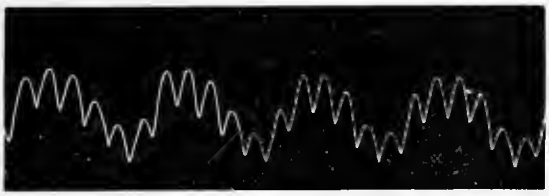

FIG. 4270.

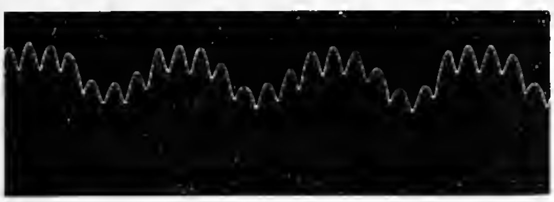

FIG. 4271.

Prophylaxis.—In the prevention of shock one must place his patient, both physically and mentally, in the best possible condition. Just before the administration of the anæsthetic, gr. $\frac{1}{40}$ of strychine with gr. $\frac{1}{8}$ or gr. $\frac{1}{4}$ of morphine may be given hypodermically with decided advantage, as both assist in supporting the heart's action and in maintaining the blood pressure, while the latter lessens to some degree the amount of anæsthetic required. In the choice of an anæsthetic if there is fear of shock, or if it be already present, ether should be administered, in preference to chloroform, as chloroform lessens very decidedly the blood pressure and favors the production of shock.

Fig. 4270 represents a kymographic tracing from the femoral artery of a dog while under the influence of ether, the dog having undergone a resection of a portion of the intestines and a gastro-enterostomy. The blood pressure had fallen at this time from 14.1 cm. to 13.2 cm. Upon substituting chloroform for ether for three and one-half minutes the pressure fell to 11.8 cm. as represented in Fig. 4271. In another experiment the blood pressure under ether stood at 14 cm. After a change had been made to chloroform it fell in one-fourth of a minute 0.2 cm.; in one minute and a half it had fallen 0.4 cm., and in two minutes 0.5 cm. Upon going back to ether the blood pressure lost was quickly regained. It has been the writer's experience that the use of chloroform will reduce the blood pressure present under ether anæsthesia 0.5, 1, or even 1.5 cm. It would seem reasonable, then, that where shock is present or is to be feared, and consequently where blood pressure is low, chloroform should not be used. The heat of the body should also be as far as possible preserved; consequently the temperature of the room, at the time of the operation, and the covering of the patient are matters of importance. The water used in the immediate preparations for the operation should be of such temperature as to abstract nothing of heat from the patient. Evaporating liquids, such as alcohol, must be used with care, and the towels about the field of operation and the sponges should be dry.

In the prevention of shock during an operation or following an accident it is of the greatest importance to limit the loss of blood to the least possible amount, as the blood pressure depends as much upon the amount of fluid within the vessels as it does upon the contraction of the peripheral arterioles or the action of the heart. The loss of only a small amount of blood will lessen at once the pressure. It is also essential, in order to limit the amount of anæsthetic used and the exposure of the patient, that the operation be done as quickly as is compatible with the performance of good surgical work. Cocainizing the main branches of the peripheral nerves before division has been recommended by Crile and Harvey Cushing for the purpose of blocking these nerves and preventing stimulating impulses being carried to the brain. The few experiments of this character which I have undertaken have seemed to show that the cocainization of a nerve causes about as much stimulation of the vaso-motor centres as would its section. It is a fact which may be easily established that the handling, stretching, manipulating, or cocainization of a sensitive nerve will, in consequence of the irritation, at once raise the blood pressure. The same is also true of the section of such a nerve. Of course, this rise is followed by a subsequent fall. It is only a question as to which is the greater evil. When a patient is under the influence of an anæsthetic, it would seem as though all of his sensitive nerves were in a sense blocked, and that not much more could be accomplished by their cocainization.

Fig. 4272 represents Dudgeon's sphygmograph which the writer has been using before, during, and after operations and before and after the administration of certain drugs which are ordinarily used in the treatment of shock. This instrument, while perhaps open to objections, is nevertheless of great value, when carefully used, in determining the height and character of the wave, which conditions correspond reasonably with blood pressure. During the past few months, for the purpose of more accurately testing the blood pressure and its relationship to shock, I have been experimenting with Ludwig's kymograph, represented in Figs. 4273 and 4274. Twenty-two dogs were used for this purpose,

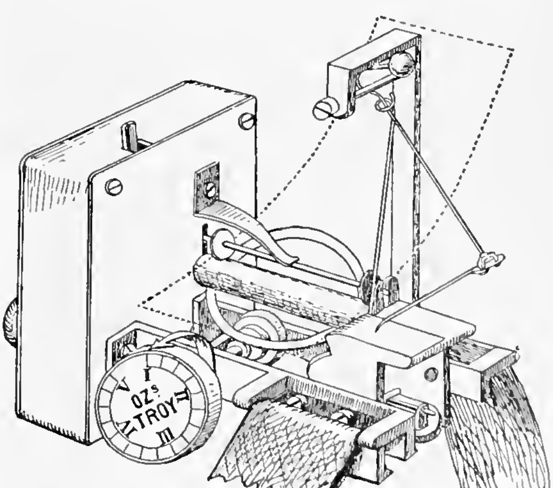

FIG. 4272. Dudgeon's Sphygmograph. The dotted outline represents the piece of blackened paper on which the sphygmogram is written.

the tube of the manometer being in the majority of cases inserted into the femoral artery, in three in the external iliac, and in a few in the common carotid. The dogs were maintained under full surgical anæsthesia by ether, a change being made for a short time, in some cases, to chloroform for the purpose of observation. The blood pressure was taken at the time of the connection of the instrument with the vessel and then its variations were recorded as different operations were being performed, until pronounced shock with loss of blood pressure was present. Various drugs were then administered subcutaneously and the effect upon the blood pressure recorded. The cannula connecting with the vessel was occasionally opened for the purpose of noting the effect of hemorrhage. While it must be admitted that the instrument is delicate and easily disturbed, it unquestionably, when working properly, records accurately the blood pressure. With the sphygmograph one must judge of the blood pressure by the height of the stroke, and with this instrument this is reasonably correct, but in the case of the kymograph the height of the stroke and the blood pressure are not at all synonymous. While the height of the

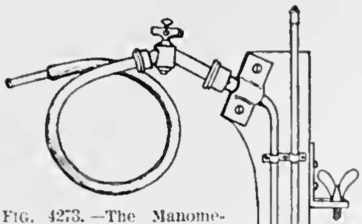

FIG. 4273.—The Manometer of Ludwig's Kymograph. It is also shown in Fig. 4274, *D*, *C*, *E*. The mercury which partially fills the tube supports a float, in form of a piston, nearly filling the tube; a wire is fixed to the float, and the writing style or pen is guided by passing through the brass cap of the tube fixed to the wire; the pressure is communicated to the mercury by means of a flexible metal tube filled with fluid.

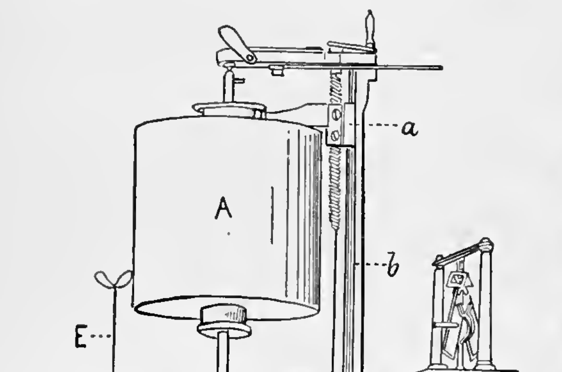

FIG. 4274.—Diagram of Ludwig's Mercurial Kymograph. *A*, Revolving cylinder, worked by a clockwork arrangement contained in the box (*B*), the speed being regulated by a fan above the box; cylinder supported by an upright (*b*), and capable of being raised or lowered by a screw (*a*), by a handle attached to it: *D*, *C*, *E*, represent mercurial manometer.

stroke depends in the kymograph in a measure upon the blood pressure, it also is influenced by the size of the artery with which the instrument is connected, its nearness to the heart, and the size of the cannula used. These conditions always being the same, as they are with the sphygmograph, the height of the stroke in a reasonable degree corresponds with the blood pressure.

Treatment of the Actual Shock.—The treatment of shock may be considered under three heads: (1) The recovery

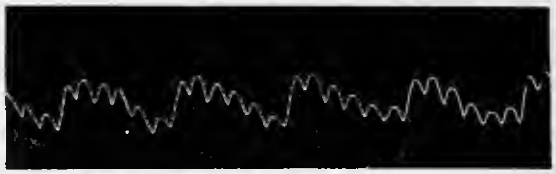

FIG. 4275.

of the normal blood pressure. (2) The re-establishment of the muscular tone; and (3) the restoration of the mental phenomena. The restoration of the blood pressure is at times more quickly affected by an intravenous infusion of the normal salt solution than by any other method, and in cases in which the condition is largely the result of hemorrhage this is the most scientific and satisfactory

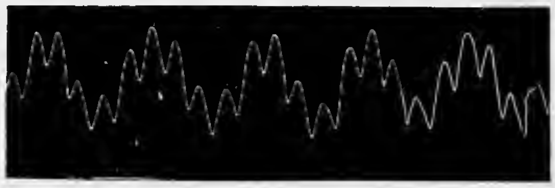

FIG. 4276.

method of treatment. The tracing in Fig. 4275 is from the femoral artery of a dog that had undergone a resection of a portion of the intestine and a gastro-enterostomy. The dog had also lost a large amount of blood. Pressure in the femoral at the time tracing in Fig. 4275 was taken was 13.2 cm. The tracing in Fig. 4276 was taken after one quart of normal salt solution had been infused into a

FIG. 4277.

vein, the pressure now having risen 2.6 cm. Fig. 4277 shows a sphygmographic tracing of a weak pulse during an operation, and Fig. 4278 a tracing of the same pulse after the injection of one pint of normal salt solution beneath the breast.

Hypodermoclysis.—In the writer's clinic at St. Joseph's and Milwaukee County hospitals, as well as in his pri-

FIG. 4278.

vate practice, it is the rule, when a pulse shows weakness, and especially if this be largely from loss of blood, to inject beneath a breast, at the border of the scapula, in the lumbar or gluteal regions, a pint of normal salt solution, and to repeat this injection in half an hour upon the opposite side if necessary. The apparatus required is an aseptic fountain syringe attached to a large surgically clean aspirating needle. While this method does not act as quickly as the intravenous infusion, it acts promptly enough for ordinary cases and is extremely simple. In cases in which the blood pressure is lowered in consequence of exhaustion of the nervous system from gross injury this treatment may still to a certain extent be advantageous, in that it produces some slight vascular stimulation and also adds to the volume of fluid circulating, and thus assists to a certain extent in compensating for the dilatation of the peripheral vessels. It is, however,

FIG. 4279.

a matter of frequent observation in cases of profound shock with great weakness of the pulse that the introduction into a vein of a quart of normal salt solution does not materially improve the patient's condition. The volume of the pulse in these cases may be restored for a few minutes, but this volume is without tension and soon disappears. This is in consequence of the fact that the vaso-motor system has become partially or completely exhausted. What is desired in these cases is the strengthening of the heart and the restoration of the functions of the vaso-motor system, and of the cerebral cortex. It is,

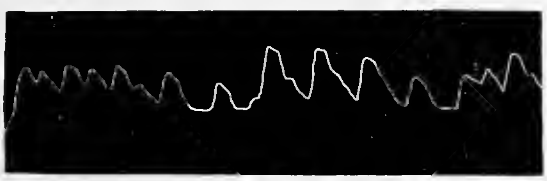

FIG. 4280.

nevertheless, true in some cases of gross injury or of prolonged operation that the exhaustion of the nervous system is so complete that no treatment which we are able to institute will be effectual.

In my experience with shock there is nothing which meets the condition and which sustains the nervous system and holds the ground gained so well as strychnine. Kymographic tracings show that strychnine increases the blood pressure in practically every instance. This pressure is often increased by a single hypodermic injection from 0.5 to 1 or even 1.5 cm. In the administration of strychnine for a serious condition of shock one-fourth of

FIG. 4281.—Before Whiskey.

a grain may be given in divided doses during the course of one hour, and, following this, one-thirtieth of a grain administered every two hours for one or two days, or until the muscles show the influence of the drug.

Nitroglycerin.—The use of nitroglycerin in shock has been criticised by many writers upon the ground that it dilated the superficial capillaries and thereby reduced blood pressure. In my experimental and clinical work nitroglycerin has always increased the height of the stroke and lessened the frequency of a rapid pulse. Gr. $\frac{1}{100}$–$\frac{1}{50}$ of nitroglycerin, injected subcutaneously, has always increased the blood pressure from 0.5 to 1 cm. Its effect, although manifested almost at once and reaching perhaps the same height as that from strychnine, is not so long sustained. The tracing in Fig. 4279 was taken from the femoral artery of a dog where the pulse was scarcely perceptible in consequence of numerous sections of both sciatic nerves, resection of a considerable portion of the small intestine, and of the entire stomach. The tracing in Fig. 4280 was taken one-half a minute after the injection of gr. $\frac{1}{50}$ of nitroglycerin. In four and one-half minutes the blood pressure had risen 1.8 cm.

Caffeine.—Caffeine acts almost as promptly and effectually in restoring blood pressure as does strychnine. Five grains injected subcutaneously in a dog raised the blood pressure from 12.6 cm. to 13.6 cm. This effect is also well sustained.

Adrenalin.—In the writer's experience adrenalin in gr. $\frac{1}{100}$–$\frac{1}{50}$ acts promptly in increasing blood pressure.

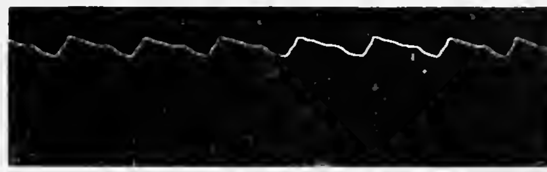

FIG. 4282.—Twenty Minutes after Whiskey.

This action seemingly, however, is not well sustained. Adrenalin is certainly deserving of further consideration in the treatment of shock.

Digitalis and Strophanthus.—Both of these substances were used repeatedly. Their immediate action, however, upon blood pressure is not pronounced. With a rapid pulse their use is indicated, as they will assist in controlling this factor and in maintaining blood pressure.

Whiskey.—The advocacy of whiskey or brandy in shock has occasioned more dispute and acrimonious de-

FIG. 4283.—Three-quarters of an Hour after Whiskey.

bate than that of all the other remedies combined. That they are capable of raising the blood pressure when injected subcutaneously or taken into the stomach there can be absolutely no doubt. A dog whose sciatic had been sectioned half a dozen times was subjected to an intestinal anastomosis and then to a complete resection of the stomach. During these procedures, which occupied one hour and twenty minutes, the blood pressure fell from 14.2 cm. to 12 cm. At 10:25, 25 c.c. of whiskey in water was injected subcutaneously, and in twelve minutes the blood pressure had risen to 13.3 cm., at 10:39 to

FIG. 4284.—One Hour after Whiskey.

13.6 cm., and at 10:40 to 13.8 cm., at which point it remained until 10:44, when it fell to 13.1 cm., where it stood for a very considerable time. The sphygmographic tracing in Fig. 4281 was taken from a weak patient's radial before giving whiskey, the tracing in Fig.

4282 twenty minutes after one ounce by stomach, that in Fig. 4283 forty-five minutes after, that in Fig. 4284 one hour after, that in Fig. 4285 one and one-half hours after, and that in Fig. 4286 two and one-half hours after.

In the treatment of shock there are conditions to be met besides those of blood pressure. One of these is the loss of muscular tone, and another the practical suspension of the mental faculties. It is probably true that anything which assists in restoring blood pressure will

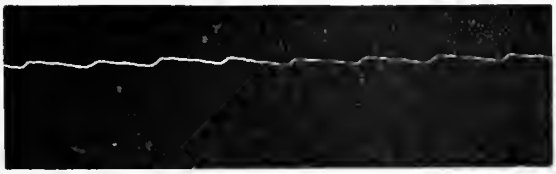

FIG. 4285.—One Hour and a Half after Whiskey.

also assist in re-establishing muscular tone and the vigor of the mental faculties. The normal salt solution, when infused into a vein, acts only mechanically, and is often without decided effect upon the profound depression of the vital functions. Remedies are wanted in shock which will restore not only blood pressure but also all of the vital functions. These conditions are met more perfectly in shock without hemorrhage by the use of strychnine, caffeine, nitroglycerin, whiskey, adrenalin, and normal salt solution than by any other remedies. In

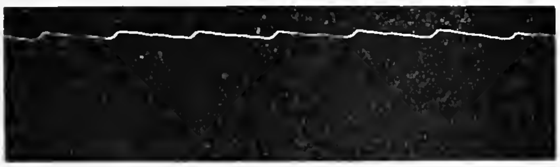

FIG. 4286.—Two Hours and a Quarter after Whiskey.

cases in which hemorrhage has been a prominent factor the normal salt solution should take precedence of all other remedies. *A. H. Levings.*

SHOULDER, THE SURGICAL ANATOMY OF.—The region of the shoulder comprises the bones forming the joint, viz., the scapula and the upper part of the humerus, the clavicle and acromio-clavicular articulation, also the upper and outer part of the thorax, which takes part in forming the axilla. These bony structures, with the softer tissues enveloping them, would be included in the term *shoulder.*

Surface Anatomy.—Beneath the skin can be easily felt the outer end of the clavicle, the acromion process, and the coracoid. Where the clavicle joins the acromion there is a distinct elevation which can be without difficulty detected by running the finger nail over it. The line of this articulation would correspond to a vertical line running up the middle of the front part of the arm. The acromion in the stoutest person may easily be made out by following the spine of the scapula, and the coracoid process is just inside the shoulder joint and below the clavicle. Between the coracoid and the acromion processes is the rounded prominence of the shoulder; this is formed partly by the thick deltoid muscle, but also in part by the upper end of the humerus which lies below it. As the arm is rotated the tuberosities can easily be felt beneath the muscles. In dislocation of the humerus, instead of a prominence there is a flattening, and in pressing with the fingers a well-marked depression is found where the head of the bone is normally felt. If in suspected dislocation the thumb be placed on the coracoid process and one of the fingers of the same hand on the acromion, the space will be found wanting in roundness and the finger can be easily pushed into a hollow; the upper end of the bone can be no more felt on rotation. The portion of the humerus which in normal joints is felt beneath the deltoid is not the head, but the tuberosities. The head can be felt through the axilla if the fingers be well pushed up and the arm be strongly abducted. The head of the humerus faces in the direc-

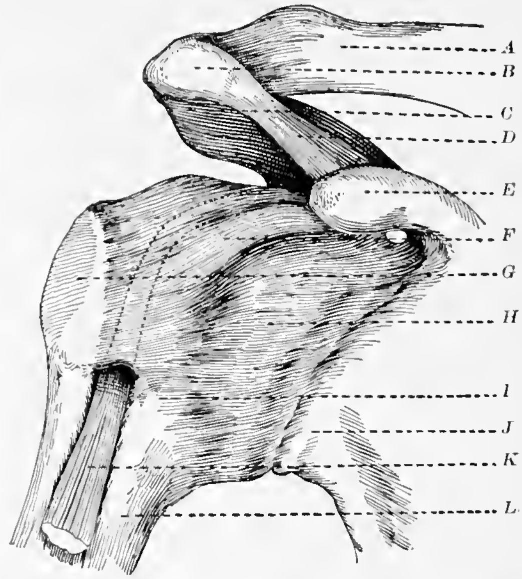

FIG. 4287.—*A*, Clavicle; *B*, *C*, acromion; *D*, coraco-acromial ligament; *E*, coracoid; *F*, coraco-humeral ligament; *G*, great tuberosity of humerus; *H*, capsular ligament; *I*, lesser tuberosity; *J*, scapular neck; *K*, long tendon of biceps; *L*, humerus.

tion of the internal condyle, this latter being always a good guide to the position of the upper end of the humerus.

The adjacent margins of the deltoid and pectoralis muscles cannot be felt below, but above there is a considerable triangular interval which forms the infraclavicular fossa below the clavicle. This fossa is well seen in thin persons, but is obliterated in subcoracoid dislocations, in fracture of the clavicle, and by inflammatory tumors and new growths. In subclavicular dislocations the depression is replaced by an eminence. The space between the two muscles lodges the cephalic vein (Fig. 4288).

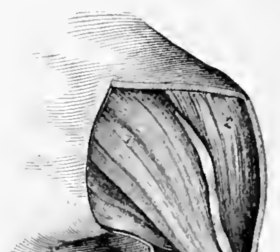

FIG. 4288.—Skin and fascia have been removed. 1, Pectoralis major; 2, deltoid; between these muscles is seen the cephalic vein; 3, biceps; 4, coracobrachialis, close to which lies the brachial artery and the median nerve drawn to one side. (After Roser.)

The back of the shoulder is comparatively flat; here the deltoid muscle is thinner. By abducting the arm the deltoid becomes prominent and various vertical elevations appear which correspond to the muscular tissue between the various tendinous intersections which run down from the acromion through the muscle. The axillary border of the scapula and inferior angle may be brought out by placing the forearm behind the back; to bring the vertebral border and superior angle into evidence, the hand should be placed over the opposite shoulder.

Surface Marking of Axillary Artery.—At a point internal to the coracoid process and below the most convex portion of the clavicle the axillary artery may be compressed against the second rib. The course of this artery can be easily marked out by drawing a line from the most convex portion of the clavicle to the inner border of the elevation formed by the coracobrachialis muscle.

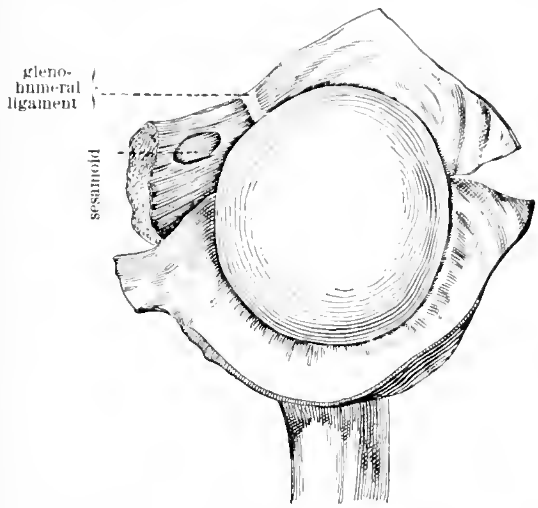

FIG. 4289.—Head of Humerus, with Part of Capsule Attached. (Morris.)

If the arm be raised from the side, the third part of the axillary artery may be felt pulsating as it passes into the arm beneath the anterior fold of the axilla, and in a line corresponding to the outer border of the axillary hair, that is, at the junction of the anterior with the middle third of the space between the axillary folds. At the junction of the upper with the middle third of the deltoid muscle the posterior circumflex vessels and nerves wind round to the back of the humerus under the muscle.

The *deltoid region* comprises the point of the shoulder and is confined to the limits of the deltoid muscles which cover the shoulder-joint and upper end of the humerus. Between the deltoid muscle and the joint is a large bursa, the subdeltoid or subacromion bursa. Owing to the exposed position of the shoulder-joint it is liable to

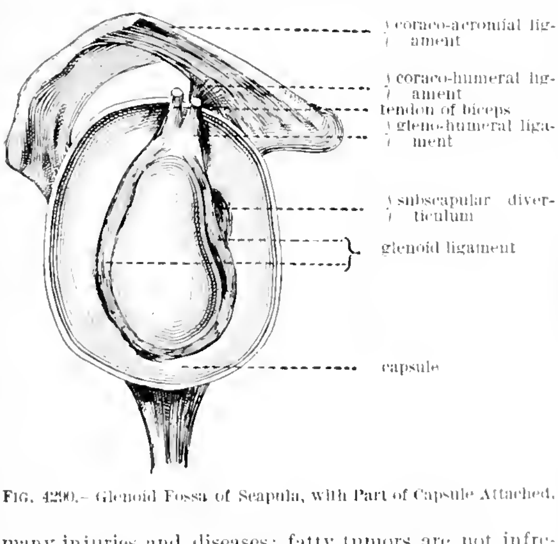

FIG. 4290.—Glenoid Fossa of Scapula, with Part of Capsule Attached.

many injuries and diseases; fatty tumors are not infrequently seen here and may attain to a large size.

The shoulder-joint is of the ball-and-socket variety (enarthrodial), and so is very freely movable; the socket in the scapula is very shallow but is deepened by the glenoid ligament, to which the long head of the biceps is attached. It is small in size compared with the large articular surface of the head of the humerus. This disparity gives greater freedom of movement with lessened security and more liability to displacement in extreme movements.

The circumflex nerve supplies the deltoid, shoulder-joint, and skin over the lower two-thirds of the shoulder and upper part of the triceps. In injuries to the shoulder this nerve is frequently damaged, and paralysis with atrophy of the deltoid may result; marked flattening of the shoulder may as a consequence ensue.

Relations of the Joint.—Muscles of great strength surround the shoulder except inferiorly; above we have the deltoid and supraspinatus, internally and in front the subscapularis, and externally and behind the infraspinatus, both these latter separated from the capsule by a bursa. The capsule of the joint, though strengthened by these muscles, is very loose, so that when the muscles

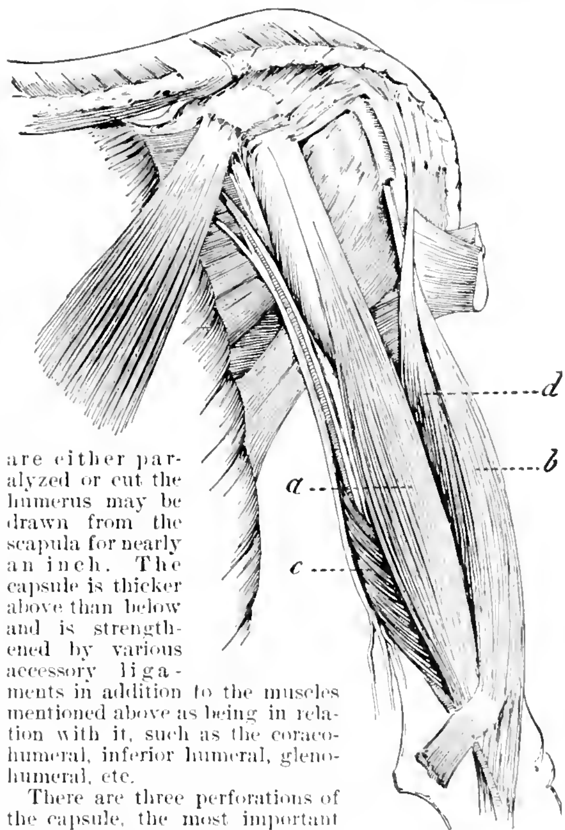

FIG. 4291.—Abnormal Arrangement of the Biceps. *a*, Coracoid head; *b*, glenoid head; *c*, humeral head; *d*, capsular head.

are either paralyzed or cut the humerus may be drawn from the scapula for nearly an inch. The capsule is thicker above than below and is strengthened by various accessory ligaments in addition to the muscles mentioned above as being in relation with it, such as the coraco-humeral, inferior humeral, gleno-humeral, etc.

There are three perforations of the capsule, the most important being that for the long head of the biceps at its lower part; it is also perforated by the supraspinatus and not infrequently by the infraspinatus. *The tendon of the long head of the biceps* has synovial membrane prolonged along it and surrounding it. This tendon keeps the head of the humerus against the glenoid cavity and prevents the bone rising up toward the acromion. This tendon is sometimes ruptured, thus causing weakening of the upper limb and a drawing up of the humerus forward and inward against the coraco-acromial arch. The tendon may be dislocated—that is, it may slip out of its groove to one side or the other. In such cases the head is prominent and drawn up under the acromion; owing to the higher position of the greater tuberosity, abduction is not so free.

Rupture of the tendon is more apt to occur in persons the subjects of rheumatic disease; in them the joint is dry and perhaps the tendon is partially worn. In old cases it is not uncommon to see the long tendon of the biceps attached to the upper end of the humerus, the head of the bone having worn through the tendon and the capsule, and entered the subacromion bursæ. In very old cases

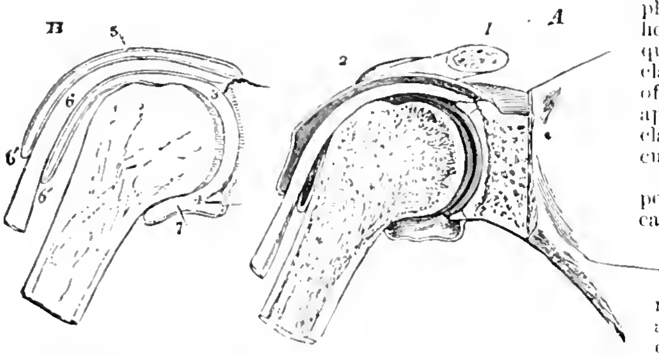

FIG. 4292.—A, Section showing the Relation of the Long Tendon of the Biceps to the Shoulder-joint. B is an outline showing the arrangement of the synovial membrane. (Allen Thomson in "Quain's Anatomy.")

the under surface of the acromion process will be eburnated as well as the surface of the humerus which has been in contact with it. As a rule the joint is well protected above by the acromion and coracoid processes, and the ligaments between these.

THE EPIPHYSES.—There are a number of epiphyses about the shoulder-joint, some of which are of importance. It is of importance to know that the epiphyseal end of the acromion, which articulates with the clavicle, may sometimes remain separated throughout life and may be mistaken for a fracture; in fact, Sir Astley Cooper described it as such. The coracoid process is also formed by a separate ossific centre, and the head of the humerus forms a single epiphysis in the fifth year; this is composed of no less than three fused secondary centres and it is limited by the surgical neck. Separation of the upper epiphysis of the humerus may be mistaken for dislocation, but the easy reduction and the fact that the glenoid cavity is always full should prevent one from falling into this error.

BURSÆ.—The bursæ about the shoulder are many, for besides the subdeltoid or subacromion bursa and the ones between the subscapularis and infraspinatus muscles, and the capsule of the joint (which was frequently continuous with the cavity of the joint), we have the bursa between the insertion of the latissimus dorsi and teres major muscles and between the teres muscle and the bone. Any one of these may become inflamed and distended with fluid as the results of strain or direct injury. Very often the inflammation is tuberculous, the subacromion is most often the seat of disease, for it is more exposed than the other neighboring bursæ.

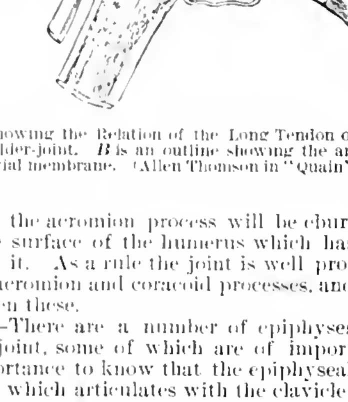

FIG. 4293. Frontal Sections of the Shoulder-joint while the Arm is Hanging. (Henle.) +, Clavicle; *ac*, acromio-coracoid ligament; *D*, deltoid muscle; *B*, tendon of long head of biceps; *Ss*, subscapularis; *Ss*[1], supraspinatus; *Al*, triceps; *Tmj*, teres major; *, posterior circumflex artery; **, trace of epiphysial union.

THE CLAVICLE.—The skin over this bone is very loose and easily rolled on the bone. Cutting down on the subclavian artery and pulling the skin firmly over the clavicle, the surgeon cuts freely on the bone, and when the skin is released the incision is well above the clavicle, and the external jugular vein, which it was intended to avoid, comes into view. Passing over the clavicle are seen the clavicular branches of the superficial cervical plexus, and these nerves may be easily injured here. In disease of the cervical spine there is frequently pain over the collar bone. Beneath the clavicle and subclavian artery, the vein and cords of the brachial plexus rest on the first rib. The apex of the lung passes up into the neck behind the clavicle, encircled by the first rib, and can be percussed in the supraclavicular fossa.

The sternal end of the clavicle is near very important structures, such as the innominate and left carotid artery, the pneumogastric and recurrent nerves, and the large venous trunks. The acromio-clavicular joint is sometimes dislocated and is hard to retain in place when reduced; the sternal end also may be displaced and this joint may be attacked by tuberculous disease.

AXILLA.—The axilla (*ala*, a wing) is the space which exists between the upper arm and side of the thorax. It is of a pyramidal shape, and is bounded in front by the pectoral muscles, behind by the subscapularis, teres major, and latissimus dorsi, on the inner side by the serratus magnus, intercostal muscles and ribs, and on the outer side by the upper part of the arm and shoulder-joint. The base is formed by the skin stretching between the anterior and posterior boundaries. The hollow between the anterior and posterior folds is commonly known as the armpit, but anatomically we imply more by the term axilla than this depression; we include all the deeper space which reaches up to between the scalene muscles, and contains the axillary vessels, brachial plexus of nerves, and lymphatics. This deeper space is surgically continuous with the neck.

Superficial Anatomy.—The skin of the armpit proper, which is very thin, sensitive, attached to the fascia beneath, and of a darkish color, is supplied with glands which secrete an odorous sweat. In some cases this sweat is of a peculiar color, and stains the linen; it may be large in amount and cause great discomfort to the individual and his friends from the disagreeable odor emitted.

The skin of the armpit is abundantly provided with hairs which never grow to any great length; their limit is generally well defined, the outer border furnishing a good surface mark for the axillary artery in the third

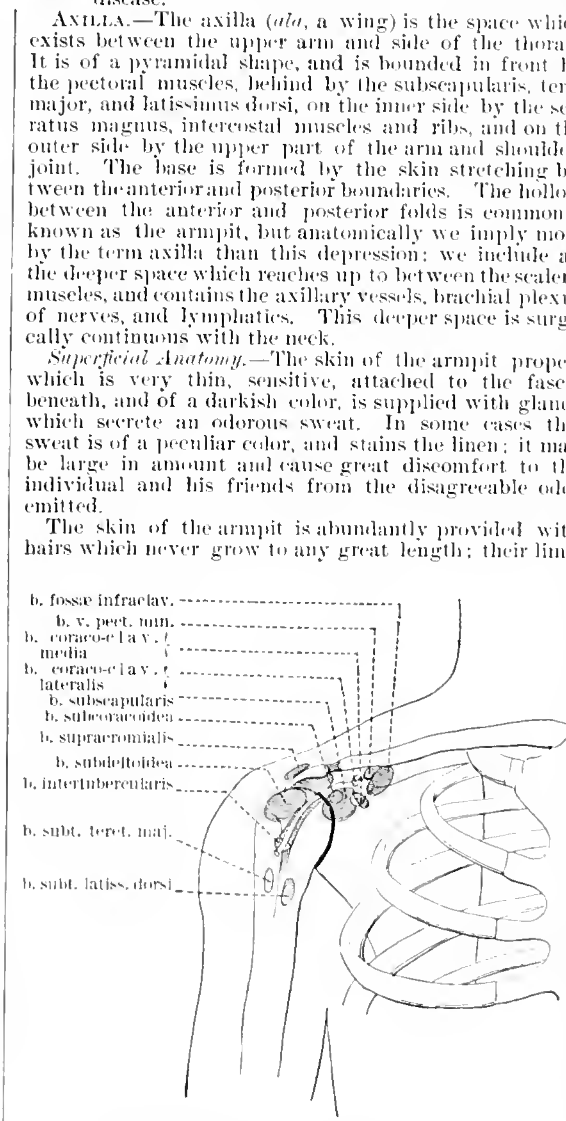

FIG. 4294. The Principal Bursæ about the Shoulder.

part of its course.* The armpit is of different depths in different individuals; in women and children it is not so well marked as in men, chiefly because in them we have less muscular development and more adipose tissue. When the arm is lifted above the head the depression almost disappears and the skin is put so much on the stretch that nothing can be felt of the deeper part; the depression deepens as the arm is lowered to the side, the skin being relaxed and thrown into folds. The fingers can now be pushed high enough to feel the head of the humerus. When it is necessary to examine the deeper structures, the arm ought only to be slightly drawn away from the side. In operations on the axilla the arm should always be abducted and raised to lessen the depression.

It is not uncommon to see suppuration of the follicles in this region; these small follicular abscesses, owing to the sensitiveness of the skin, are very painful and should be opened early.

The skin covering the anterior fold is thick, not closely adherent to the deeper structures, and free from hairs. Close below the clavicle and internal to the shoulder, the coracoid process can be felt.

The lower border of the great pectoral muscle follows the line of the fifth rib; the first visible serration of the serratus magnus on the inner side of the space is the sixth. The posterior fold is thicker than the anterior on account of the great thickness of the teres major muscle. When the arm is raised from the side the axillary artery can be felt pulsating as it passes into the arm, and may be easily compressed.

Fascia.—On removing the skin from the axilla we come upon a strong fascia, the disposition of which it is important to know because of its influence on the course of abscesses, which not infrequently form in the neighborhood. The strong fascia which covers the great pectoral muscle and is attached to all the subcutaneous bony prominences, winds round its lower border and splits into two portions, one of which continues to ensheath the pectoralis muscle on its inner surface, while the other forms the floor of the axilla and, after covering the latissimus dorsi and teres major muscles, passes upward and backward and is lost in the strong deltoid aponeurosis. The portion of this fascia which covers the pectoralis major muscle externally sends a process between it and the deltoid muscle, and this process becomes continuous with the costo-coracoid membrane.

The costo-coracoid membrane (Fig. 4295) is a strong aponeurosis which is continuous with the deep cervical fascia; it splits to enclose the subclavius muscle, is attached to the clavicle and to the coracoid process, and is continued to the capsule of the shoulder. It is also attached to the cartilages of the first and second ribs, and is continuous with the aponeurosis over the serratus magnus muscle. This fascia is the costo-coracoid membrane proper, and covers the first part of the axillary vessels and nerves. When it reaches the edge of the small pectoral muscle it again divides to enclose it; reuniting again, it passes down to the base of the axilla, and becomes attached to the skin and the fascia covering the great pectoral; externally it is continuous with the brachial aponeurosis. Gerdy calls this process the *ligamentum suspensorium*, because he says it is the ligament of the skin of the armpit, which it pulls upward. This suspensory ligament, then, divides the axilla into an anterior and a posterior compartment, the posterior containing blood-vessels and nerves, and the anterior the loose cellular tissue which separates the two pectoral muscles and intervenes between the lower part of the fascia and the great pectoral. Now, when an abscess forms in front of the suspensory ligament—that is, below the small pectoral or between the two pectorals—it would tend to point at the lower border of the anterior axillary fold, or in the interspace between the deltoid and the great pectoral muscle; but if pus forms behind the suspensory ligament and is not evacuated early, it may burrow into the neck and thence find its way, through the upper opening of the thorax, into the mediastina; it may also find its way beneath the latissimus dorsi and point in the back, or it may burrow into the subscapular fossa and thence get into the shoulder-joint.

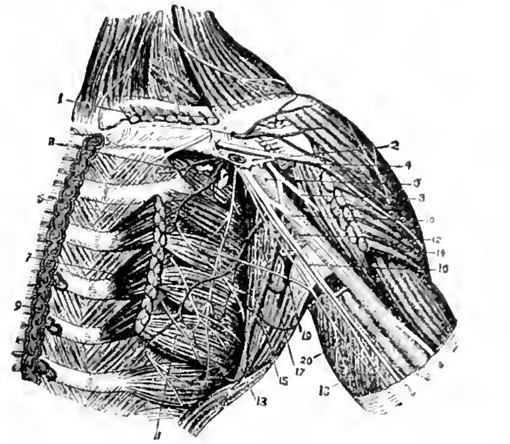

FIG. 4295.—Brachial Plexus and Axillary Artery. 2, Costo-coracoid membrane; 3, superior thoracic and ulnar arteries; 5, long thoracic artery; 6, axillary artery; 8, musculocutaneous nerve; 10, median nerve; 15, subscapular artery; 16, ulnar nerve; 18, internal cutaneous nerve; 19, circumflex nerve; 20, nerve of Wrisberg, joined by intercosto-humeral.

Abscesses in the axilla should be opened early and after the manner of the late Mr. Hilton. He advised that the skin alone should be cut with a knife, that a grooved director should then be pushed into the deeper structures till pus wells out. The deeper parts may be still further opened up by introducing a pair of dressing forceps, opening them widely in the abscess and withdrawing them open. If axillary abscesses are opened in this way, there is no danger of wounding any of the displaced vessels in the neighborhood, as they are pushed aside by the director. The finger answers often quite as well as a director.

Boundaries of the Axilla.—The *anterior boundary* (Fig. 4288) is formed by the two pectoral muscles, the great pectoral alone forming the lower border of the anterior fold. It is important, surgically, to remember that the fibres of the large pectoral go downward and outward, and those of the lesser upward and outward. The interspace between the great pectoral and the deltoid may be often very small or wanting, and the division between the two muscles can be made out only by the position of the cephalic vein and a branch of the acromial thoracic artery.

Owing to the pectoralis major muscle having an origin from the clavicle, it is necessary, in fracture of that bone, that the arm should be placed close to the side to prevent the muscle pulling down the inner fragment, and so delaying union. In females the lower edge of the anterior border of the axilla, owing to the presence of the mammary gland, is not so easily seen as in the male. In the female the mammary gland moves freely on the great pectoral muscle, there being an abundance of cellular tissue between the muscle and the gland; but in advanced cases of cancerous disease of the breast every movement of the pectoral muscle is painful because of the gluing together of the breast and the muscle by infiltrated tissue.

The acromial thoracic vessels and the internal and external thoracic nerves are seen on the inner surface of

* According to Mr. A. W. Martin (Edin. Med. Journal, June, 1884): "The presence of hair in the pubic region is sufficient, by the law of correlation of growth, to account for the presence of hair in the corresponding part of the fore-limb, the axilla." He also says that the hair of the axilla has a fixed ratio to that of the pubes and also corresponds closely in color; he regards sexual selection as sufficient to account for it on the pubes, and also remarks that its quantity in both sexes will be in proportion to the sexual passion. With this last statement I certainly am not prepared to agree.

the pectoral muscle. The long thoracic artery generally runs along the lower border of the lesser pectoral.

In rare cases the great pectoral muscle is wanting altogether, or the clavicular portion alone may be wanting. The lesser pectoral may be attached to as many as five

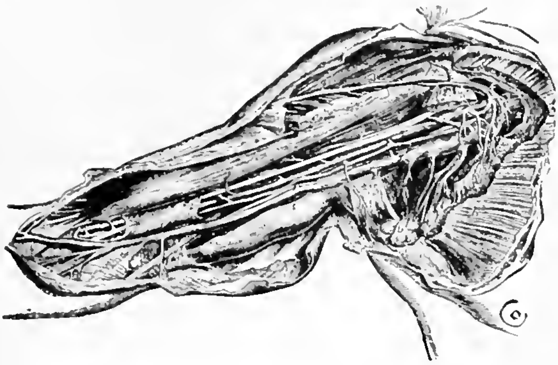

FIG. 4296.—Dissection of Axilla, showing the Axillary Vein (2, 2) and Parts in Relation with it. 1, 1, Axillary artery; 2, 2, axillary vein; 3, 3, basilic vein; 4, cephalic vein; 5, 5, pectoralis minor; 6, axillary glands.

ribs or as few as one. Its insertion may be transferred from the coracoid process to the coracobrachialis muscle or humerus itself.

The *posterior boundary* of the axilla is formed by three muscles which are supplied by the same set of nerves, viz., the three subscapular, and all three muscles are internal rotators of the humerus. The tendon of the latissimus dorsi, with the teres major, forms the lower edge of the posterior fold, the posterior wall of the deeper portion being principally formed by the subscapularis. The axillary vessels rest on this posterior wall, held together by a dense cellular sheath, and separated from the rest of the axilla by the above-described suspensory fascia.

The *internal boundary* of the axilla is formed by the ribs, intercostal muscles, and the upper digitations of the serratus magnus. On this wall, which is somewhat convex, a large nerve is seen running down in a vertical direction, to be distributed to the serratus magnus muscle. This nerve is a branch of the brachial plexus, and is called the long thoracic. We also find here branches of the posterior and long thoracic vessels. Abscesses and tumors, as a rule, lie along this wall, and are fortunately well away from the axillary vessels; in removing tumors we always dissect toward the inner wall.

The *external boundary* of the axilla is formed by the upper part of the humerus and coracobrachialis muscle; along this boundary, and on the inner side of the coracobrachialis are seen the axillary vessels and nerves closely bound down by their fascial covering.

The *inferior boundary* or *base* of the axilla, which is formed by the skin and fascia stretching between the anterior and posterior folds, has already been described.

The apex of this cone-shaped space may be said to be continuous with the posterior triangle of the neck, as vessels, nerves, lymphatics, cellular tissue, and fascia reach the axilla from the neck through this apex. It is the space between the upper edge of the scapula, clavicle, and first rib. Abscesses of the neck have been seen passing through this opening and pointing in the axilla.

Contents of the Axilla.—The axillary vessels, with the lymphatic glands, fat, and loose cellular tissue, are the principal contents of the axilla. The loose cellular tissue permits of free movements of the arm to and from the body, but it also permits of the collection of large quantities of blood and pus. The vessels and nerves are bound together by a sheath of thick cellular tissue; they lie on the outer wall of the space internal to the coracobrachialis.

Axillary Vein (Fig. 4296).—This is the most superficial of the contents of the axilla. In the upper part of its course it is so fixed by fascia connecting it with the coracoid process and pectoralis minor muscle, that if wounded it tends to gape, and air is apt to enter. The vein is formed by the junction of the venæ comites with the basilic vein. This union may occur low down or high up; the normal point of union is at the lower edge of the subscapularis muscle, though the junction not infrequently takes place higher up, sometimes as high as the clavicle. It is always shorter than the artery, measuring about 7.5 cm. (3 in.) in length. Union occurring high up complicates operations upon the artery, owing to the numerous transverse communicating branches which cross the artery. The vein lies to the inner side of the artery, and generally overlaps it. When the arm is drawn away from the side it almost altogether covers the artery. In the course through the axilla, this vein receives many tributary branches, the largest of which is the subscapular. It receives the cephalic vein immediately above the lesser pectoral muscle. In operations on the axilla, the vein and its branches are frequently wounded—more often than the artery—but it is rarely injured by external violence. In reducing dislocations of the shoulder, and using extreme traction, the artery is much more frequently injured than the vein, owing to its proximity to the heart and its fixed position; the vein, when wounded, bleeds freely, and there is great danger of air entering it. This accident has many times occurred, especially in operations for removing diseased glands, and not a few fatal cases are on record. It is always well before dividing the veins, especially about the neck and axilla, to tie them with a double ligature and cut between.

In almost all diseases of the axilla there is swelling of the arm caused by pressure on the veins and absorbents.

Axillary Artery (Fig. 4295).—This vessel, which is the continuation of the subclavian, extends from the lower border of the first rib to the lower border of the teres major muscle; it measures about 15 cm. (6 in.) in length, and its direction is altered with the position of the arm. When the arm is close to the side, it forms a curve having its convexity upward and outward; when the arm is held at right angles to the body, the artery is in almost a straight line; and again, when the arm is held above the head, the slight curve thus formed has its concavity upward. Its upper portion lies close to the chest and rests on the upper serrations of the serratus magnus; the long thoracic nerve is behind it, and in front is the costo-coracoid membrane. Its lower part lies principally on the subscapular muscle. The vein is superficial to the artery above, and the nerves of the brachial plexus lie to its upper and outer side; lower down the vein becomes more internal and the nerves surround the vessel, the two heads of the median embracing it. For convenience of description the axillary artery is divided surgically into three portions—the part above,

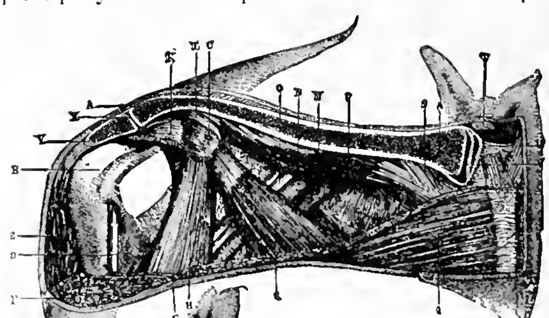

FIG. 4297.—Portion of Clavicle and Acromion Process removed with Pectoralis Major and Deltoid Muscles. Pectoralis minor muscle (*R*) crossing the space; relation of axilla to the shoulder shown, and also contents of axilla; *M*, axillary vein; *N*, axillary artery; *O*, brachial plexus; *P*, subclavius muscle. (From Anger's "Anatomie Chirurgicale.")

that beneath, and that below the pectoralis minor muscle. It lies deepest above this muscle and is most superficial below it. The large thoracico-acromial branch is given off immediately above the pectoralis minor, and might be wounded in the operation of tying the axillary in its first part. A number of small branches are given off which are not surgically important. The subscapular artery, given off near the lower edge of the subscapular muscle, is a large branch, which runs to the side of the chest and near its origin gives off the dorsalis scapulæ. The external mammary is given off below the lesser pectoral, and is sometimes of large size; it is always cut in the operation of excision of the breast, and may give rise to slight hemorrhage. The circumflex arteries closely embrace the neck of the humerus, and should be looked for and avoided in excision of the head of the humerus. In wounds of the first part of the axillary artery the vein is so closely in relation with it that it rarely escapes; lower down the artery may be wounded and the vein remain intact. Wounds of the axillary artery may result from stabs, fracture of the neck of the humerus (Fenwick), violence during the reduction of old dislocations. Hemorrhages may be slight or severe, according to the size of the wound. The loose tissues of the axilla admit of great and rapid distention by bleeding from either vein or artery. The treatment is first to compress or temporarily ligature the third part of the subclavian and then cut down on the artery in the axilla, turn out the clots, and ligature above and below the wound in the vessels. It is well to remember that in reduction of an old dislocation the artery has been torn when simple manipulation was practised, owing to the adhesions which had formed between the capsule and the vessel. The artery is usually tied in the third part of its course, where it is most superficial. It has been tied on the first part, but owing to its depth and the thick covering of muscle, and also its close connection with the vein, ligature of the third part of the subclavian is preferred, as being the safer and simpler operation. The third part of the subclavian is more easily compressed than the first part of the axillary.

Aneurism not infrequently affects the axillary artery; this is, perhaps, owing to its nearness to the heart and to the curve the artery makes at its upper part. It has been occasionally ruptured in reducing dislocation of the shoulder.

Nerves of the Brachial Plexus (Fig. 4295).—These nerves are derived from the lower four cervical and first dorsal. They are to the outer side of the artery in the first part of its course, but lower down they surround it. When the axillary artery divides into two trunks, one of which gives off all the branches, this latter is, as a rule, embraced by the two heads of the median. The axillary nerves are rarely torn by traction on the limb; when forcibly stretched they may be torn away from their attachment to the cord in the cervical region, as in a case recorded by Flaubert, where this accident happened in endeavoring to reduce a dislocated shoulder. The median is the nerve most frequently injured in wounds of the axilla, the musculospiral, from its very deep and protected position, always escaping. The axillary nerves are occasionally injured in fracture of the neck of the humerus, and may be compressed in dislocation of the shoulder.

Lymphatics (Fig. 4298).—The axilla is richly supplied with lymphatic vessels and glands. The glands, which are ten or twelve in number, are mostly placed along the axillary vessels and form a continuous chain with the cervical glands. They receive the lymphatics of the arm, and are often much enlarged in inflammatory affections of the hand and arm. A few glands are situated on the serratus magnus muscle and near the lower edge of the pectoral muscles. When enlarged these glands may be felt under the axillary border of the pectoralis major. The lymphatics from the pectoral group of glands drain into the axillary glands as do the lymphatics from the subscapular group. They receive most of the lymphatics from the side of the chest and mamma, and also the superficial lymphatics of the abdomen as

low down as the umbilicus (Treves). These are the glands which are first enlarged in certain affections of the breast, *e.g.*, cancer, and also when the chest or abdomen is inflamed superficially, as from blistering, etc. Their efferent vessels join the axillary glands. There are some glands situated at the back of the axilla along the subscapular vessels; these receive the lymphatics from the back. In the interspace between the great pectoral and deltoid muscles near the clavicle, one or two small glands are found; they receive the lymphatics of the shoulder and outer side of the arm; above, they are connected with the lower cervical, and below with the axillary glands. The efferent vessels of the axillary glands pass up with the subclavian vein and join the thoracic duct on the left side, and on the right the lymphatic duct of that side. Sometimes they open separately into the subclavian vein. The axillary lymphatics which pass upward under the clavicle anastomose freely with the subclavian lymphatics and the lymphatics of the deep cervical glands.

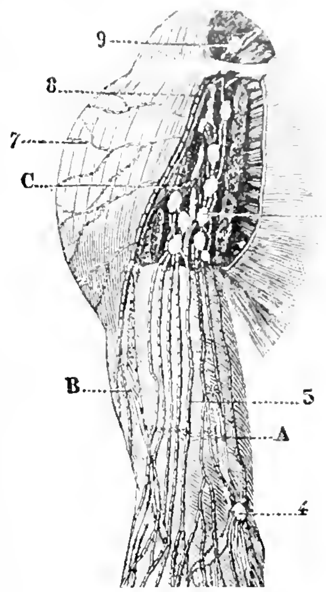

FIG. 4298.—Lymphatics of the Axilla. (From Testut.) 4, Epitrochlear gland; 5, superficial lymphatics of arm; 6, axillary glands; 7, lymphatic of shoulder; 8, lymphatic trunk accompanying the cephalic vein; 9, glands of neck; *A*, basilic vein; *B*, cephalic vein; *C*, axillary vein.

The glands of the axilla are frequently enlarged from sympathy with disease or inflammation of neighboring parts, and not infrequently run on to suppuration. They may be the subject of cancerous infiltration when the breast is affected with malignant disease; occasionally, malignant disease first affects these glands. Scrofulous enlargement of the axillary glands is not uncommon, and their removal is sometimes called for. Professor Verneuil (*Gazette des Hôpitaux*, October 10th, 1879) recommends linear division of the pectoral muscles previous to excision of deeply seated glands. As these glands lie chiefly along the vessels, there is great danger of hemorrhage, and even if the main vein itself is not wounded, some of the large veins going to it may be easily nicked and give rise to free hemorrhage.

In excision of the breast, when the axillary glands are affected they must always be removed, and this is often a difficult operation. The glands are very apt to become adherent to the vessels, especially the vein, which has often been wounded during removal of glandular tumors. When clearing the axilla of diseased glands the fingers will be found more serviceable than any cutting instrument, and infinitely safer. The deep lymphatics of the breast anastomose freely with the lymphatics of the fascia covering the great pectoral muscle and unite with the trunk of the deep lymphatics which go to the axilla. The lymphatics of the pectoral fascia do not anastomose freely with those of the muscle beneath, for the direction of the lymphatic flow is from the muscle to the fascia. Abscess of the axilla, originating in the glands, is not uncommon, the glands most liable to suppurative inflammation being those under the edge of the great pectoral muscle. The course which pus takes when it forms in the axilla has already been described with the fascia. Strumous glands in the axilla frequently break down and suppurate, leaving sinuses which are very difficult to heal.

Supernumerary mammæ have been frequently reported as occurring in the axilla. Dr. Garland (*Edin. Med. Jour.*, 1877) reports cases in which there were swellings in the axilla during pregnancy and suckling; and Dr. Sharpe (*Med. Times and Gazette*, 1855) mentions a case in which a supplementary mamma, which enlarged greatly during pregnancy, occurred in each axilla, and milk could be squeezed out apparently through pores in the skin; there was no appearance of nipples.

Mr. Birkett (*Med. Times and Gazette*, vol. ii., 1868) describes several cases of cystic tumors occurring in early life in the axilla and extending into the neck. He strongly advocates excision in these cases.

Fatty tumors frequently develop in this region; they can be removed without much difficulty.

Francis J. Shepherd.

SIALAGOGUES.—This term is applied to remedies that increase the secretion of saliva. In the normal state of the organism the secretion of saliva is a reflex process excited by chemical and mechanical stimuli. These affect the gustatory nerves and the sensory filaments of the trigeminal and glossopharyngeal nerves of the whole buccal cavity. Such stimuli are all foods and drinks that have a perceptible taste and the mechanical movements necessary in masticating. The stimulating impressions upon the sensory nerves are conveyed by them to the salivary centres, especially to the centre in the medulla oblongata; from these centres impulses are transmitted through the efferent nerves to the salivary glands, and as a result of these impulses there are an increased flow of blood to the glands and an abundant secretion of saliva. Hence it is observed that the saliva is most abundant when food has a very decided and agreeable taste and the process of mastication is slowly and thoroughly performed. In abnormal states of the buccal cavity, especially in the various forms of stomatitis, in consequence of the irritation of the sensory nerves, a more or less abundant flow of saliva takes place reflexly. (See also the article on *Saliva*.)

Most sialagogues act in the same manner as the normal stimuli of the secretion, that is, reflexly; by notably impressing the sensory nerves of the buccal cavity they excite the salivary centres and these transmit impulses to the salivary glands. Hence the greater the stimulating effect of sialagogues upon the sensory nerves of the mouth, the more abundant the salivary secretion. Very pungent substances, such as pellitory, mezereum, cubeb, capsicum, mustard, and ginger, if kept in contact with the buccal mucous membranes for some time, cause a free flow of saliva. Numerous other remedies having a decided action upon the sensory nerves of the buccal cavity, such as vegetable and mineral acids, alkalies, simple bitters and aromatics, ether, chloroform, and alcoholics, reflexly increase the flow of saliva.

Some sialagogues, however, do not act reflexly; they cause a very free flow of saliva when they are injected into the subcutaneous tissue or when they enter the blood by other routes. They act directly upon the peripheral ends of the secretory nerves of the salivary glands, and hence are called remote or specific sialagogues. The principal one of them, and the only one used therapeutically, is pilocarpine; others are physostigmine, muscarine, and nicotine. The preparations of mercury also act specifically; but when they have produced stomatitis the local irritation is necessarily followed by reflex salivation. The preparations of iodine and chlorate of potassium also increase the secretion of saliva by acting upon the secretory nerves.

Sialagogues are used when the salivary secretion is insufficient. This occurs in some persons who eat very rapidly; it is also frequently observed in prolonged febrile diseases, and it is one of the results of poisoning with certain alkaloids and ptomaïnes.

In the dyspepsia of persons eating too hastily sialagogues are probably of little or no benefit; but the adoption of correct habits in eating is generally soon followed by normal digestion. Such patients should be advised to masticate very slowly and at each meal to eat a sufficient amount of hard and dry food, such as stale bread, dry toast, crackers, to excite an abundant flow of saliva. When the teeth have become so defective that food cannot be thoroughly masticated, the patient should be advised to consult a dentist.

The salivary secretion is always diminished in high fevers, and it is sometimes almost completely arrested. When the patient constantly breathes through his mouth, the buccal mucous membrane sometimes becomes so dry that the movements of the tongue, articulation, and deglutition become difficult. In consequence of the dryness, the mucous membrane becomes fissured and abraded, thus presenting numerous openings for the entrance of micro-organisms. Various annoying and dangerous morbid conditions may result, such as soreness, ulceration, and bleeding of the gums, caries of the teeth, fœtor of the breath, glossitis, inflammation of the glands of the neck, of the Eustachian tube and the middle ear. Hence, while sialagogues are used to maintain the secretion of the saliva, all other appropriate means should be employed to prevent the dryness of the mucous membrane. The air of the patient's apartment should be kept moist; the patient should frequently drink water, at least every hour; a piece of wet wide-meshed fabric should be laid over his open mouth; and every three or four hours the entire buccal cavity should be moistened by means of a large camel-hair brush with a mixture of one part of glycerin and two parts of peppermint water. The only sialagogues appropriate in fevers are the acids; of these the most agreeable one is citric acid as contained in lemonade, which has been used from time immemorial as a pleasant drink to quench thirst in high fevers. The other acids that may be used are tartaric, acetic, phosphoric, and hydrochloric, very much diluted and given at short intervals. Some authors hold that only vegetable acids should be given, because they do not, like the mineral acids, diminish the alkalinity of the blood, which, according to some researches, always becomes diminished in prolonged fevers; others are of the opinion that the mineral acids deserve preference because they do not increase oxidation.

The buccal mucous membrane becomes intensely dry from arrested secretion of saliva and mucus in poisoning with belladonna, hyoscyamus, and stramonium, and to a somewhat less degree in poisoning with decayed meat, fish, and cheese. The arrested salivary secretion is, of course, only one of the symptoms; but it may be abated and some of the other symptoms allayed by the cautious administration of pilocarpine.

Pungent sialagogues have been used to allay toothache, earache, and other congestive and inflammatory affections of the nose, ear, and other parts of the head. During the profuse flow of saliva excited by their mastication, the salivary glands are very abundantly supplied with blood, and doubtless this hyperæmia may lessen the flow of blood to adjacent parts of the head and be of some benefit. For this purpose pyrethrum was generally preferred.

Samuel Nickles.

SIDE-CHAIN THEORY OF PAUL EHRLICH.—(Synonyms: Lateral-chain theory; Receptor theory. German, *Seitenkettentheorie*; French *Théorie des chaînes latérales*.)

Definition.—An hypothesis which attempts to explain according to chemical laws the mechanism of the processes of infection and immunity.

The side-chain theory first appeared as an explanation of the mechanism of the assimilation of foods (Ehrlich, Paul: "Das Sauerstoffbedürfniss des Organismus," 1885). According to this hypothesis a food must become chemically bound to a cell in order to be assimilated. Union of food and cell depends upon chemical structure. No matter what may be the chemical structure of a food, it must at least contain a chemical group which allows it to unite with a cell. This chemical group in a food is its "binding group" or "haptophorous group" (from the

Greek ἅπτειν, to bind to). The cell also must contain a binding group or haptophorous group with chemical affinity for the corresponding group of the food. When a food in the circulation passes near the cell, the chemical affinity between the haptophorous group of the cell and that of the food leads to the withdrawal of the food from the circulation and to the chemical union of the food and cell by means of their mutually attractive haptophorous groups. When thus chemically bound to the cell the food can be elaborated into an integral part of the cell, or it can be used up and thrown off as waste products. That portion of the cell which contains the haptophorous group is called by Ehrlich the "side chain" or "lateral chain" or "receptor" of the cell.

Side chain or lateral chain is a term used in chemistry to designate certain substitution products of the benzene ring. The term is used by Ehrlich to suggest an analogous condition in the cell. Receptor simply indicates that this portion of the cell "receives" the food or other material to be mentioned later.

Ehrlich supposes that a cell is composed of two parts: the side chains and the "Leistungskern" or "Central Group." The central group consists of a great number of complicated molecules whose interaction upon each other and upon the foodstuffs is the chemical basis for all vital phenomena manifested by the cell. The special function of the side chain is to bring food to the cell. Each cell possesses a number of different side chains with affinities for different foods, and, furthermore, at least some of the side chains of one cell differ from the side chains of other cells.

This theory of assimilation was first adopted by Ehrlich in 1897 as an explanation of the mechanism of infection by soluble toxins, such as diphtheria and tetanus, and of antitoxin formation (Ehrlich, Paul: "Die Werthbemessung des Diphtherieheilserums," etc. "Klinisches Jahrbuch," 1897). A little later he extended the theory to explain the mechanism of bactericidal immunity and also to account for all those reaction products which are known as cytotoxins, cytolysins, agglutinins, precipitins, coagulins, etc.

The explanation of infection and immunity is simple if one remembers Ehrlich's assimilation theory. If a toxin such as tetanus toxin is injected into an animal the toxin causes no injury unless it becomes chemically united to some vital cells of the animal. If such union does occur it means that the toxin chances to possess a binding group or haptophorous group with affinity for a corresponding haptophorous group or side chain of the cell. Only after union between the cell and toxin by means of their corresponding groups can the specific action of the toxin be directed against the cell.

Ehrlich assumes that the toxin consists of two parts. One, the haptophorous or binding group, happens to resemble the haptophorous group of some normal foodstuff so closely that it can unite with the side chain of some of the body cells. The second part of the toxin is the specific functioning part. This Ehrlich calls the "toxophorous group" of the toxin. These groups may be independent of each other. Either group may be injured without affecting the other. Ehrlich obtained evidence that the toxophorous group is actually less stable than the haptophorous group. Under various conditions a toxin may lose its power of producing the symptoms of poisoning, while it still possesses its power of uniting. Such a toxin Ehrlich called a "toxoid," that is, a "toxin-like" body. A toxoid is a toxin whose toxophorous group is destroyed while its haptophorous group remains intact.

If a dose of toxin is injected into a naturally immune animal the result is negative, for the toxin finds no side chains with affinity for its haptophorous group. In other words, the toxin is unable to unite with any cells of the experimental animal and one fundamental prerequisite of intoxication is absent.

If, however, the toxin is injected into a susceptible animal, the toxin molecules become bound by the haptophorous groups to the corresponding side chains of the cell, and thereupon the toxophorous group of the toxin acts upon the central group of the cell to produce the phenomena of the specific disease. If the virulence of the toxin is great the animal dies; that is to say, if the chemical energy of the toxophorous group is great, the central groups of the cells of vital organs are injured and thrown out of function and the death of the animal results.

But the toxin may be less virulent. The toxophorous group may have such little energy that the central groups of the cells of the animal are not thrown out of function. In this case the toxin is anchored to the side chain of the cell by means of the haptophorous group, and the toxophorous group causes little injury to the cell. The cell then functions normally except that the side chain occupied by toxin is not free to pick up food. The toxin remains attached to the side chain, for not being a food stuff it cannot be digested and thus removed from the side chain. The side chain thus occupied by toxin is a useless encumbrance to the cell and is accordingly removed as if it were a foreign body, the combined toxin and side chain being thrown off as a waste product.

But the cell requires just such a side chain for the normal process of assimilation. Therefore the cell repairs the defect caused by the loss of its side chain by forming a new side chain whose properties are identical with those of the one that was thrown off.

According to a law formulated by Weigert, tissue formed to repair a defect tends to be formed in excess of the original tissue lost. Ehrlich applies this law to the repair of the side chains and supposes that whereas possibly one side chain is lost, several or many side chains are formed to replace it.

But the cell requires only one such side chain under normal conditions, and all more than one are superfluous. The superfluous side chains are really encumbrances to the cell and are thrown off as waste products.

It is seen that these side chains arise to repair the defect caused by the loss of a pre-existing side chain. The pre-existing side chain was distinguished by having a chemical affinity for a certain foodstuff, and chanced to have the same affinity for a toxin. The newly formed side chains being identical with the ones which pre-existed must, therefore, have the same chemical affinity for the same foodstuff and same toxin.

Such side chains, formed as reaction products of the cell to the toxin and thrown off into the circulation, are the antitoxins. Of course the side chains thrown off into the circulation still retain their affinity for the foodstuff and for the toxin. Enormous amounts of such free side chains or antitoxins may accumulate in the plasma of an animal which then possesses a high degree of antitoxin immunity. If toxin is injected into such an animal, it is picked up at once by the circulating free side chains or antitoxins, union occurring between the mutually attractive haptophorous groups of the toxin and antitoxin. The toxin is thus rendered innocuous, for the means is removed by which it could otherwise unite with the body cells. It is seen that the antitoxin does not necessarily destroy the toxin, but simply neutralizes it by blocking its haptophorous group.

Serum taken from such an immune animal and injected into a susceptible animal confers a temporary immunity (passive immunity) upon the second animal, the mode of action being the same that has just been described. The antitoxic serum must be injected before the toxin has become anchored to the body cells. Otherwise enormous doses of antitoxin are needed and the result is even then uncertain.

Evidently the affinity between the side chain of the cell and the haptophorous group of the toxin is specific, and specific in a chemical, not a biological sense. That is to say, the side chain will not unite with any substance which has not an affinity for the haptophorous group of the side chain, but will unite with any substance possessing such an affinity, whether it be foodstuff, toxin, or other material.

Each cell contains a number of different side chains with affinities for different food materials in the circulation. While one or two side chains of a cell are concerned in the process of intoxication and antitoxin formation, the rest continue to function normally.

Ehrlich's theory explains readily the origin and mode of action of the cytolysins, agglutinins, etc.

If an animal be treated with inoculations of bacteria in doses less than fatal, the serum of the animal acquires several new properties.

If a few drops of the serum are added to a few drops of suspension of bacteria of the species injected, the bacteria lose their motility and collect in clumps and balls, that is to say, they become "agglutinated." Those substances in the serum which produce agglutination are termed "agglutinins."

The serum of the inoculated animal frequently shows another new property. If a few drops of the serum are added to a culture of the bacterium in fluid medium some products of bacterial action dissolved in the liquid are precipitated from solution. These substances in the serum which cause such a precipitation are called "precipitins."

Frequently the serum of the inoculated animal acquires the power of completely dissolving the bacteria. Such a serum is called a "bacteriolytic" serum. The substances in the serum which cause the dissolution of the bacteria are called "bacteriolysins," or less strictly "lysins." The process of disintegration of the bacteria is called "bacteriolysis" or simply "lysis."

The process of bacteriolysis was first described by R. Pfeiffer, and is known as "Pfeiffer's phenomenon." Several valuable additions were made to Pfeiffer's description by Metschnikoff and Bordet. The most important discovery was made by Bordet, who found that it is just as easy to immunize animals against other cells as against bacteria. Bordet inoculated guinea-pigs with the red blood corpuscles of rabbits, and found that the serum of the guinea-pig acquired the power of agglutinating and also of dissolving the corpuscles of the rabbit. These observations have been extended so that now it can be stated as a general law "that the serum of an individual of species A, which has been treated with . . . inoculations of the erythrocytes of species B acquires new properties which enable it to dissolve the erythrocytes of species B" (Sachs, Lubarsch-Ostertag, vii. Jahrgang).

The substances in the serum which cause the dissolution of the red corpuscles are called "hæmolysins"; the serum is "hæmolytic," the process is "hæmolysis."

It is possible to produce sera which will dissolve other cells also. In the literature of the day one finds accounts of "leucolysins," sera which dissolve leucocytes; "nephrolysins," sera which dissolve kidney cells; "hepatolysins," sera which dissolve liver cells, etc.

In the same way there can be produced "haemoagglutinins," etc.

"Precipitins" can be formed by inoculating one animal with the serum of another. "Coagulins" have been produced by inoculating one animal with the milk of another.

An animal is said to be "immunized" when it is treated with inoculations, whether of toxins, bacteria, red blood corpuscles, serum, or any other material, and the animal thus treated is spoken of as an "immune" animal. Thus a guinea pig can be immunized against cholera vibrios, the guinea-pig's serum dissolving the vibrios. The guinea-pig can be immunized against typhoid bacilli, the serum agglutinating the bacilli. A rabbit can be immunized against human serum, the serum of the immune rabbit producing a precipitate in human serum. The goat can be immunized against the red blood corpuscles of the ox, the serum of the immune goat producing lysis of the red blood corpuscles of the ox, and so on.

In all such cases the serum of the immune animal becomes toxic for the species from which material was taken for inoculation. In the last case mentioned the serum of the immune goat is toxic for oxen. A serum which is toxic for the cells of another animal is called a "cytotoxin," though of course cytotoxin includes all other cell toxins also. The general name for the process of dissolution of cells is "cytolysis." Sera which cause the dissolution are "cytolysins," though of course any other substance which produces solution of cells is a cytolysin also. All of these reaction products in the serum of an immunized animal appear to have their energies especially directed against material like that with which the animal was inoculated; hence these reaction products are termed "antibodies."

Much information concerning the process of cytolysis, especially of hæmolysis, has been furnished in recent years by the investigations of Ehrlich and his pupils (see particularly the works of Ehrlich, Morgenroth, and Sachs). In their first researches Ehrlich and Morgenroth worked with the serum of a goat which had been immunized against the red blood corpuscles of a sheep, the goat's serum, therefore, dissolving the red blood corpuscles of the sheep. Subsequently, a great number of different combinations was employed. Ehrlich and Morgenroth corroborated Pfeiffer and Bordet in their conclusion that there are two substances in the serum concerned in producing cytolysis. One of these substances appeared as the result of inoculating or immunizing the animal. It was, therefore, called the "immune body."

Ehrlich and Morgenroth found that the immune body in the serum of the immunized goat readily unites with the red blood corpuscles of sheep. This immune body by itself, however, even when united to the corpuscles of the sheep, produced no change in them. The lysis of the red blood corpuscles resulted only when a second constituent of the serum was added. This substance was, therefore, called "complement," because it completed the action of the immune body.

The immune body was a new constituent of the goat's serum which first appeared after the goat had been inoculated with red blood corpuscles of the sheep. The immune body was quite a stable body with marked resistance to heat, light, and chemical reagents. It possessed the property of uniting with the red blood corpuscles of sheep. This union occurred quickly and even at low temperatures. The immune body had an affinity for the red blood corpuscles of sheep which was specific. This specificity, it was found, was of a chemical nature, as described above. The distinguishing feature of immune body was that when immune body, complement, and red blood corpuscles of sheep were brought together at a suitable temperature (about 37° C.) lysis of the red blood corpuscles resulted.

The complement was a normal constituent of the goat's serum, being neither increased nor diminished by the inoculations with corpuscles of sheep. The complement occurred in normal goats which had not been inoculated. It was also found in the serum of normal sheep and of other normal animals. Complement was a very unstable body with little resistance to heat, light, and chemical reagents. It could not be made to unite directly with red blood corpuscles. Only after the immune body had united with the sheep's corpuscles was it possible to bring about union of the complement, and even then union would not occur at low temperatures. The distinguishing feature of complement was that when complement, immune body, and the red blood corpuscles of sheep were brought together at a suitable temperature, lysis of the red blood corpuscles was produced.

Ehrlich was able to explain in terms of the side-chain theory the various phenomena manifested by the antibodies mentioned in the outline just given. He concluded that there must be several forms of side chain. The simplest form is a side chain whose only function is to unite with the foodstuff, thus bringing the food within reach of the central group of the cell. This form of side chain has been considered at length in describing the side-chain theory of assimilation and of antitoxin immunity.

A second form of side chain is so constructed that it not only unites with the foodstuff but also exerts a certain digestive or enzyme-like action upon it before the central group comes into play. This type of side chain contains two chemical groups: the haptophorous group and the zymophorous or enzyme-like group.

If any inoculated material happens to have an affinity for an haptophorous group of such side chains union occurs. The side chain is thrown off from the cell, new formation, overproduction and setting free of side chains follow according to the requirements of the side-chain theory. The side chains set free in the circulation being identical with the pre-existing side chain, are characterized by having both an haptophorous and a zymophorous group. When such a free side chain or antibody encounters material for which it has an affinity, in the first place, union occurs between the mutually attractive groups, and then the zymophorous group of the side chain exerts its action upon the material.

Agglutinins and coagulins are to be classed as free side chains or antibodies of this order, for they not only unite with substances for which they have an affinity, but also produce definite changes in those substances.

A third type of side chain remains to be considered. Here the side chain possesses both a haptophorous group with affinity for some foodstuff and also a second binding group with affinity for an enzyme-like substance in the circulation. Suitable food molecules unite with the haptophorous group of these side chains, whereupon the second binding group picks up the enzyme-like substance for which it has an affinity, and changes are brought about in the food by this enzyme-like substance.

If inoculated material happens to have an affinity for the haptophorous group of such side chains, union occurs, the side chains are thrown off, new formation and overproduction follow, and the new side chains are set free in the circulation. The free side chains or antibodies, being like the pre-existing side chains, are capable of uniting with two substances: first, the inoculated material; the other, the enzyme-like substance in the serum of the immune animal.

If such a free side chain or antibody encounters material for which it has an affinity, union occurs between the mutually attractive groups, and then the second binding group of the antibody picks up from the circulation the enzyme-like substance, which in turn exerts its action through the antibody upon the inoculated material.

This is the mechanism of cytolysis. The inoculated cells have led to the new formation, overproduction, and setting free in the circulation of certain side chains. These free side chains or antibodies are the immune bodies in the serum of the immunized animal. The enzyme-like substance normally present in the serum of the animal is the complement. If some cells of the sort inoculated are treated with serum of the immunized animal under proper conditions the immune body unites with the cells, the complement unites with the immune body, and lysis of the cells results.

It is not yet definitely settled whether precipitins are antibodies of the second order like agglutinins, or of the third order like cytolysins. Recent investigations indicate that the precipitins are antibodies of the third order.

These three types of side chain suffice to account for all the reaction products thus far investigated. There are many features of the side-chain theory which cannot be entered into in this review. In general it may be said that the chemist's point of view has been adhered to by Ehrlich in dealing with all the complicated phenomena met with in studies in immunity. From what has been said it is evident that the prerequisites of antibody formation are few—a substance inoculated into an animal must possess a chemical group (the haptophorous group) which will unite with the side chain of some cell of the animal. If the cell is not injured and if the inoculated substance is not removed by digestion by the central group, conditions are favorable for antibody formation.

Several other antibodies are known in addition to those already mentioned. By inoculating an animal with ferments it has been possible to produce "antiferments" which are of the same type as antitoxins. By inoculating with a serum rich in agglutinins or coagulins it has been possible to produce antibodies which prevent the action of the agglutinin or coagulin. These substances are termed "antiagglutinins" or "anticoagulins." They are really "anti-antibodies." It has also been possible to produce substances which prevent the action of the complement, *i.e.*, "anticomplements" and substances which prevent the action of the immune body, *i.e.*, "anti-immune bodies."

Many of the substances mentioned above, such as agglutinins, cytolysins, anticomplements, etc., have been found in the serum of many normal animals. Such normal antibodies can be readily accounted for as free side chains.

It has been found that the physical and chemical properties of the immune body and of the complement are subject to quite wide variations, and also that there are great numbers of different immune bodies and complements in the serum of any one animal.

Evidence goes to show that the complement arises from cells in the circulation, probably leucocytes. It has been found also that a certain quite definite chemical substance, lecithin, can act as complement.

It has been possible to apply nearly all of the deductions made from studies with hæmolytic sera to the various infectious diseases and to various animal and vegetable poisons.

There seems to be no fundamental antagonism between the side-chain theory of Ehrlich and Metschnikoff's phagocytic theory of immunity.

In concluding it will be well to give a list of other terms used in the literature of immunity. It has been stated that the complement is the unstable enzyme-like material normally found in certain animals. This material is also spoken of as "addiment," "cytase," or "alexin."

The immune body is also called "amboceptor" (that is, receptor with two binding groups), "substance sensibilisatrice," "präparator," "fixateur," "copula," "desmon," "intermediary body," or "Hilfskörper." The anti-immune bodies are also spoken of as "anti-amboceptors."

Harry T. Marshall.

SIDEROSCOPE.—The use of a magnetic needle for detecting foreign magnetic bodies in the eye was first advocated in 1880 by Thomas R. Pooley, of New York, but the suggestion did not attract much attention until the subject was taken up by Edward Asmus in 1894, who utilized the principle in an instrument which he called a *sideroscope*. Since then several modifications of the instrument have been brought forward, but for practical purposes Hirschberg's model is probably the best. This consists essentially of a magnetic needle suspended by a vertical thread, to which is attached a small mirror. The deflections of the needle produced by a foreign body in the eye of a patient is indicated by a beam of light from a lamp which is reflected by the mirror upon a graduated scale. The chief disadvantage of the instrument lies in its instability, for which reason it can be used with success only in places free from vibration. While it is quite delicate, many ophthalmologists claim that it is entirely unnecessary where Haab's giant magnet and an *x*-ray apparatus are available. *Frederick Herman Verhoeff.*

SIDEROSIS.—Ordinarily this term is used to designate the pigmentation of the lungs produced by the inhalation of any sort of metallic dust, but strictly it should refer to the deposition of iron pigment alone in any of the tissues of the body. A full account of siderosis used in the former sense will be found under *Pneumokoniosis*. True siderosis is usually due to the breaking down of the red corpuscles of the blood, and is best spoken of as *hæmatogenous siderosis*. This takes place to some extent in many chronic diseases, but especially in pernicious anæmia, and involves particularly the liver, spleen, bone marrow, and kidneys. It also occurs as the result of the disintegration of hemorrhages, as is the case, for instance, in chronic passive congestion of the lungs, and not infrequently in tumors. For this reason tumors should always be subjected to the test for iron before a conclusion is drawn as to their melanotic nature.

A condition of considerable importance in ophthalmology is *siderosis bulbi*, which is due to the presence of iron within the eye that has lodged there as the result of an injury. This is of little importance where the severity of the injury has been so great as to destroy sight at once, or where it has given rise to panophthalmitis, but not infrequently a small bit of iron may penetrate the globe without producing much damage or setting up serious inflammatory disturbances. Under these conditions the iron gradually disintegrates, and minute particles of iron rust are carried to various parts of the eye, especially the iris and retina, which take on a brownish-red color. In the specimens examined by the writer, the iron has been deposited in the form of small pigment granules, which are always found within cells. They are not confined to any special type of cell, though the connective-tissue cells of the iris stroma and the pigment cells of the retina, including those over the ciliary body and iris, seem to take them up most freely. Both the circular and radial muscle fibres of the iris, however, take them up, as do also to some extent the ganglion cells and nuclear bodies of the retina. The connective-tissue cells about the canal of Schlemm, as might be expected, are markedly involved. The cornea does not seem to be involved unless iron particles have lodged in its stroma, in which case the corneal corpuscles may become packed with iron pigment to such an extent that the cornea assumes a rust color. The epithelial cells beneath the lens capsule may also take up the pigment. The writer has never seen the choroid involved, nor the optic nerve, though the disc may be pigmented. The iron pigmentation of the retina leads to atrophy of the latter, as is manifested subjectively by night blindness, contraction of the visual field, and finally total blindness. Siderosis bulbi, however, does not always result when a particle of iron remains in the eye, because in many cases the foreign body is thoroughly encapsulated in connective tissue. In one of the writer's specimens the eye became intensely pigmented within three years after the injury, and in this case the foreign body was not encapsulated but was simply adherent to the retina, where it had sunk down and come in contact with it below. Siderosis bulbi can also be hæmatogenous in origin, sometimes resulting from an intraocular hemorrhage. In order to distinguish this from the siderosis dependent upon the disintegration of a foreign body, von Hippel applies the term *xenogenous siderosis* to the latter. *Siderosis conjunctivæ* may be produced by the long-continued use of sulphate of iron as a collyrium. The best differential method of staining histological sections for iron is to place them for six hours in a two-per-cent. solution of equal parts of potassium ferro- and ferricyanide, and then in acid alcohol for six hours. In this way both the ferrous and ferric salts give a beautiful blue reaction.

Frederick Herman Verhoeff.

SIDONAL, piperazine quinate, is a compound designed to combine the solvent power of piperazine for uric acid with the power of quinic acid to restrain uric acid formation. Blumenthal and Levin found the compound to reduce the excretion of uric acid and to increase that of hippuric acid. Bardet, in three cases of gout, administered 3–5 gm. (gr. xlv.–lxxv.) a day, and tested the urine twice a month; there was a moderate but steady decrease in uric acid. Salfeld speaks highly of the remedy in gout, but obtained no effect in a case of acute articular rheumatism. F. F. Ward, of New York, applied the remedy in various cases with gouty, rheumatic, or neuralgic pains. In those cases with excessive secretion of uric acid there was marked amelioration, and in all other cases no effect. The dose of sidonal is 1 gm. (gr. xv.) several times a day. Its combination with lithium citrate is called "urosin."

"New sidonal" is described by Huber and Lichtenstein as quinic anhydride. It is given for gout in dosage of 2.5 gm. (gr. xl.) a day.

W. A. Bastedo.

SILICOSIS.—The term applied to the pulmonary condition arising from the inhalation of *quartz dust.* The histological changes and the symptomatology are identical with those of *chalicosis*, or "marble-cutter's lung." Silicosis is of much less frequent occurrence than the latter condition, and is seen chiefly in those parts of the country in which mining, crushing, and stamping of quartz ores are carried on ("miner's consumption"). In granite-workers silicic dust is deposited in the lungs in association with the dust of the other constituents of the stone. The condition of silicosis may also be seen in the lungs of individuals exposed to silicic dust, in such occupations as the crushing of flints in glass manufacture, polishing and cutting of rock crystal, agate, etc. It has been said that the symptoms of silicosis develop more rapidly than those of chalicosis, and as a rule are more severe, for the reason that the quartz dust is more irritating and less capable of solution by the body juices than is dust composed of calcium carbonate. The clinical picture of silicosis is that of a fibroid pneumonia, and, as secondary tuberculosis is of very frequent occurrence, the final course of the disease is usually that of a fibroid tuberculosis. (See also *Pneumonokoniosis*).

Aldred Scott Warthin.

SILVER.—I. GENERAL MEDICINAL PROPERTIES OF COMPOUNDS OF SILVER.—In medicinal dosage the most important effect that follows persistent internal medication with silver is the tendency to a bluish-black discoloration of the skin and mucous membranes. This staining shows first on the mucous membranes, so that by inspection of the inner surfaces of the lips and of the fauces, during a course of medication by silver, and by stoppage of the medicine upon the first beginning of a bluish discoloration of those parts, no serious risk of staining of the skin need be incurred. As a rule, efficient dosage with silver can be maintained for from one to three months before coloration begins. In overdosage silver is a constitutional poison, impairing nutrition generally, and deranging the nervous system particularly. Therapeutically, impregnation of the system with silver tends to oppose, albeit feebly, the onward march of certain diseases of the nervous system, such as epilepsy and tabes dorsalis. But in the more intractable of these diseases, such as tabes, the influence is so slight as to be of no value—if, indeed, it exist at all—and in epilepsy other remedies are far more potent. The use of silver for constitutional effect is, therefore, in modern practice, quite abandoned.

Locally, the effects of silver compounds differ with the individual preparations according to their solubility, and will be described in connection with the several compounds themselves.

II. THE COMPOUNDS OF SILVER USED IN MEDICINE.—These comprise the *oxide*, *iodide*, and *nitrate*. The *cyanide* is also official in the United States Pharmacopœia, but for pharmaceutical purpose only.

Silver Oxide: Ag_2O. Silver oxide is official in the United States Pharmacopœia as *Argenti Oxidum*, Silver Oxide. It is a heavy, dark brownish-black powder, odorless, but of a metallic taste. It is liable to undergo reduction upon exposure to light. It is very slightly soluble in water and is insoluble in alcohol. It should be kept in dark amber-colored bottles, protected from the light. This oxide readily yields its oxygen in presence of oxidizable matter, and hence should not be triturated with any such material. It dissolves in water of ammonia. From its comparative insolubility this compound has little local effect, but when swallowed, probably through chemical conversion, it is capable of absorption, and exerts the constitutional effects of silver such as they are. In such operation the oxide is thought to be less prone to discolor the skin than the nitrate, but it is certainly not wholly innocent of this tendency. Upon the stomach and bowels silver oxide has quite a marked potency to allay irritability, tending to quell vomiting, even in such complaints as ulcer and cancer of the stomach, and to control diarrhœa when arising as a reflex of nervous irritation. The principal employment of the medicine is in such disorders of the digestive apparatus. The average dose is about 0.06 gm. (gr. i.), best given in powder or capsule. The pill form is bad, because of the deoxidation of the compound by the organic matter of the excipient, which reaction may even be attended by explosion. Gum arabic is recommended as the least objectionable excipient.

Silver Iodide: AgI. The salt is official in the United States Pharmacopœia as *Argenti Iodidum*, Silver Iodide. It is a heavy, light yellow powder, which, when pure, is not affected by light other than to change color to a greenish-yellow. It is insoluble in water or alcohol. It should be kept in dark, amber-colored bottles, protected from the light. Silver iodide is, medicinally, substantially a duplicate of the oxide, and may be used for the same purposes and in the same dose.

Silver Nitrate: $AgNO_3$. This, by far the most important compound of silver, is official in the United States Pharmacopœia in three conditions, namely, in crystals, in cylindrical sticks moulded by fusion, and in similar sticks in admixture with equal parts of potassium nitrate.

Argenti Nitras, Silver Nitrate. This title signifies the salt in crystals. These crystals are small, transparent rhombs, originally colorless, but gradually becoming grayish-black on exposure to light and air. They are odorless, but have a strong metallic taste. They dissolve freely in water, in twenty-six parts of cold alcohol, and in five parts of boiling alcohol. When heated to about 200° C. (392° F.), the crystals fuse to a faintly yellow liquid, which, on cooling, congeals to a purely white, crystalline mass. Silver nitrate should be kept in dark amber-colored vials protected from the light. These crystals constitute the purest form of the nitrate, and are used for internal giving or for the making of solutions.

Argenti Nitras Fusus, Moulded Silver Nitrate, "Fused Nitrate of Silver," "Lunar Caustic." The crystals are melted by heat, and the fused salt poured into moulds where it sets on cooling. But inasmuch as the pure nitrate is, when fused, inconveniently brittle, the Pharmacopœia provides for a trifling admixture of silver chloride, which is a tough compound. To this end about four per cent. of hydrochloric acid is added to the melted crystals, whereby a small portion of the nitrate is converted into chloride. Reaction having ceased, the mixed mass is ready for moulding. Lunar caustic is cast in narrow cylindrical sticks, which are hard, brittle, and, when freshly made, white in color. As commonly found, however, they are gray, or even blackish, through chemical reaction with matters present in the atmosphere. Fused nitrate of silver should be used only for its legitimate purpose, that of external application. The sticks should be kept protected from the light.

Argenti Nitras Dilutus, Diluted Silver Nitrate. Silver nitrate and potassium nitrate, the latter in double the quantity of the former, are melted together by heat and the fused mass moulded into sticks like those of the simple moulded silver nitrate. The sticks of the diluted nitrate resemble those of the pure nitrate except that they are granular rather than fibrous in texture. They are commonly called "mitigated sticks" of silver nitrate. They should be kept protected from the light. The sticks dissolve freely in water and possess the same properties as the undiluted lunar caustic, only in milder degree. They are used only for local application.

Silver nitrate differs from the oxide and iodide in the essential particular of free solubility, on which property depend the most valuable medicinal virtues of the salt. The most important reactions of the nitrate are that its solutions are precipitated by soluble chlorides to form the very insoluble salt, silver chloride. This reaction is one of the most delicate in chemistry, and since traces of chlorides are present in almost all natural waters, the use of distilled water is necessary for solutions of silver nitrate, if a clear, bright solution be desired. Silver nitrate also reacts on organic matter generally, suffering decomposition, and forming, with the organic substance, compounds insoluble and acquiring a rusty brownish black color under the action of light. Hence sticks of lunar caustic grow gray and black on the surface by keeping, by reaction with the organic dust of the atmosphere, and solutions of silver nitrate deposit a fine black sediment, and stain textile fabrics and skin. The stain on the skin, if recent, can be removed fairly well by rubbing with a moistened lump of potassium cyanide, and washing—always remembering the very irritant and poisonous character of such cyanide. But if the stain be old, and fixed by exposure to sunlight, the cyanide fails, and the following means may be resorted to: Moisten the stains, drop on them a little tincture of iodine, and then wash in a six-per-cent. solution of sodium hyposulphite. Or, very efficient, mix in a saucer a few bits of iodine with a little water of ammonia; rub the stains quickly with the resulting preparation, and immediately wash both skin and saucer while they are still wet. This latter precaution is necessary, since the compound of iodine and nitrogen produced by the mixture of chemicals spontaneously explodes upon slight agitation when dry. Other reactions of silver nitrate are its precipitation by sulphuric, hydrosulphuric, phosphoric, hydrochloric, and tartaric acids and their salts; by the alkalies and their carbonates, lime water and the vegetable astringents, and arsenical and albuminous solutions.

Silver nitrate is an irritant astringent, with also the peculiar specific effects of silver compounds already detailed, viz., the allaying of gastric irritability, and the induction of certain constitutional control over nervous disease. The local effects are the more important, and are as follows: The salt readily combines with albumin to make an insoluble compound, the albuminate of silver; hence, when in strong solution or in solid stick, its application to the surface of a mucous membrane or of granulation tissue produces a white streak of cauterization, which, by the insolubility of the compound formed, limits the action of the caustic to the production of such shallow slough. Concentrated applications to the skin speedily blacken the epidermis, and, more slowly, raise a blister. In solutions less than ten per cent. in strength the salt is hardly caustic, but acts only as an irritant astringent. When swallowed, quite small doses act locally like the oxide, while large produce irritant poisoning. Therapeutically, local applications of silver nitrate judiciously made have a marked tendency to promote absorption in such tissues as are capable of undergoing this process; to induce healing; to limit and abate the catarrhal process; to destroy skin parasites, though not very searchingly; and to neutralize the virulence of specifically noxious pus.

The medicinal uses of silver nitrate are such as may be deduced from the foregoing. Internally the medicine may be given, for constitutional or local effect, in doses of from 0.015 to 0.03 gm. (from about one-fourth to one-half grain) in pill or solution. In neither way of giving does the salt probably reach the stomach as nitrate; for, if in solution, a medicinal dose must almost certainly be decomposed in the swallowing, and, if in pill, be acted on similarly by the necessary organic matter of the excipient. To obviate this effect as far as possible in the case of pills, it is advised that bread-crumb be particularly avoided as an excipient, because of its containing a soluble chloride (common salt) as well as organic matter, and that some vegetable extract, or a dry powder made sticky by a minimum of gum, be selected. In any case the crystallized silver salt should alone be prescribed. Externally, silver nitrate may be used as a caustic, but only where a superficial effect is wanted, as for the destruction of the lining membrane of a cyst. The fused stick is in such cases used, its moistened surface being swept over the surface to be destroyed. More common is the application to promote absorption, as in case of exuberant granulation tissue or trachoma bodies; to determine healing, as in unhealthy ulcers, or to shorten and abate the course of a catarrh. For such purposes various strengths of the nitrate are used, from application of the pure or diluted sticks of lunar caustic to that of solutions of not more than the one-fifth of one per cent. strength. To determine absorption the stronger applications are necessary, to control catarrhs the weaker; but in all cases care should be taken not to overdo the matter, and, by too strong or too frequent application, actually to interfere through excess of irritation with healing or with resolution. In the case of catarrhs, moreover, the remedy should not be used at all until the second stage of the process is reached, as betokened by the establishment of the catarrhal secretion and abatement of the initial pain or sensitiveness. Then, too, the strength of the application should be adjusted to the different degrees of sensibility of the different mucous membranes; for while the comparatively insensitive membranes, such as those of the fauces or vagina, may take a five-per-cent. solution, or even stronger, hardly more than the one-tenth of this strength can be applied without undue irritation to the nasal passages or to the male urethra. When a very brief action is wanted, the application of silver may be followed immediately by one of a solution of common salt, which salt immediately precipitates all excess of nitrate as the insoluble, and therefore inert, compound, silver chloride.

Silver Cyanide: AgCN. This salt is official in the United States Pharmacopœia as *Argenti Cyanidum*, Silver Cyanide. This salt is an insoluble white powder, not used in medicine, and official only for the making, by the pharmacist, of diluted hydrocyanic acid.

Besides the foregoing, a number of unofficial preparations of silver deserve brief notice.

Silver Vitellin, Argyrol.—This remarkable compound has recently been prepared and proposed for medical use by Barnes and Hille, of Philadelphia (*Medical Record*, May 24th, 1902). A salt solution of vitelline, a derived proteid obtained from gliadin, is precipitated by silver nitrate. Such precipitate—silver vitelline—properly dried, appears as a dark-brown powder. The substance contains thirty per cent. of silver, about half the amount contained in silver nitrate, and is remarkable for being extremely soluble in water, while at the same time it does not precipitate albumin or sodium chloride, and is wholly unirritating. Its solution also penetrates albuminoid tissues very readily and thoroughly. Silver vitelline thus possesses all the desiderata for an ideal silver preparation, and has been used with great success as a local application in inflammations of the mucous membrane of the eye, ear, nose, vagina, urethra, and bladder. It is employed in aqueous solution ranging in strength from one-tenth of one per cent. to twenty-five per cent. and upward, according to the character and sensitiveness of the part. Even a ten-per-cent. solution applied as an injection in acute gonorrhœa produced no irritation (Christian).

Colloidal Silver (Soluble Silver, Collargol).—This is a bluish green substance obtained by precipitating with silver nitrate a mixed solution of ferrous sulphate and sodium citrate. Collargol contains 97.2 per cent. of silver, dissolves in 25 parts of water forming a dark reddish-brown solution, and is easily decomposed. Its aqueous solution, on standing, deposits a small sediment of insoluble silver.

Collargol, introduced into the general circulation, has been declared by Credé and others to exercise a remarkable curative power over the conditions of general septic infection, whether by action on the micro-organisms themselves or on their toxins is not clear. At the same time the remedy is non-poisonous and, being rapidly eliminated after absorption, does not produce argyria. The only untoward effect observed has been a slight chill and rise of temperature, but even this is not seen if (using by intravenous injection) care is taken that the solution be free from sediment.

Collargol may be administered by inunction or by intravenous injection. For the latter method a carefully prepared, freshly made solution in distilled water is to be used, of a strength of one-half to one per cent. If a sediment forms, the supernatant liquor must be decanted. Of such a solution from half a fluidrachm to five fluidrachms may be injected directly into some superficial vein once or twice daily, or every two or three days. The more common method of administration, however, is by inunction. For this purpose a fifteen-per-cent. ointment is used, of which the quantity of from thirty to forty-five grains is rubbed thoroughly into the skin of the inner side of the arms or thighs, or of the back, from one to three times daily. Collargol ointment decomposes readily and should not be exposed to the air. An ointment should not be used that shows white crystals on the surface, or that fails to color the skin black on inunction. An ointment having the official sanction of Professor Credé is on the market under the title "Unguentum Credé." This ointment contains fifteen per cent. of collargol in a mixture of lard, wax, and benzoic ether.

Silver Sulphocarbolate, $C_6H_4(OH)SO_3Ag$. This compound occurs as a white crystalline powder soluble in water. It contains twenty-eight per cent. of silver. If exposed to light and air it decomposes spontaneously. It has been proposed as a substitute for silver nitrate because non-corrosive.

Silver Citrate: Itrol, $Ag_3C_6H_5O_7$. This compound is a fine, dry powder, without taste or smell, very slightly soluble in water. Its solution is immediately decomposed by organic matter. Like silver vitelline, it is non-irritant and penetrating, and has been proposed as a surgical disinfectant and for injection in gonorrhœa and cystitis. The strength of solution ranges from 1 to 4,000 to 1 to 8,000.

Silver Lactate: Actol, $AgC_3H_5O_3$. This compound is a white powder, without taste or smell, and soluble in from fifteen to twenty parts of water. It is a powerful germicide, and penetrates tissues, although decomposed by contact with the same. It is used as a surgical antiseptic, and strong, even saturated solutions may be applied to infected parts. Ordinary strengths are 1 to 1,000 or 2,000 parts of water.

Silver Quinaseptolate or *Oxy-chinolin-sulphonate: Argentol,* $C_9H_5N.OHSO_3Ag$. This compound is a yellow powder, slightly soluble only in water. In contact with septic substances it decomposes into oxyquinolin and metallic silver. It is used in surgery as a dusting powder, or applied in ointment (1 or 2 parts to 100 of ointment) or in solution, 1 to 3 parts to 1,000 of water.

Argentamin.—This name is given to a solution of silver phosphate (10 parts) in a ten-per-cent. aqueous solution of the organic base ethylendiamin. It is a clear fluid, strongly alkaline, and is devised to give a non-poisonous and unirritating antiseptic solution which shall not precipitate albumin. It is diluted one thousandfold for use.

Argonin.—This name is given to a body obtained by precipitating with alcohol a mixed solution of silver nitrate and a sodium compound of casein. Argonin is a white powder, neutral in reaction; insoluble in cold water, but readily soluble in warm or albuminous water. Solutions must be kept away from exposure to light. It has been used in gonorrhœa in solutions of from 1 to 7 parts in 1,000 of water.

Largin.—This name is given to an albumin compound of silver occurring as a gray powder soluble in 9 parts of water. Largin is powerfully germicidal while non-irritating, and is not precipitated by albumin or sodium chloride. It has been used in gonorrhœa in solutions ranging in strength from one-fourth to one and a half per cent.

Protargol.—This name is given to a silver albumose containing eight per cent. of silver. It is a yellow powder, freely soluble in water; unaffected by heat, albumin, or sodium chloride in weak solution, and wholly unirritating. It may be used with great freedom as a local application, being employed in solutions varying in strength from five to twenty-five per cent.

Edward Curtis.

SILVER, POISONING BY.—See *Argyria.*

SIROLIN is a ten-per-cent. syrup of thiocol. (See *Thiocol.*) *W. A. B.*

SITKA HOT SPRINGS.—Location on Baronoff Island, Alaska, sixteen miles south of Sitka. They are reached from Sitka by boats only. Four houses have been built at this place, three with bath-rooms attached. In 1860 a hospital for rheumatism and skin and blood diseases was opened by the Russian-American Company. The baths were found to be very beneficial in syphilitic affections. The Indians have resorted to the springs for many years. They are about thirty feet above the sea-level, and distant from salt water about fifty yards. The springs are four in number, but the rate of water flow is unknown. The temperature of the water is 120° F., and it is said to contain sulphur, iron, manganese, and chlorine. The weather in this region is generally clear during the summer months, with a temperature ranging from 60° to 80° F. The spring and fall seasons are rainy, and the winters cold and cloudy, the temperature varying from zero or a little below to 40° F. The spring season is considered preferable for visiting the springs. Other hot springs are located on Chickagoff Island, about eighty miles from Sitka, but as yet no name has been given to them. Little is known concerning them, except that they have some reputation among the Indians in the same diseases as those mentioned above. Within half a mile of Sitka, on a road called Davis Avenue, there is an iron spring flowing from a rock. It has not been analyzed, but it was formerly esteemed by the Russians for its tonic properties.

James K. Crook.

SKAGG'S HOT SPRINGS.—Sonoma County, California.

Post-Office.—Skagg's Springs. Hotel and cottages.

Access.—From Tiburon Ferry, San Francisco, 7:40 A.M. and 3:30 P.M.; arrival at Geyserville, where connection is made with stage for springs at 11 A.M. and 7 P.M. Connections from Sacramento by Carquinez and Santa Rosa Railroad to Santa Rosa, thence viâ San Francisco and Northern Pacific Railroad to Geyserville.

Skagg's Hot Springs are pleasantly located in the Coast Range Mountains, in a picturesque spot, nine miles west of Geyserville and twenty miles east of the coast. The surrounding mountains are clothed with every variety of California verdure, and they abound with trout streams. Many varieties of game are also found, including bear, deer, grouse, and quail. We are informed that a new road from the springs to the coast has recently been constructed, making accessible the Gualalla River, a widely celebrated trout-fishing stream. The springs, four in number, yield fifteen gallons per minute, the water having a temperature of about 120° to 140° F., and a somewhat pungent, agreeably alkaline taste. Excellent bathing facilities have been provided. Analyses have been made by Prof. Eugene W. Hilgard and Dr. Winslow Anderson, which show no material difference in their results. That of Professor Hilgard is as follows:

One United States gallon contains (solids): Sodium chloride, gr. 5.90; sodium bicarbonate, gr. 161.27; sodium biborate, gr. 26.47; magnesium carbonate, gr. 11.11; calcium carbonate, gr. 2.20; silica, gr. 7.02; sodium iodide, potassium chloride, potassium sulphate, potassium iodide, magnesium sulphate, ferrous carbonate, barium carbonate, lithium carbonate, strontium carbonate, alumina, and organic matter, very small quantities. Total solids, 214.80 grains.

Free carbonic-acid gas, 124 cubic inches.

The waters here are very useful in rheumatism, neuralgia, sciatica, etc., as well as in affections involving the bladder and kidneys. They are highly recommended by medical men on the coast, and the proprietor has determined to keep the resort open all the year.

James K. Crook.

SKIN, ANATOMY OF.—See The Appendix.

SKIN, FUNCTIONS OF.—The functions of the skin may be conveniently classified as follows:

I. Protective; II. Excretory; III. Temperature regulating; IV. Absorptive; V. Sensory.

I. Protective Functions of the Skin.—As an outer covering of the body, the skin protects the deeper parts (*a*) from evaporation, (*b*) from excessive wear and tear, and (*c*) from mechanical violence. The outer layer of the skin (epidermis) has a structure like horn, and forms a shell over the entire body. The deeper layers of the skin and the subjacent tissues and organs are constantly bathed with lymph, which must be renewed from the blood, and if it were not for the horny covering of the epidermis the lymph would evaporate from the surface more rapidly than it could be renewed, and the nerve endings and other delicate structures in the deeper layers would be thrown out of function. The secretion of the sebaceous glands (oil glands), by keeping the epidermis slightly permeated with oil, is of material aid in preventing this evaporation. It is very important that some water should be evaporated from the surface of the skin, but this is provided for through the sweat glands, whose function will be considered in Sections II. and III.

The epidermis of the skin is obviously a great protection against wear and tear, which the softer parts, underneath, would not stand. It varies in thickness in different parts of the body, being thickest in those parts which are most used in such a manner as to wear them away; for example, the palms of the hands and the soles of the feet. In some places it is reinforced by nails and by hair, which are in structure simply modified epidermis. As the outer layer of epidermis is worn off it is replaced from the deeper layers.

Lying immediately under the epidermis comes the dermis (cutis vera, true skin), and beneath this is the subcutaneous connective tissue (superficial fascia). In this connective tissue there is a large amount of fat in an ordinarily well-nourished individual. This fat, in proper quantity, not only covers the angularity of muscles and joints, thus giving beauty to the figure, but it forms a protective pad, which breaks the force of blows, prevents the penetration of foreign bodies (as in puncture wounds and cuts) to important deeper lying structures (arteries, nerves, etc.), and otherwise adds to the protective function of the skin. As a protection against mechanical violence the hair often plays an important part, as on the scalp.

II. The Skin as an Excretory Organ.—The chief excretions of the skin are the sebum (oil) and the sweat. In many of the lower animals the skin is an important respiratory organ—a frog will live for days with his respiratory centre destroyed—and this function is not entirely lost in man. It is certain that some carbon dioxide is given off by the skin of man, and it is probable that a very slight amount of oxygen may be taken in, but in either case the amount is so small that for practical purposes it may be disregarded.

The sebum (oil) is secreted by the sebaceous glands, which are found all over the skin with the exception of the palms of the hands and the soles of the feet. Where hairs occur the sebaceous glands commonly empty into the hair follicles. One of the chief functions of the sebum is to keep both the hair and the skin from becoming harsh and brittle.

The sweat glands are the most important excretory organs of the skin, but it is a common error to suppose that *in health* they play a *prominent part* in the elimination of waste products, such as urea and allied substances. Chemical analysis shows that the sweat contains about 98.8 parts of water and 1.2 parts of solids. Of these solids common salt (sodium chloride) is the most abundant—the salty taste of sweat is probably known to every one. By weight there are only 8 parts of urea to 10,000 of sweat, and sometimes it is present merely in traces, while the amount of urea in urine is about two per cent. In disease, however, this relation is greatly altered, and when the kidneys refuse to secrete nitrogenous waste products, the sweat glands take up this function to a large extent, so that they form the great safety valve against what is commonly called uræmic poisoning. By far the most important function of the sweat is to furnish the surface of the skin with water, which, by its evaporation, produces a loss of heat from the surface of the body. This will be more fully taken up under the temperature-regulating functions of the skin. The quantity of sweat varies greatly. It depends upon the temperature of the surrounding air, muscular activity, the amount of liquid drunk, the activity of the kidneys, etc.

The secretion of sweat is intimately under the control of the nervous system. The effect of certain mental states (such as fear) upon sweating is proverbial. There is a definite set of secretory nerves to the sweat glands. The course of these fibres has been fairly well mapped out. The best experimental evidence is also in favor of the view that there are sweat centres in the spinal cord, and that these are all dominated by a chief sweat centre in the medulla oblongata. This arrangement helps us to understand the localized sweating in certain nervous diseases; and the moist skin, in the crisis of fevers, can best be interpreted as a return of the centres to normal action after a temporary suspension of activity.

When the skin of an animal is varnished, the animal in most instances dies. A case is on record in which a boy was covered with gold foil in order to represent an angel at a religious ceremony, and lost his life as the result of such coating. These cases are often quoted as showing the baneful effects of retention of the perspiration with the poisonous waste products which it was supposed to contain. This explanation, however, is erroneous. In numerous animals, experimented upon by varnishing, it was found that the body temperature falls with great rapidity, that they may be kept alive for a long time by artificial warmth, and that there is no such accumulation of poisons in the blood as would be called for by the old theory. The cause of death is the excessive and rapid loss of heat from the skin.

III. Temperature-Regulating Function of the Skin.—This is certainly one of the most important functions which the skin has to perform. The temperature of the body depends upon two factors, viz., the heat produced in the body, and the heat lost from the body; or, as they are generally called, heat production and heat dissipation. Each of these is controlled by the nervous system, and each may vary independently of the other. The constant temperature of warm-blooded animals depends upon a constant balance between these factors. For a fuller discussion of this question, see article *Calorimetry*, this Handbook, Vol. II., especially pp. 567–570.

The skin is the chief seat of heat dissipation. This is regulated by the nervous system in two ways, viz., through the blood supply to the skin, and by perspiration. When heat dissipation is to be increased, the vaso-motor centre, acting through the vaso-dilator nerves to the blood-vessels of the skin, causes these vessels to dilate, and thus to receive an extra supply of blood. The skin becomes flushed and warm, and a large amount of heat is radiated off. On the other hand, when heat dissipation is to be reduced the vaso-motor centre acts through the vaso-constrictor nerves to the vessels of the skin, causing their calibre to diminish. The blood is driven from the skin to the deeper parts of the body; the skin becomes pale, or blue, and cold and the radiation of heat from the surface is consequently diminished.

The vaso-motor centre responds readily to impulses reaching it through afferent nerves and is also probably capable of being stimulated by changes in the temperature of the blood itself, so that it forms a self-regulating machine for controlling heat dissipation, and is probably the most delicate mechanism involved in maintaining the temperature of the body constant. For a more detailed discussion of vaso-motor nerves, containing much that has a direct bearing on vaso-motors to the skin, the reader is referred to the article *Circulation of the Blood*, this Handbook, Vol. III., especially pp. 115–118.

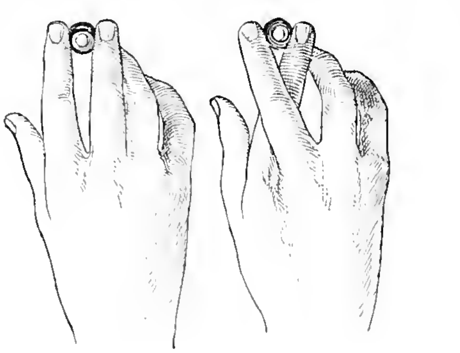
As an important adjuvant to vaso-motor changes in the skin, and their influence on body temperature, we have the sweat glands. These are directly under the control of the nervous system, and are commonly called into activity at the same time that the vessels of the skin are dilated. This relation is so pronounced that for a time it was contended that the blood supply was the cause of their secretion. The question was settled, however, by the simple experiment of stimulating the sciatic nerve in an amputated leg (cat), and observing that drops of sweat appeared on the balls of the feet; though, of course, the blood pressure was *nil*, thus proving that true secretory nerve fibres to the sweat glands exist. The sweat centres are therefore important regulators of the body temperature.

The sweat glands are always in a state of greater or less activity. Most of the time the sweat evaporates as soon as it reaches the surface, and is not perceived by us. This is commonly called insensible perspiration. The amount thus evaporated from the entire surface of the body in twenty-four hours may be considerable. Some have estimated it as high as two litres, though this is probably excessive. Half that amount would be a fairer average. When much heat is produced in the body, as during muscular work, or when the air about us is hot, the quantity secreted may be several times as great. In this case the amount of heat lost through the warm sweat which rolls off the body is considerable, but the main loss of heat is always by evaporation. In the dry hot skin of certain fevers, the trouble is probably in the nervous system (involving the sweat centres), and the lack of sweat and evaporation helps materially to keep up the fever temperature (see article *Calorimetry*, § 6).

IV. Absorptive Function of the Skin.—Under ordinary circumstances the skin absorbs practically nothing, so that from a physiological standpoint it might be disregarded; from a practical standpoint in clinical medicine its absorptive powers are of great importance, especially as a channel for the administration of drugs. It is commonly stated that medicines injected hypodermically will produce their effects four or five times more rapidly than when given by the mouth, when the skin and the stomach each exhibit their normal powers of absorption; but far more important than this is the *certainty* of absorption by the hypodermic method. The stomach is very treacherous as an absorptive organ. In many cases its absorptive function seems to be suspended for hours, and is then suddenly resumed with full vigor; repeated doses of strong medicines fail to produce any effect, and then without warning the patient exhibits symptoms of an overdose, amounting even to poisoning. When given by the hypodermic method the medicine is thrown into the subcutaneous tissue where the absorption takes place by the blood capillaries. When the skin is used for the absorption of drugs by inunction, the material to be absorbed is finely divided and rubbed up with some fat. The fat penetrates the skin and carries the drug with it. The old method of blistering the skin to raise the epidermis, and applying the drug to the raw surface for more ready absorption, has now been replaced by the hypodermic method.

V. Sensory Functions of the Skin.—A superficial view of the sensory functions of the skin would make them appear to be manifold and complex, though a more careful study will reduce them to compounds of several simpler senses. In order to understand this a certain knowledge of the central nervous system is absolutely necessary. In attempting to get at them from a skin standpoint merely, we should be very much in the position of one who would try to study the electrical call apparatuses of a great city, and who would consider only the fire-alarm boxes, the police-patrol boxes, the telephones, etc., without going into the engine houses, the police stations, and the telephone central offices to see how the calls were received and how they were treated there. It is, therefore, necessary to remember that the nerves from the skin communicate with centres in the nervous system, just as the wires referred to above run to definite offices. These centres are in communication with each other, and the effect of a nervous message from the skin may be simple or complex according to the centres which are called into activity. Again, it must be remembered that what we call a "sensation" is a function of the brain centres and not of the skin which contains the call-box or sending organ. Properly speaking, there is no sensation in the skin; it is entirely in the brain. The brain centres *interpret* the receipt of a message from the skin in accordance with their *experience*, and they act accordingly. This often gives rise to sensory illusions, as is illustrated by Aristotle's experiment. If a small round pebble be held, as shown in Fig. 4299, position A, we feel only one pebble; but in position B, while we know from sight that we have only one pebble, we "feel" two. This is especially marked if we rotate the pebble. The explanation is that we have never, as the result of experience, had a small round surface touch the thumb side of the index finger and the outer side of the middle finger at the same time, unless there were two small round bodies to furnish the touching surfaces, so we *interpret the message* received by the brain in accordance with the *past experience* of the *receptive centres*. After the amputation of a limb the patient often has sensations of pain, of heat or cold, of tingling, of numbness, etc., "in the amputated member." This is due to irritation of the nerve in the stump. A certain message reaching a certain centre has always meant a certain condition in the part where that nerve formerly ended, and he continues to interpret the receipt of such a message as he had always done before.

The compound character of the sensations referred to the skin may be illustrated by the following example: If we touch a knife-blade to our finger, we may feel simply a gentle touch or pressure, or we may perceive that it is cold or hot, or that it is rough or smooth. If we draw it along, we perceive the sense of motion and



A *B*

FIG. 4299. Aristotle's Experiment.

notice whether it is sharp or dull. If it cuts we have the added feeling of pain. Touch (including pressure), heat, and cold, are generally regarded as simple special senses, because they obey laws which hold good for other special senses, have definite areas on the skin which, when stimulated, produce a definite sensation, and probably have definite nerve fibres and end organs which belong to them exclusively, and more or less definite cerebral centres which receive the impulses over these fibres.

A *B* *C*

FIG. 4300.—Chart of Portions of Palm of Left Hand, showing the Distribution of Sense Spots for Touch, for Heat, and for Cold. In *A* the black spots mark the areas on which touch can *not* be perceived. In *B* are shown the areas which may be stimulated by heat. The degree of sensitivity is marked by the shading; the black areas are most sensitive, the line-shaded next, the dotted next, and the blank areas cannot be stimulated by heat at all. In *C*, the same thing is shown for cold as is shown in *B* for heat. (After Goldscheider; from Sherrington, in "Schäfer's Physiology.")

All of this, however, cannot be regarded as definitely proved at present.

Pain is usually classified with what are called common sensations, because it does not obey all the laws of the special senses, its skin areas are not as sharply localized as those of touch and temperature, and its possession of exclusive nerves and end organs is more doubtful, though continued researches are tending to lessen this distinction rather than to accentuate it. In accordance with the above we will, therefore, classify the cutaneous sensations as follows:

Special sensations	Touch (including pressure). Heat. Cold.
General sensations	Pain. Muscle sense, etc.

SPECIAL CUTANEOUS SENSATIONS.—*Touch (Including Pressure), Heat, and Cold.*—If the skin be tested by appropriate experiments, it may be mapped out into areas which are connected with one kind of sensation but not with another. For example, if we touch one point of the skin with a small warm body, like a blunt needle, we shall feel the sensation of touch, but not of heat, while on an adjacent area we shall feel the heat, but not the touch. In the immediate vicinity another area might be found where the warm needle would give rise to no sensation, but where a cold needle would "feel cold," and still produce no sensation of touch. Touching either of these latter areas with a needle having the same temperature as the skin would elicit no sensation whatever. Again, areas might be found which did not call forth any sensation of touch or temperature, but whose stimulation would produce pain. These various areas are called "sense spots," and are designated as "touch spots," "hot spots," "cold spots," and "pain spots," respectively. They nearly always overlap, so that we commonly find the same area of the skin capable of awakening at least two or three of the four sensations mentioned. This is well shown in Fig. 4300, which is Goldscheider's chart for the distribution of the spots for touch, for heat, and for cold, in part of the palm of the left hand. By superimposing *A*, *B*, and *C*, it is readily noticed that most of the area is connected with all three sensations, but the parts marked by black spots in *A* would be devoid of the sensation of touch.

The touch spots are not evenly distributed over the surface of the body. In some parts they lie very close together, and practically cover nearly all of the area in question, as is shown in Fig. 4300, *A*, the whole white area being covered by them; on the finger tips they would be even closer. In other parts, such as the skin of the back and certain areas on the arm and on the thigh, the touch spots may be separated from each other by oval areas measuring about 10 cm. (4 in.) along the major axis, and about 6.5 cm. (2½ in.) along the minor axis. As a rule the touch spots bear a close relation to the hairs on the skin. Where these exist, the touch spots radiate from the point at which the hair comes to the surface, and are grouped most thickly on the side away from that to which the hair slopes. On hairless parts of the body they are also grouped around central points. The hairs are important factors in exciting the end-organs which are connected with the sensory nerves. They act as levers, and thus magnify the stimulus. Their sensory functions in some of the lower animals is very marked, as in the case of the whiskers of a cat.

The nerve endings for touch are stimulated by unequal stress on the ridges of the skin. If we plunge our finger into mercury which has the same temperature as the finger, we do not feel the mercury on the submerged part, though it is under considerable pressure. We only feel it at the surface, and if we move the finger up and down, the sensation is like slipping a ring on and off. This is because the liquid fills the crevices between the ridges of the skin, and makes equal stress in all directions.

The smallest observable pressure varies with the different parts of the skin, due largely to the structure, and hence the greater or less pressure it takes to deform the ridges. Touch is the most delicate of the skin senses—a pressure of less than 1 mgm. (about gr. $\frac{1}{70}$) may be perceived. With delicate stimuli a push (pressure) or a pull (traction) produces the same sense of touch, and to the same degree (von Frey). Tactile and pressure sensations obey the Weber-Fechner law, that is, the intensity of the sensation varies (approximately) as the logarithm of the strength of the stimulus. Nerve endings are necessary for the true perception of touch. If the exposed nerve be touched, pain is the only sensation perceived. A stimulus too weak to excite the exposed nerve is sufficient to excite the tactile end-organ in the skin.

Our ability to *locate* the point touched varies greatly on different parts of the body. This sense of locality is often called the "local sign" (Lotze, Wundt). Two compass points 65 mm. (2½ in.) apart, if touched simultaneously to the skin of the back, would be felt as one point. On the tip of the finger they would be recognized as two points when 2.2 mm. ($\frac{1}{12}$ in.) apart, and on the tip of the tongue at half this distance. In using the æsthesiometer to test impaired cutaneous sensibility in nervous diseases, we commonly employ this method.

The question as to whether specific nerve endings exist for the various cutaneous sensations is an old one. It existed before our present knowledge of mapping the skin was thought of, but with that knowledge it assumed a greater importance than before. After mapping out the areas on portions of their own skin, some observers (Blix, Donaldson) had these pieces of skin cut out to see what nerve endings correspond to the respective areas, and many investigations have been made on human skin from the cadaver, to determine the kind of end-organs which are distributed more or less in the same way as the various sense spots. The result of all this work has been to throw considerable light on the subject, but it would be premature at present to say that any definite end organ had been identified beyond doubt as the specific and exclusive nerve ending for a given cutaneous sense. According to von Frey (quoted by Bowditch): "The free nerve endings are sense organs for pain, the end bulbs for cold, the terminal coils or networks for heat, and the tactile corpuscles for pressure sensations."

The evidence from clinical study and from pathological lesions is clearly in favor of the assumption that there are specific nerves for the different cutaneous sensations, and that these have pathways in the spinal cord and centres in the brain, which are not identical. Cases are recorded (especially of lesions of the cord) in which one or two of the cutaneous senses was lost while the others remained. There seems to be a tendency for touch and cold, and for heat and pain to be retained or lost together, though this is disputed. In the brain the fibres, which are concerned with cutaneous sensations, are found to run to the optic thalamus, the corpora quadrigemina, and parts of the cortex. The cortical centres are not sharply localized, but are probably much scattered. They are supposed to be located principally in the limbic lobe (especially the gyrus fornicatus) and among the motor areas in the Rolandic region.

General Cutaneous Sensations.—*Pain, Muscle Sense, etc.*—By muscle sense we mean the sense of weight or tension which we feel on lifting a weight. Muscular fatigue is also, probably, a modification of this sense. Muscle sense is generally considered with the general senses like pain, sexual sensations, etc.; the paths of its nerves and its cerebral centres are closely allied to those for the cutaneous senses of neighboring regions. These general senses are distinguished from the special ones by the lack of sense of locality (local sign). This is especially marked for pain. The pain may be referred to a spot widely remote from the point of irritation. Again we may interpret as pain something which apparently has to do with a totally different sense, as headache from eye strain. Pain was formerly thought to be due to excessive stimulation of any special sense, but stimulation of the optic nerve gives no pain, and touch spots are found where a pin may be thrust in without producing any sensation but that of pressure. On the other hand, there are pain spots where a pin causes pain, but no sense of touch. In spinal diseases pain may be lost, and yet touch and temperature sense (especially cold) remain. In some cases pain may be inhibited at will, probably by suggestion (hypnotism). This, of course, involves the receptive centres rather than the nerve endings in the skin.

In discussing the relation of stimuli on the surface of the skin to the various nerve endings, Sherrington gives the following apt figurative illustration:

"The surface of the skin is found to be a mosaic of tiny sensorial areas. . . . The individual fields may be reduced to mere 'spots.' Each of these 'spots' is found to subserve a specific sense—touch, cold, warmth, or cutaneous pain. Each doubtless coincides with the site of some sensorial 'end-organ' or with a tiny cluster of such. Rather, indeed, than to a mosaic may the skin be likened to a sheet of water wherein grow water plants, some sunken and some floating. An object thrown upon the surface moves the foliage commensurately with the violence of its impact, its dimensions, and with their propinquity to its place of incidence. Where the foliage grows densely, not a pebble striking the surface but will meet some leaf; and beyond that or those directly struck, a number will be indirectly disturbed before the equilibrium of the surface is re-established."

George T. Kemp.

SKIN-GRAFTING.—Since the appearance of the last edition of this work no noteworthy advance has been made in the subject of skin-grafting. The method devised by Thiersch has in this interval come into much more general use, not because it has been improved upon, but simply because with the lapse of years its transcendent merits have received a wider recognition. There is still room for improving the technique in the direction of taking grafts of larger size and more expeditiously. Some mechanical devices with these ends in view have appeared, but they are as yet so inadequate as not to deserve special mention. The chief value of the Thiersch method of skin-grafting lies in the fact that it prevents the deformities that would result from the natural healing of the wound by granulation and the subsequent contraction of the scar. A second advantage, in some cases one of extreme importance, lies in the fact that even very large surfaces may be healed promptly.

The grafts consist of shavings of the superficial portions of the skin removed by a razor, and are applied so as completely to cover a wound surface which is free from granulations and presents only normal tissues. A special dressing is applied. The grafts adhere, and by the end of two days they are receiving blood from their new site. The formation of granulation tissue ceases, the wound is healed, and no contraction takes place. A soft, pliable integument is provided, of good vitality and well able to withstand the wear and tear to which a cutaneous surface is exposed. In removing the grafts, the razor does not cut deep enough to include the hair bulbs. No hair will grow from the grafts. Grafts from a hairy thigh may be planted upon the face or hands without fear of transplanting hairs.

This form of skin-grafting has a very wide sphere of usefulness. Where there is extensive loss of skin in the vicinity of a joint, as may follow a burn or other injury, it will entirely prevent cicatricial limitation of motion. Similarly, where the healing of a wound by granulation would result in a distortion of soft parts, it will prevent the deformity. Large areas of malignant disease may be freely removed and rapid healing secured. Thus, extensive areas of tuberculous skin may be dissected off, leaving a healthy wound surface, and the defect covered at once by grafts. Cancerous breasts may be radically removed, regardless of flaps, and the large raw surface, consisting of fat, muscle, and periosteum or bare bone, all covered by a good integument. A thick graft contains a sufficient supply of anastomotic vessels to allow the graft to bridge over a slight interval, independently of nutrition from beneath. For example, after a burn involving the outer half of the little finger, causing superficial necrosis of the bones and opening the first joint, the author applied rather a thick graft so as to bridge over the interval from bone to bone and close the joint. The graft retained its vitality perfectly, and the joint is neatly closed and capable of a little motion. Congenital deformities which could be relieved by making an incision, drawing the edges of the skin apart and covering the wound surface with integument, can be remedied by this method. In cases in which scar contraction has already caused deformity, the scar tissue should be freely and completely excised, the parts brought into their natural position, retained by splints if necessary, and then the wound covered by grafts. If the faulty position has not caused grave damage to the deeper structures, deformity can be relieved and lost function restored. In short, Thiersch's method of skin-grafting finds application wherever it is desired to interpolate an area of soft and healthy integument and normal tissues can be provided for its reception.

Certain details of the operation are of the first importance. The excellence of the results obtained and the extent of surface that can be covered in a given space of time depend much on the skill and experience of the operator, but the operation is not a difficult one, and no surgeon should hesitate to undertake it.

The following is a condensed description of the technique which the author has chiefly used:

As was said above, the surface to be grafted should be one of normal tissues. An operative wound usually needs no preparation for the reception of the grafts. A granulating surface may be washed every other day with soapsuds and with sublimate solution and dressed with iodoform gauze saturated with balsam of Peru, until it presents a smooth, firm, and red surface. Preparatory to operation it may be dressed with sublimate gauze. If the patient has syphilis, it is well to give iodide of potassium or mercury for a week or two before operating; otherwise the grafts are liable to perish.

If there is freedom of choice as to the place from which the grafts shall be taken, the thigh should be chosen. The day before operation it should be shaved, scrubbed with soapsuds and with 1-to-1,000 sublimate solution, and wrapped in sublimate gauze. Shortly before operation it should be washed again with sublimate solution. Time will be saved at the operation if two sublimate towels are applied as follows: Let the lower edge of one come below the knee, wrap it round the limb, and secure its lower border by a sublimate gauze bandage round the knee; let the upper edge of the other towel encircle the thigh as high as possible and secure it similarly by a bandage. When the second towel is turned up and the first down, the thigh is at once exposed and is neatly bordered by sublimate towels. Wrap the thigh in wet sublimate gauze, and secure the towels over it.

Select a razor ground flat on one side. It is well to be provided with two. The edge must be very keen. For scraping away granulations, any instrument with a blunt edge will serve. Cicatrized borders can be removed by the Volkmann scoop or the knife. A probe aids the fingers in nice adjustments of the grafts. A pair of rough bathing mittens are a help to the assistant in getting a proper grip upon the skin. The mittens should be boiled or baked before using. The razors may be soaked in five-per-cent. carbolic solution for fifteen minutes and dipped in salt solution before being used.

During the operation the only solution to be used is one of sodium chloride of the strength of 6 parts to 1,000 of water. This is the so-called "physiological salt solution" and does a minimum of damage to the grafts. A large tin-pail of this solution should be boiled for an hour, and then kept at blood heat by being set in a vessel of larger size and surrounded by water which is kept lukewarm. At the operation four sterilized bowls should be filled with this solution, one for the hands, one for sponges, one for gutta-percha strips, and one to receive the grafts as they are cut.

Prepare strips of gutta-percha tissue three-quarters of an inch wide, and long enough to reach across the wound and lap over on each side. These should be washed with soap and water and with sublimate solution and placed in salt solution before being used. Sublimate gauze and sublimate gauze bandages should be wrung from salt solution to serve as the inner dressing. Sponges should be taken from carbolic solution and wrung out in salt solution for use.

Much depends on the position of the patient on the operating table. Build up the table by pillows placed beneath the body and head, and a smaller prop under the foot, so as to elevate the patient half a foot above the table, and allow the thigh to form a bridge, and thus be readily got at from all sides. If the surface to be grafted is on an extremity, it should be suspended vertically, in order to check hemorrhage and to permit of free handling without altering the position of the limb.

Unless the operation is a very trifling one, and in a patient of especially good endurance, ether or chloroform should be given.

This operation is performed not with antiseptic, but with aseptic, precautions. The field of operation must be sacredly guarded from the ingress of germs. The hands must be scrupulously disinfected with soap and water and with sublimate solution, and the operative field surrounded by bichloride towels. The first step of the operation is to remove any abnormal tissues. Granulations may be scraped away and cicatrized borders cut away or removed by the Volkmann scoop. Then wash with salt solution and apply at once a compress of gauze. Bind it on, or have an assistant maintain the pressure. Next throw back the towels from the thigh, take off the gauze, let an assistant grasp the skin with both hands and draw it tense transversely. Place the thumb of the left hand on the tense skin at one end of the thigh, to make a little longitudinal tension, and apply the razor to the skin at a moderate angle. Make a short sawing motion, and at the same time increase the angle at which the razor meets the skin until the edge bites into the skin and begins to raise its upper portion. This angle is then maintained, and with the continuance of the short sawing motion a graft is cut whose length is limited only by the length of the thigh. The tough corium is of great assistance in preventing the razor from cutting too deep. In width the grafts will vary from half an inch to two inches, according to the locality from which they are taken and the skill of the operator and his assistant. Very wide grafts may be got from the comparatively flat surface over Scarpa's triangle. As fast as cut, the grafts should be dropped into a bowl of salt solution.

The manner of cutting the grafts is illustrated in Fig. 4301.

In about ten minutes oozing will have ceased, the compress may be removed, and the grafts applied. It will be found that they have curled, with the cut surface inside. To uncurl them, place one end on the surface to be grafted, uncurl it, and keep it uncurled by pressure with a finger of the left hand. The whole graft may now be uncurled by making a rapid to-and-fro motion with a finger of the right hand, and carrying it along the entire length of the graft. The graft is now flat upon the surface and can be moved about with the fingers or probe. The grafts should be made to meet or overlap each other, and also the surrounding skin. Overlapping does no harm, for the superficial edge of a graft will die from lack of nutrition and come away, leaving a mere line of union visible. If not enough grafts have been cut, more should now be cut and applied directly. When the whole surface has been covered, douche it gently with salt solution, and apply the gutta-percha strips in the following manner: Lay one end upon the sound skin at one side of the wound and secure it by a thumb, then, with a winding motion, lay the strip across the wound and out upon the sound skin beyond. In this way the strip is laid on without in any way disturbing the grafts. Let the next strip slightly overlap the first. Continue imbricating each upon the last till the whole surface is covered by the tissue. If the surface is on an extremity, take a wet gauze bandage and apply a snug spiral to hold the tissue and grafts firmly in place. Next apply damp salt gauze, a sheet of gutta-percha tissue to maintain the moisture, sublimate gauze, cotton, a bandage, and a splint suitable to the region. The surface from which the grafts have been taken may be covered with gutta-percha tissue and moist gauze. This is a particularly comfortable dressing, but any simple dressing will answer.

Fig. 4301. Taking the Grafts.

It is advisable to change the dressings every two days for the first eight days. At the end of six days the gauze had best be allowed to dry, by omitting from the dressings the sheet of gutta-percha tissue. This will obviate too great maceration of the horny layer of the grafts, and fit them sooner to withstand the wear and tear of exposure. At the end of ten days the gutta-percha strips are no longer needed. If there are any spots of granulation from faulty adjustments of the grafts, they had best be covered with yellow adhesive plaster. If the surface is uniformly covered with grafts, it needs only to be protected for a few days by a piece of cloth spread with lanolin or vaseline.

To illustrate the value of Thiersch skin-grafting, the citation of a single case in which it was particularly called for and achieved its fullest function will suffice.

In August, 1889, C. A——, a girl, aged twelve, met with an injury by which a very large skin flap was torn from about the right knee. It involved the inner side of the thigh, knee, and leg, and extended outward beyond the ligamentum patellæ and crest of the tibia. In the following November I grafted the surface. Her general condition was poor, and I did not think it wise to continue anæsthesia long enough to cover the large area completely; a portion was only partially covered with grafts, and intervening spaces about half an inch wide were left to cicatrize. In four weeks healing was firm. The limb had been in splints for more than a third of a year, and, when they were left off, there was scarcely any motion at the knee. A cylinder of cloth, stiffened by a covering of oiled muslin, was spread with vaseline and suspended about the limb for a few weeks to guard it from harm. Exercise of the limb was encouraged, and occasionally moderate force was used to aid flexion. In March, 1890, the knee came to a right angle, and she was able to go upstairs one foot after the other. Freedom of motion became progressively greater until it was as perfect in the right knee as in the left, and the limb as useful as before the injury. The accompanying figure (4302) is from a photograph of the case taken in May, 1892, and shows how the grafted area offers no hindrance whatever to complete flexion.

Theodore Dunham.

Fig. 4302.—Shows the Condition of the Knee (in Case C. A.) in May, 1892.

SKIN, TUBERCULOSIS OF THE.—The discovery of the tubercle bacillus by Koch has had two effects on modern dermatology. One is the formation of a new group of dermatoses in which actual proof of the existence of the organism has been furnished according to the laws of general pathology, and the other is the attempt at reconstruction in the disturbed pre-existing dermatological classifications. This second effect has in turn caused another group of diseases to appear which in contradistinction to the true tuberculoses of the skin have been called toxituberculids. The group is a large one and includes lichen scrofulosorum, erythema induratum, lupus erythematosus, lupus pernio, and certain rare dermatoses. Although it is not unlikely that future investigations may yet place some of the toxituberculids in the list of cutaneous tuberculosis, they should not at the present time be so regarded.

As in tuberculosis situated in other parts of the body, three methods are known by which a lesion may be recognized as tuberculous. (1) The recognition of the tuberculous granuloma which consists of new-formed connective tissue and giant cells, and which is sufficiently characteristic for diagnostic purposes. (2) The actual presence of the bacilli. (3) The test by inoculations of guinea-pigs with the suspected tissue. Briefly speaking, all the cutaneous diseases which have up to the present time been identified by either of the last two methods as tuberculous have all contained the tuberculous granuloma, and those diseases which have from time to time been regarded as of possible tuberculous nature on clinical grounds, and which have not contained the specific granuloma, have failed to give positive bacteriological results in the end.

While there are a few other rare affections which might be added, roughly speaking, true cutaneous tuberculosis may be classified under five heads:

(1) Tuberculosis verrucosus cutis.
(2) Tuberculosis cutis orificialis.
(3) Tuberculosis disseminata.
(4) Lupus vulgaris.
(5) Scrofuloderma.

I. Tuberculosis Verrucosus Cutis. — (Synonyms: Verruca necrogenica; Lupus verrucosus; Lupus scléreux [Vidal]).

This type of cutaneous tuberculosis was first well described in 1886 by Riehl and Paltauf. These authors gave a description of the histology of the lesions and identified the bacillus in cases inoculated from diseased animals. They also showed the similarity of their cases with anatomical wart, and since the publication of their paper the two affections have been classified together.

Verruca necrogenica, or anatomical wart, consists in a lesion due to the handling of dead bodies, and is due to direct inoculation from this source. Its favorite site is on the back of the knuckles, and consists of the occurrence of pea-sized warts, which are extremely chronic in their course. They are apt to be fissured and pigmented, and at times become crusted from superficial infection and pustulation. The typical lesion of tuberculosis verrucosus cutis has slight clinical differences. Its favorite site is the back of the hand and forearm. The lesions start as small ovoid warty patches which extend peripherally at an extremely slow rate until they involve considerable areas of the skin. Associated with the warty development are often papules of a dark purple color and more or less hyperæmia of the skin. The surface is apt to be moist and crusted, and pus can usually be expressed from between the warty excrescences. The central portion may undergo involution into the scar-like atrophic skin seen in an old lupus case. True ulceration does not occur, but involvement of the lymph glands draining the area is not infrequent. As rare sequelæ may be mentioned infection of the lymph channels with the formation of tuberculous nodules which break down and form ulcers, and the extension of the disease to the lungs.

Etiology.—The known sources of infection are the sputum of phthisical subjects and infected meats. As regards the first, mention may be made of children who in creeping around the floors of hospital wards have become infected on the front of the knees, direct infection during ritual circumcision, and cases of auto-infection in phthisical subjects. Infection from meats occurs in cooks, butchers, handlers of hides, and in those who have charge of tuberculous cattle.

Pathology.—In these lesions the tubercle bacilli exist in larger number than in lupus vulgaris, but they are less numerous than in tuberculosis cutis miliaris. They cause less reactive connective-tissue growth than in lupus vulgaris, and the corium is not completely filled with the granulomatous development. The papillæ above the infiltration are enormously hypertrophied in height, and if seen without the underlying tuberculous corium they cannot be distinguished from many other warty growths. In this type the tuberculosis appears as a linear infiltration quite unlike the nodular appearance of lupus vulgaris, but both giant cells and cheesy degeneration are always present. In cases that have been infected from without, small abscesses and cocci can be noted in the superficial portion of the section, but they have no pathological value.

Diagnosis.—Small anatomical warts may at times be distinguished with difficulty from simple warts, especially if the history of the patients does not show the mode of origin. In such cases excision of a piece for diagnostic purpose is justifiable, and will clear up the diagnosis. The larger types of verrucous tuberculosis somewhat resemble patches of chronic eczema, but they can usually be differentiated by the fact that eczema is harder and less friable, instruments do not easily penetrate the lesion, and there is never any tendency to the formation of scar tissue in eczema.

Treatment.—The indications for treatment do not differ from that of other forms of tuberculosis of the skin. The overlying hypertrophic tissue should be removed by instruments and the tuberculous tissue thoroughly scraped away with the curette or destroyed by caustic applications. Strong salicylic-acid plasters repeatedly applied have been recommended for the removal of the excessive epithelial growth. These in turn have to be followed by some caustic, as acid nitrate of mercury. This method is especially valuable in lesions of large area in which it is desirable to treat small portions at a time, but it has the disadvantage of being painful.

II. Tuberculosis Cutis Orificialis. — (Synonyms: Tuberculosis cutis vera; Miliary tuberculosis of the skin; Tuberculosis ulcerosa.)

This form of cutaneous tuberculosis is due to the secondary involvement of the skin either by contiguous extension from tuberculosis of the mucous membranes or by an infection from a contaminated discharge of a remote tuberculosis of the viscera.

In the beginning the lesions consist in a number of miliary tubercles. These rapidly coalesce and break down, the resulting ulcer forming the typical lesion of the disease. The main characteristics of the ulcer are the same as those of tuberculous ulcers situated on the mucous membrane. The floor is made up of indolent reddish-yellow tuberculous tissue in which the single miliary tubercles are apparent, if they are not covered up by a superimposed development of granulation tissue, and the edges are, as a rule, rather irregular in contour. The compactness of the tuberculous tissue and the superficial nature of the ulceration allow of only a thin purulent discharge, which may or may not result in the formation of a crust. Generally there is little pain. The course is slow, although more rapid than that of lupus vulgaris. Although cases have been reported to have healed by cicatrization, nearly all the ulcers show no tendency to improve, but gradually spread by peripheral extension.

The regions commonly affected are those of the mouth, anus, and genitalia. Kaposi has reported twenty-two cases, and has added much to the accepted knowledge of the disease. He states that the condition is not of extreme rarity, nor is it confined to advanced stages of tuberculosis of the lungs or other viscera.

Treatment.—Treatment consists usually in palliative methods, as dusting with iodoform or applying antiseptic solutions, but little hope can be entertained of a cure of the lesions without destructive interference with the base of the ulcers.

III. Tuberculosis Disseminata.—In this class are included the rare examples of tuberculosis which show a general cutaneous distribution. Very few cases have been reported, but they are in sufficient numbers to demonstrate the possibility of tuberculosis becoming disseminated by the circulation. The diagnosis in the cases reported by Pelagatti and others was confirmed by pathological findings. Most of the patients were young children, but the lesions do not seem to be identical. At times the eruption is unusually acute for a tuberculosis, and consists in the formation of papules, pustules, and vesicles in which the bacilli can be demonstrated, and at other times the lesions have appeared more like the papules of lichen scrofulosorum, in which case their evolution shows the distinctive chronicity of the process.

Little needs to be said on the diagnosis, for it depends on the demonstration of the germs either by sections or by inoculation. The prognosis is subservient to that of the other lesions of tuberculosis which are commonly present. The treatment does not differ from that of lupus vulgaris or other tuberculous deposits.

IV. LUPUS VULGARIS. See *L. Vulgaris*.

V. SCROFULODERMA. See *Scrofuloderma*.

Oscar H. Holder.

SKULL, THE.—The characters that may be noted in the skull are very numerous. They can be divided into *descriptive*, which gives an account of the conformation of the bony structure of the skull and its parts; *topographical*, which is of special importance in practical medicine; *craniometrical*, which gives the dimensions of the various parts of the skull by exact measurements taken by means of special instruments; and *comparative*, in which the human skull is contrasted more particularly with those of the anthropoids.

The skull may also be investigated from the points of view of embryology and general morphology.

This article will deal especially with the applied anatomical and the craniometrical characters of the skull, though presenting very briefly such descriptive and comparative matter as is necessary for an adequate treatment of the subject.

THE EXTERIOR OF THE SKULL (Figs. 4303 to 4305).—The skull in a general way is spheroidal in shape. It is flattened and uneven below, compressed from side to side, and smooth above. It presents, externally, six regions for investigation, viz.: an inferior region or base (*norma basilaris*), two lateral regions (*norma lateralis*), a posterior or occipital region (*norma occipitalis*), an anterior or frontal region (*norma frontalis*), and a superior region or vertex (*norma verticalis*).

Many *sutures* can be noted. The sutures are the lines of union of the facial (excluding the mandible) and cranial bones.

The uneven edges of the bones form closely fitted articulations (*synarthroses*) and are separated only by a fibrous membrane continuous with the dura mater and periosteum. The only places where cartilage intervenes, forming *synchondroses*, are the basilar and jugular portions of the occipital bone at the base of the skull. These cartilages are ossified in the adult. The sutures bind the bones so firmly together, by being bevelled alternately on each side, that dislocations are practically impossible. They diminish shocks, and during early life permit a rapid growth of the skull. The sutures, with the exception of the coronal (fronto-parietal), sagittal (interparietal), and lambdoid (occipito-parietal), are best named from the bones which form them.

The skull, whether viewed from the norma frontalis, the norma lateralis, the norma basilaris, or the norma occipitalis, displays well the teeth.

In its highest development the typical mammalian dentition is indicated by the following formula:

$$\mathrm{i}\,\tfrac{3}{3}\ \mathrm{c}\,\tfrac{1}{1}\ \mathrm{pm}\,\tfrac{4}{4}\ \mathrm{m}\,\tfrac{3}{3} = \tfrac{22}{22} = 44.$$

Man presents the following formula:

$$\mathrm{i}\,\tfrac{2}{2}\ \mathrm{c}\,\tfrac{1}{1}\ \mathrm{pm}\,\tfrac{2}{2}\ \mathrm{m}\,\tfrac{3}{3} = \tfrac{16}{16} = 32.$$

Accordingly in man two incisors and four premolars are wanting in each dental arch. Anatomists entertain divergent views as to which teeth have been suppressed; most probably the second incisors on either side of the median line, and the first and second premolars on either side are the ones that have disappeared.

All the teeth are alike in form in most vertebrates below mammals and in them the dentition is *homodont*. The dentition is described as *heterodont* in most of the mammals, since in them the teeth are arranged in groups of different form and size.

The jaws of the oldest known fossil mammals have tritubercular teeth with the tubercles arranged in an antero-posterior line. Since practically all the lower vertebrates possess simple conical teeth, it is quite prob-

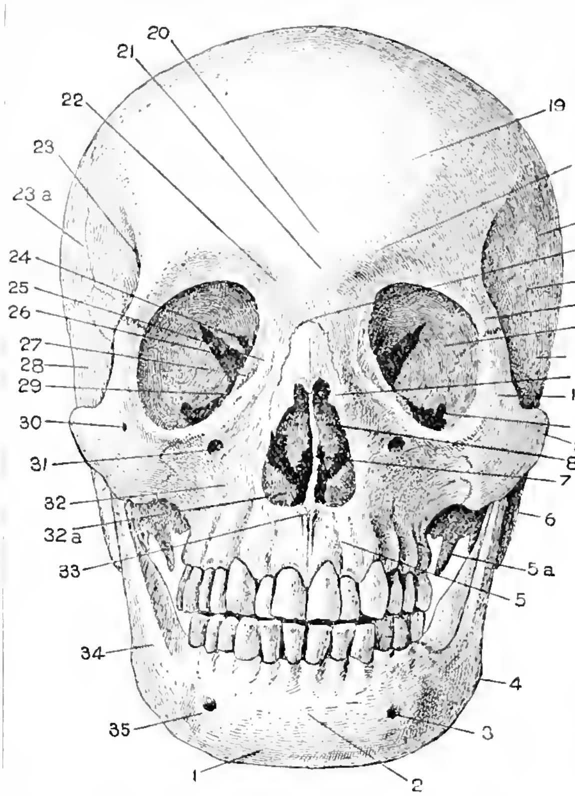


FIG. 4305.—Norma Frontalis. 1, Mental tubercle; 2, symphysis menti; 3, mental foramen; 4, angle of jaw (gonion); 5, incisor fossa; 5*a*, styloid process; 6, mastoid process; 7, nasal septum in middle of anterior nasal aperture; 8*a*, middle turbinated bone of ethmoid; 8, zygomatic arch; 9, sphenomaxillary fissure; 10, malar bone; 11, nasal bone; 12, 15, 17, temporal fossa, the sutures of which are obliterated; 13, orbital surface of great wing of sphenoid; orbital sutures are obliterated; 14, external angular process of the frontal bone; 16, nasion; 18, superciliary ridge; 19, site of frontal eminence; 20, ophryon; 21, glabella; 22, supra-orbital margin; 23 temporal crest of frontal bone; 23*a*, antero-inferior angle of parietal bone, articulating with frontal, great wing of sphenoid, and squamous portion of temporal; 24, optic foramen; 25, nasal process of superior maxilla; 26, sphenoid fissure; 27, lachrymal groove bounded posteriorly by lachrymal crest; 28, squamous portion of temporal bone; 29, lachrymal tubercle; 30, malar foramen; 31, infra-orbital foramen; 32, canine fossa; 32*a*, inferior turbinated bone; 33, subnasal point at root of anterior nasal spine; 34, ramus of mandible; 35, mental foramen.

able that the earliest toothed vertebrates in the phylogenetic series likewise possessed simple conical teeth. The method of development of the tritubercular mammalian tooth from the simple conical one has given rise to much speculation. One theory teaches that the single conical tooth developed lateral buds which, growing larger, induced in the tooth the antero-posterior tritubercular form. A second theory is that in consequence of the shortening of the jaw and crowding together of the several simple conical teeth, fusion into tritubercular teeth occurred. By rotation of two of the tubercles from the antero-posterior direction *laterally* either in or out, a form of tritubercular molar was produced in certain other fossil skulls which makes easy the transition to an ordinary mammalian molar.

The roots of the upper bicuspids and of the lower canines and incisors are flattened, and hence must be loosened by lateral movement in extracting them; the lower bicuspids and the upper incisors and canines have cylindrical roots, therefore these teeth should be first loosened by a slight rotatory movement during extraction; the roots of the first and second upper molars are three and they are frequently divergent; the roots of the wisdom teeth are convergent, generally curved backward and welded together, particularly in the lower jaw.

THE INTERIOR OF THE SKULL.—A study of the interior of the skull is of the greatest importance from a topographical point of view. In order that the interior of the skull may be investigated to the greatest advantage it is necessary to make sections in three different planes—horizontal, sagittal, and coronal. These sections not only facilitate the study of the numerous points on the interior of the skull, but also reveal the great preponderance in size of the cranial cavity over those situated in other parts of the skull.

A skull bisected in any of the planes recommended shows that its walls consist of an outer and inner table of compact bone and an intervening or connecting cancellous diploë. The spaces of the diploë contain veins communicating in the interior of the cranium with the meningeal veins and the sinuses of the dura mater, and on the exterior of the skull with the veins of the pericranium. There are other apertures in the cranial wall through which *emissary veins* pass that also establish communication between the sinuses of the dura mater inside the skull and the veins external to it.

These veins pass through the mastoid, parietal, the posterior and anterior condyloid foramina; others pass through the foramen ovale, the foramen lacerum medium, and through the foramen of Vesalius. Through these diploic and emissary veins pyogenic infection may extend from the outside of the skull, leading to osteophlebitis of the diploë and inflammation of the membranes of the brain. By means of the emissary veins blood may be abstracted almost directly from the sinuses of the dura mater, as, for instance, where leeches are applied over the mastoid process to abstract blood from the lateral sinus.

The thickness of the cranial wall varies very much in different places; it is very thick at the external occipital protuberance, and along the ridges bounding the grooves for the lateral, longitudinal, and occipital sinuses, the mastoid process, and the lower part of the frontal bone. It is comparatively thin and translucent in the cerebellar fossæ, the squamous portion of the temporal bone, and the antero-inferior angle of the parietal. The average thickness of the bones of the cranial vault is 5 mm. In *trephining*, the pin of the trephine should not penetrate over 3 mm.

A Horizontal Section of the Skull.—This section of the skull should be made to traverse the ophryon and the maximum occipital point, passing 1 or 2 mm above the pterion.

The removal of the calvarium or vaulted skull cap by a horizontal section (Fig. 4307) shows the floor of the cranial cavity, consisting of three irregular depressions, viz., the anterior, middle, and posterior fossæ.

The weak areas of the floor of the cranial cavity through which fractures are liable to extend are: The horizontal plates of the ethmoid and frontal bones in the anterior cranial fossa; the region of the foramen ovale of the sphenoid bone, and of the glenoid fossa of the temporal, in the middle cranial fossa; the cerebellar fossæ of the occipital bone in the posterior cranial fossæ. The internal auditory canal and the tympanum weaken the otherwise strong petrous portion of the temporal bone.

A Sagittal Section of the Skull.—A sagittal section should be made a little to one or the other side of the mesial plane so that one-half will reveal the nasal septum in position while the other half will display the lateral wall of the nasal fossa (Fig. 4308, *A*).

It will be very instructive to remove the middle turbinated bone in order to observe structures of great importance. There will then be observed two prominent objects on the lateral wall of the middle meatus, viz., a bulging of one of the ethmoidal cells (*bulla ethmoidalis*), and immediately below it the well-defined curvilinear border of the uncinate process (*processus uncinatus*) of the ethmoid bone. A narrow semilunar opening (*hiatus semilunaris*) occurs between the two projections. The air cell in the bulla communicates directly with the meatus by an opening upon or close to its superior surface. The hiatus serves as a direct and only communication between the meatus and the important *infundibulum*, and is a deficiency in the mesial wall of the latter. The infundibulum is a small gutter-like channel immediately external to the hiatus. It corresponds in direction and length to the border of the uncinate process. In the majority of cases the infundibulum continues up, as the *naso-frontal duct*, to the *ostium frontale*. Sometimes

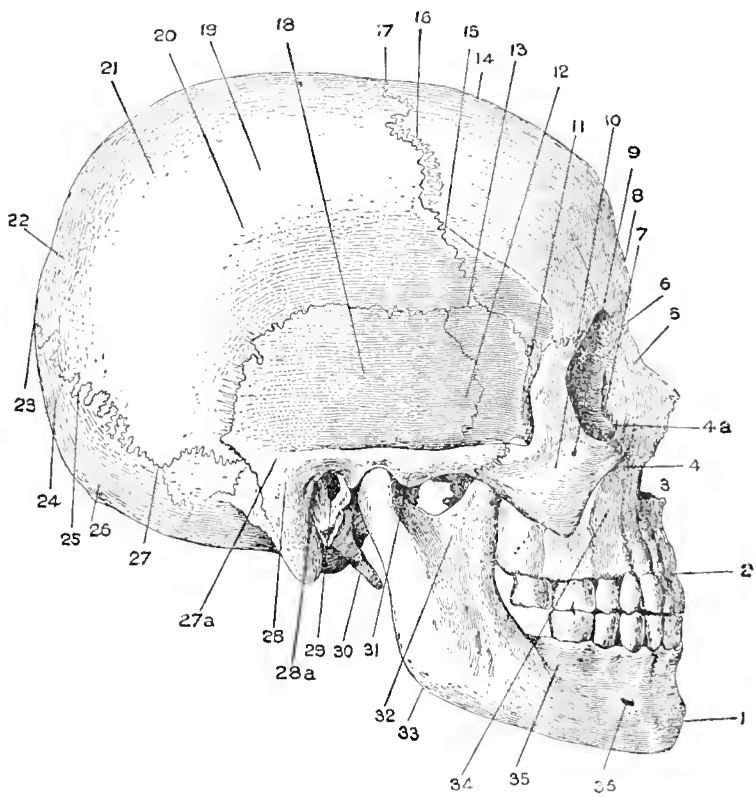

FIG. 4304.—Norma Lateralis. 1, Mental tubercle; 2, alveolar point; 3, anterior nasal spine; 4, infra-orbital foramen; 4*a*, lachrymal tubercle; 5, nasal bone; 6, nasion; 7, lachrymal groove for nasal sac; 8, glabella; 9, malar foramen; 10, malar bone; 11, great wing of sphenoid; 12, temporal fossa; 13, pterion; 14, frontal bone; 15, stephanion; 16, coronal suture; 17, bregma; 18, squamous portion of temporal bone; 19, site of upper temporal ridge; 20, site of lower temporal ridge; 21, parietal bone; 22, obelion; 23, lambda; 24, occipital bone; 25, lambdoid suture; 26, inion (or external occipital protuberance); 27, asterion; 27*a*, supramastoid crest; 28, mastoid process; 28*a*, suprameatal spine with the suprameatal fossa immediately back of it; 29, aperture of external auditory canal; 30, styloid process; 31, zygomatic arch; 32, ramus of mandible; 33, gonion; 34, superior maxilla; 35, body of mandible; 36, mental foramen.

the supero-anterior end of the infundibulum terminates in a bony lamina; in these cases the naso-frontal duct opens into the middle meatus in front and independently of the infundibulum.

The opening of the maxillary sinus (*ostium maxillare*) is situated in the most depressed part of the infundibulum beneath the bulla. It is concealed from view by the uncinate process. The size of the opening varies from 2 to 18 mm. There may be one or more accessory maxillary openings in the membranous portion of the outer wall of the middle meatus, varying in size from 1 to 8 mm. They do not open into the infundibulum but directly into the meatus at the posterior part of the infundibulum. The middle ethmoidal cell, when present, opens into the meatus above the bulla. The anterior ethmoidal cells open into the superior part of the infundibulum.

A Coronal Section of the Skull.—The most instructive coronal section of the cranium is through the basio-bregmatic axis (Fig. 4309). Such a section of the skull facilitates the examination of the parts about the posterior nares; it divides the parietal bones slightly in front of the parietal eminences, and thus makes it possible to indicate the greatest transverse measurement of the cranial cavity by a line drawn transversely across the cavity. The section will traverse the petrous portion of the temporal bone in such a way as to pass through the external auditory canal and expose the tympanum proper (atrium) and its attic, as also the vestibule. It will also pass through a part of the internal auditory canal.

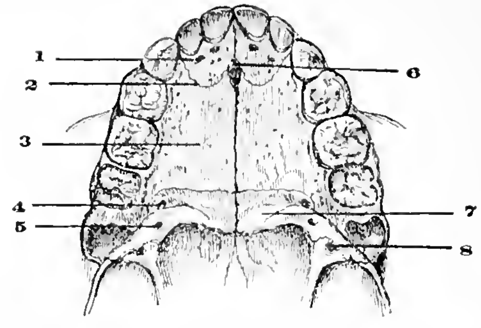

FIG. 4306.—Hard Palate of a Child (about the sixth year). 1, Premaxilla; 2, maxillo-premaxillary suture; 3, palate process of maxilla; 4, posterior palatine canal; 5, and 8, accessory palatine foramina; 6, anterior palatine fossa; 7, horizontal plate of palate bone.

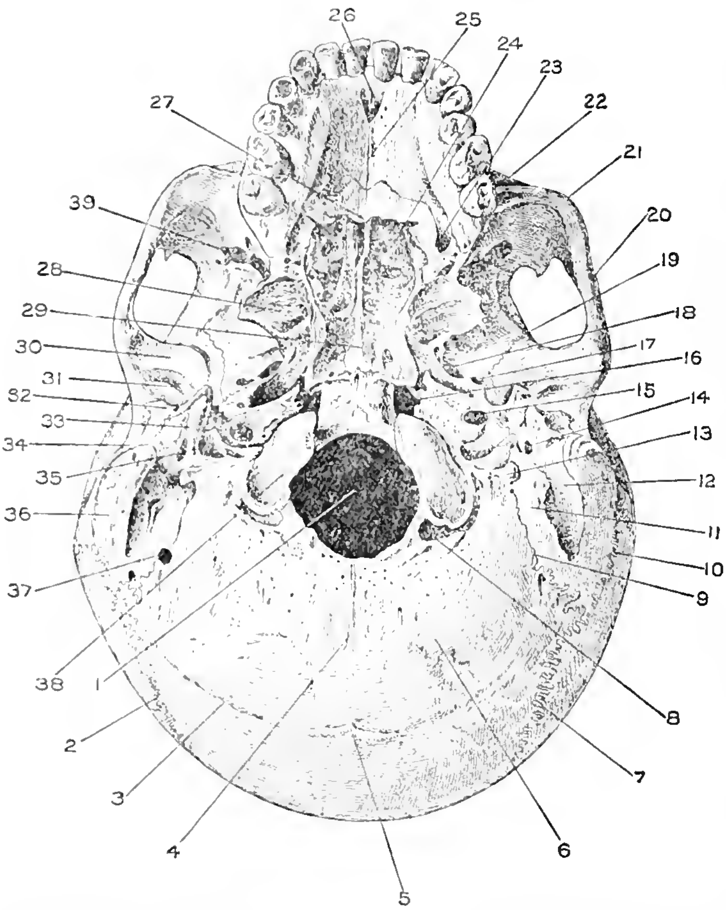

FIG. 4305. Norma Basilaris. 1, Foramen magnum; 2, lambdoid suture; 3, superior curved line of the occipital bone; 4, external occipital crest; 5, inion; 6, site of inferior curved line; 7, lambdoid suture; 8, posterior condyloid foramen; 9, occipito-mastoid suture; 10, parieto-mastoid suture; 11, groove for occipital artery; 12, digastric fossa; 13, jugular process of occipital bone; 14, stylo-mastoid foramen; 15, carotid canal; 16, foramen lacerum medium; 17, foramen spinosum; 18, foramen ovale; 19, sphenosquamous suture; 20, zygoma; 21, malar; 22, superior maxilla; 23, posterior palatine canal; 24, lateral mass of ethmoid in nasal fossa; 25, intermaxillary suture between the palate processes of the superior maxillæ; 26, anterior palatine canal or fossa; 27, posterior nasal spine on palate bones; 28, pterygoid fossa; 29, part of nasal septum (vomer); 30, eminentia articularis (anterior root of zygoma); 31, glenoid fossa; 32, auditory process floofing the external auditory canal; 33, styloid process; 34, supramastoid crest (posterior root of zygoma); 35, jugular foramen; 36, mastoid process; 37, mastoid foramen; 38, condyle of occipital bone; 39, sphenomaxillary fissure.

The inner surface of the cranial wall shows certain grooves and depressions, viz., for (1) the meningeal arteries (especially the middle meningeal), (2) the dural sinuses, (3) the Pacchionian bodies, and (4) the cerebral convolutions. In trephining, these facts should be borne in mind.

It may be stated here that in studying the macerated skull, through which no sections have been made, *transillumination* with a small electric bulb, such as that used in laryngological work, will be found very instructive. Especially is this the case in studying the nasal fossa, the grooves for the lateral sinuses, the maxillary sinus, the tympanum, the relations of the carotid canal and jugular fossa to the tympanum, etc.

The skull presents certain *buttresses* where the bones are thicker and stronger than the intervening thinner and weaker regions. The latter regions are the more readily fractured. These buttresses pass from the vertex to the foramen magnum. The *anterior buttress* is represented by the median portion of the frontal, the ethmoid, the body of the sphenoid, and the basilar portion of the occipital. The *posterior buttress* passes through the external occipital protuberance and crest to the foramen magnum. On either side there are two *lateral buttresses*—an antero-lateral one which extends from the vertex to the external angular process of the frontal and thence through the great wing to the body of the sphenoid; and a postero-lateral one which runs through the parietal eminence, the mastoid process, the posterior part of the petrous portion of the temporal bone, the jugular process and condyle of the occipital bone.

There are several factors that lessen the liability of the cranial wall to fracture: (1) The elasticity of the wall due to its shape and its formation of a number of elastic bones separated by sutures and suture membranes which act slightly as buffers; (2) a rounded form favoring glancing blows; (3) the mobility of the head on the spinal column; (4) the mobility and density of the scalp.

From the fact that there is much membrane and cartilage between the bones the skull of the infant is much more elastic than that of the adult. The yielding character of the infant's skull is shown during delivery, when frequently the parietal bone may be flattened by pressure against the sacral promontory or by the forceps without producing fracture.

A Comparison of the Human and Anthropoid Skulls.—The principal difference between the skull of man and that of the anthropoid apes is in the excessive development of the brain cavity (Fig. 4308, *A* and *B*). The average weight of a man's brain in European races is 1,360 gm. These figures may fall to 1,025 gm. or rise to 1,675 gm. Brains weighing less than 1,000 gm. are pathological. On the other hand, the brains of the anthropoid apes have an average weight of 360 gm. In a few isolated cases this weight may rise to, but never exceed, 420 gm. The excessive development of the cranial cavity induced by the enlarged brain has been the main factor, according to Prof. J. Ranke, in determining the change in attitude of our anthropoid progenitors from the semi-erect to the erect posture. Several peculiarities in the anatomical structure of man compared with those of the anthropoid apes give this theory an air of plausibility. In the majority of mammals very powerful *cervical ligaments* maintain the equilibrium of the head. In the anthropoids *very strong muscles* extend from the occiput to the spinous processes (twice as long as those of man) of the cervical vertebræ, thus preventing the massive muzzle from falling upon the chest and pressing on the organs of respiration. In man those structures are very feebly developed. In him the very voluminous brain case suffices to counterbalance the weight of the much reduced face, thus permitting the head to be balanced on the spinal column. But in connection with this point it should be remembered that Broca and other anthropologists teach that the assumption of the erect attitude was one of the conditions of the development of the brain and its large cranial cavity, since this attitude alone permits the free use of the hands and an extended range of vision.

In order to convince ourselves that the excessive development of the human brain and its enclosing cranial cavity are correlative with the reduction of the facial part of the skull, we have only to compare the human skull with that of an anthropoid, placing both in the same horizontal plane and approximately parallel to the line of vision.

As a rule the bony structure of the human skull, when viewed from the norma verticalis, leaves nothing of its facial part to be seen; at the very most, in rare instances, may be observed the alveolar segment of the upper jaw, or the lower portion of the nasal bones. In the anthropoids almost all of the facial part of the skull is observed

On comparing the profiles (norma lateralis) of the human and anthropoid skulls it is noted in the latter that the facial portion forms a bestial and massive muzzle in advance of the cranium, while in the former the much-reduced face is placed below the anterior portion of the cranium. The mastoid processes in the anthropoid are relatively much smaller than in man. In the anthropoid the facial part of the malar bone is greatly developed in comparison with its temporal portion. The contrary obtains in man.

The skulls, when viewed from the norma occipitalis, reveal plainly the foramen magnum in the monkeys, while the foramen is not seen at all in man.

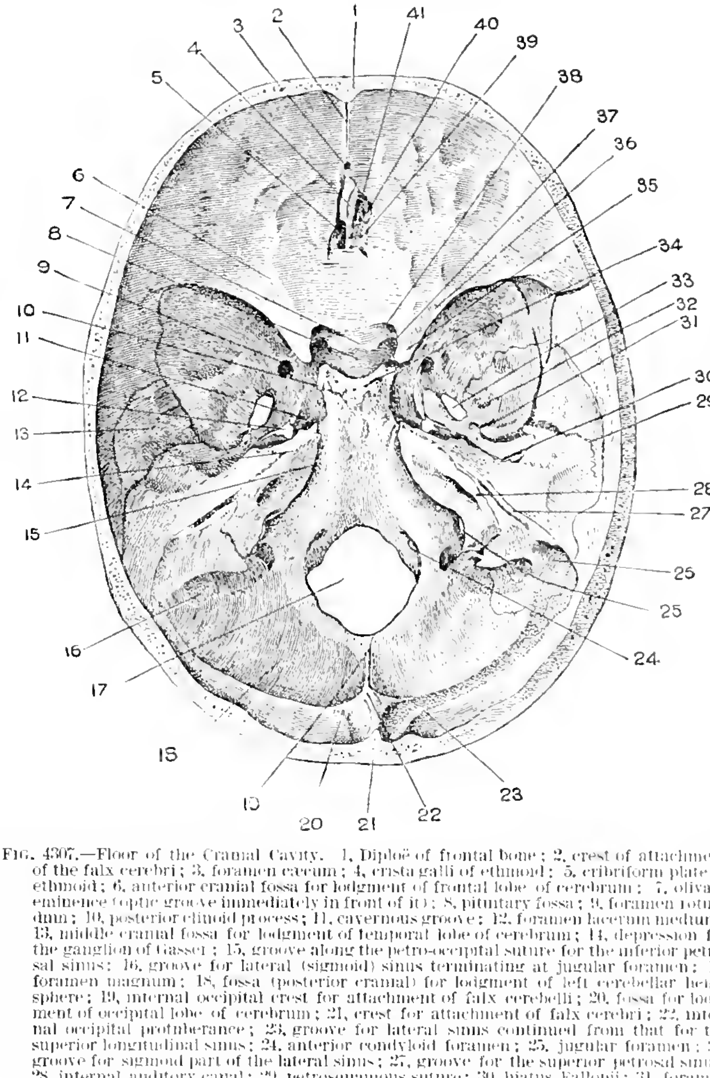

Fig. 4307.—Floor of the Cranial Cavity. 1, Diploë of frontal bone; 2, crest of attachment of the falx cerebri; 3, foramen cæcum; 4, crista galli of ethmoid; 5, cribriform plate of ethmoid; 6, anterior cranial fossa for lodgment of frontal lobe of cerebrum; 7, olivary eminence (optic groove immediately in front of it); 8, pituitary fossa; 9, foramen rotundum; 10, posterior clinoid process; 11, cavernous groove; 12, foramen lacerum medium; 13, middle cranial fossa for lodgment of temporal lobe of cerebrum; 14, depression for the ganglion of Gasser; 15, groove along the petro-occipital suture for the inferior petrosal sinus; 16, groove for lateral (sigmoid) sinus terminating at jugular foramen; 17, foramen magnum; 18, fossa (posterior cranial) for lodgment of left cerebellar hemisphere; 19, internal occipital crest for attachment of falx cerebelli; 20, fossa for lodgment of occipital lobe of cerebrum; 21, crest for attachment of falx cerebri; 22, internal occipital protuberance; 23, groove for lateral sinus continued from that for the superior longitudinal sinus; 24, anterior condyloid foramen; 25, jugular foramen; 26, groove for sigmoid part of the lateral sinus; 27, groove for the superior petrosal sinus; 28, internal auditory canal; 29, petrosquamous suture; 30, hiatus Fallopii; 31, foramen spinosum; 33, foramen ovale; 34, dorsum sellæ; 35, anterior clinoid process; 36, lesser wing of sphenoid; 37, cavernous groove; 38, optic foramen; 39, 40, cribriform plate of ethmoid; 41, slit for nasal nerve.

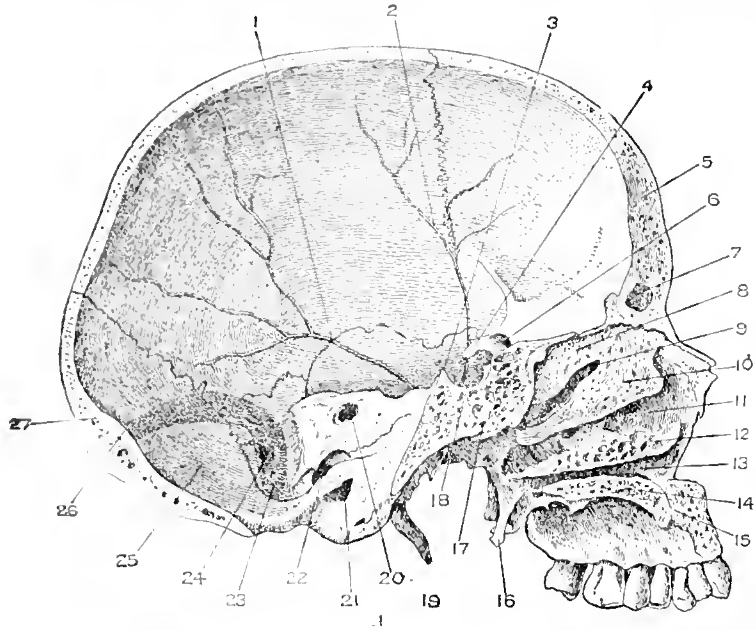
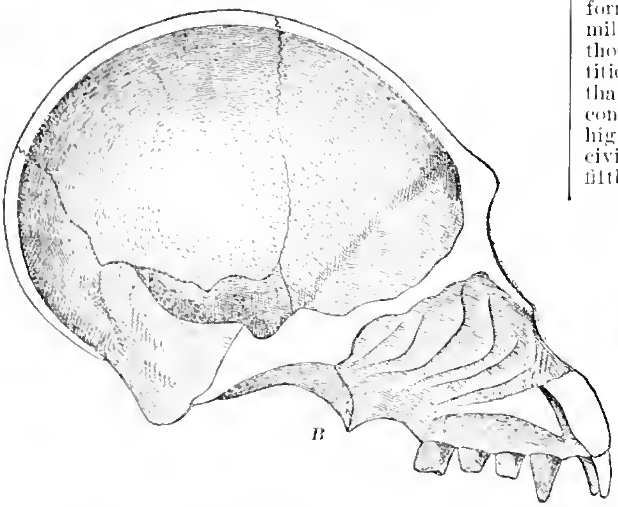
Viewed from the front, or norma frontalis, the human skull shows that the top of the nasal opening is always situated higher than the lowest point of the infra-orbital margin; in the anthropoid apes it is always observed below this point.

All the other characteristics which distinguish the human from the anthropoid skull are the direct results of the excessive development of the human brain case at the expense of the face, and the assumption of the erect attitude and biped progression.

The adult chimpanzee and gorilla possess those enormous crests which give so horrible an aspect to their skulls. These bony ridges are adaptations and are due to the extreme development of the muscles of mastication and of those cervical muscles which insure the equilibrium of the head on the spinal column. The cranium, being too small to afford sufficient room for the insertion of these muscles, has been forced, in the course of development, to deposit these crests for the purpose of affording an enlarged bony area for muscular attachments. In this connection it is interesting to note that the young of these anthropoids have no crests, and that the distance on their skulls between the temporal lines marking the insertion of the temporal muscles is almost as great as in man.





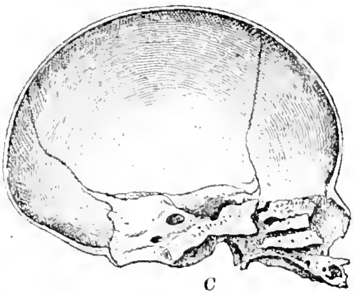


FIG. 4308.—Sagittal Sections of Human (A), Chimpanzee (B), and Infantile (C) Skulls, showing Relative Proportions of Cranium and Face and Relative Sizes of the Three Skulls. A: 1, Posterior division of middle meningeal artery; 2, anterior division of the artery; 3, dorsum sellæ; 4, anterior clinoid process; 5, diploë of frontal bone; 6, optic foramen; 7, frontal sinus; 8, superior turbinated bone of the ethmoid; 9, superior meatus; 10, middle turbinated bone of the ethmoid; 11, middle meatus, showing antral openings; 12, inferior turbinated bone; 13, inferior meatus; 14, hard palate; 15, anterior palatine canal; 16 hamular process of the internal pterygoid plate; 17, body of sphenoid (diploetic instead of pneumatic); 18, pituitary fossa; 19, styloid process; 20, internal auditory canal; 21, anterior condyloid foramen; 22, jugular foramen; 23, groove for lateral sinus; 24, mastoid foramen; 25, cerebellar fossa; 26, internal occipital protuberance (site of torcular Herophili); 27, diploë of occipital bone.

The size of the teeth in proportion to that of the body is much greater in the anthropoids than in man.

Ignoring the canines and incisors, we may state that the size of the premolars and molars, in apes, is larger in relation to the length of the face. In man the arrangement of the teeth on the alveolar border is in a compact line forming a continuous series; there is no conspicuous projection of any one tooth above the common level. On the contrary, in all apes there is observed an interval (*diastema*) between the lateral incisors and the canines of the upper jaw, and between the canines and the first premolars of the lower jaw. These diastemæ receive, in each jaw, the projecting part of the opposite canine.

Man and the anthropoid apes have alike five tubercles in the lower molars. Very often the fifth posterior tubercle is missing in the last two molars of man. In the anthropoids the wisdom tooth is of the same size as, or a little smaller than, the other molars, and this is usually the case in man, though in the latter it is often entirely wanting. The dental arch in the anthropoids usually has the form of **U**, while in man it tends to the elliptical or parabolic form.

It is in consequence of the inequality of the development of the face that the size and form of the teeth are different in man and the apes. The milk teeth of man present a much greater similarity to those of the anthropoids than the teeth of the second dentition. It is an instructive fact that all the characters that distinguish man from the anthropoids tend to become more marked with the change from a natural to a highly artificial environment, as in the development of civilization. Thus in European races the absence of the fifth tubercle in the molars of the lower jaw is more frequent than in Melanesians and Negroes. The wisdom tooth is apparently in a state of retrogressive evolution among several populations. In the white races especially it is almost always smaller than the other molars and the number of its tubercles is reduced to three instead of four or five; very often it does not erupt, remaining permanently in its alveolus. It is interesting to know that the differences between man and the anthropoids that have been noted above are very pronounced only when adult individuals are compared. The fœtus of the gorilla at five months bears a very close resemblance to a human fœtus of the same age. Young chimpanzees or gorillas, by their not very prominent muzzle, by their globular skull and relatively large cranium, and other traits, remind one of young Negroes. In comparing the skulls of chimpanzees, from the fœtal state through all the subsequent changes to the adult, we can follow step by step the transformation of a face that is almost human into a muzzle of the most repellent and bestial aspect. As has been indicated above, all of these changes have been brought about by the development of the cranium upward and behind in man, and the growth of the face below and in front in the anthropoids, "as if these parts moved in different directions in relation to a central point in the interior of the skull near to the *sella turcica*."

Craniology.—The races of mankind display great variations in their physical attributes, and these differences are more or less characteristic of the stock to which they belong. For instance, the various races manifest great differences in the size and form of the cranial cavity and of the face. Variations are observed in the prominence of the chin, and in the form of the dental arch, the palate, the nasal aperture, the orbit, etc. Craniology deals with these variations to the extent that they affect the skull. In order that the differences between skulls may be recorded, it is necessary that accurate measurements, in many details, should be made. Some craniologists have multiplied the measurements to more than a hundred, but those worth mentioning are comparatively few. These measurements constitute Craniometry. In order to make the various measurements required, many complicated instruments have been invented, but for all practical purposes the calipers designed by Fowler are sufficient.

While there is a great difference of opinion as to the value of the various measurements, all anatomists endeavor to select such fixed *anatomical points* on the skull as may be easily located. Some of these "anatomical points" are as follows (Figs. 4304, 4305, 4306, 4307, 4308, A):

Nasion.—The middle of the naso-frontal suture.

Glabella.—The mid-point between the two superciliary ridges.

Ophryon.—The mid-point of the narrowest transverse diameter of the forehead.

Bregma.—The point of junction of the sagittal and coronal sutures.

Vertex.—Highest point of the cranial vault.

Obelion.—A point in the sagittal suture on a line extending between the parietal foramina.

Lambda.—The point of junction of the sagittal and lambdoid sutures.

Maximum Occipital Point.—That point on the squamous portion of the occipital bone and in the sagittal plane that is most removed from the glabella.

Inion.—The external occipital protuberance.

Opisthion.—The mid-point of the posterior margin of the foramen magnum.

Basion.—The mid-point of the anterior margin of the foramen magnum.

Mental Tubercle.—The tubercle of the chin.

Alveolar Point.—The mid-point of the anterior margin of the alveolar border of the upper jaw.

Subnasal Point.—The mid-point of the inferior margin of the anterior nasal aperture at the base of the nasal spine.

Stephanion.—The point where the temporal crest crosses the coronal suture.

Pterion.—The region of the antero-inferior angle of the parietal bone. As a rule there is a *sphenoparietal suture* so that the squamous portion of the temporal bone is separated from the frontal.

Asterion.—The region of the postero inferior angle of the parietal bone.

Jugal Point.—Located at the angle between the upper border of the zygomatic process and the posterior border of the frontal process of the malar bone.

Gonion.—The outer surface of the angle of the mandible.

Auricular Point.—The centre of the aperture of the external auditory canal.

Preauricular Point.—That point which lies immediately in front of the upper end of the tragus on the posterior root of the zygoma.

Postauricular Point.—That point on the supramastoid crest which lies immediately behind and 18 mm. (a finger's breadth) below the upper attachment of the auricle.

Dacryon.—That point at the supero-internal angle of the orbit where the fronto-nasal suture meets the lachrymomaxillary suture.

Another anatomical point used in craniometry is the *mid-point* of the *spheno-ethmoidal suture* (called by some anatomists the gonion).

The Temporal Crest (linea temporalis).—Curving in a longitudinal direction over the lateral region of the calvarium is the temporal crest. It is often double. The upper ridge marks the limit of attachment of the temporal fascia, whilst the lower line defines the attachment of the temporal muscle. It commences in front on the external angular process of the frontal bone at the fronto-malar suture and sweeps backward and upward across the lower part of the frontal bone, and then crossing the coronal suture at the stephanion, passes to the parietal bone. Curving over this toward the postero-inferior angle of the parietal, it is continued on to the temporal bone to form the supramastoid crest.

The Supramastoid Crest.—The upper edge of the zygomatic process of the temporal bone passes back over the external auditory canal and becomes confluent with a ridge (posterior part of the temporal ridge or crest) that separates the mastoid from the squamous portion of the temporal bone; this ridge is the supramastoid crest or posterior root of the zygoma.

The *basicranial axis* is represented by a line drawn from the basion to the mid-point of the spheno-ethmoidal suture, and is formed by the basi-occipital, the basisphenoid, and the presphenoid bones.

The *basifacial axis* is indicated by a line drawn from the mid-point of the spheno-ethmoidal suture to the subnasal point.

The *craniofacial axis* comprises the basi-occipital, basisphenoid, presphenoid, and mesethmoid bones.

The *basibregmatic axis* extends from the basion to the bregma.

The *craniofacial angle* is the one formed by the basicranial and basifacial axes. It is useful in making comparative measurements of crania.

The *longitudinal arc* of the cranium is measured from the nasion along the vertex to the opisthion, and may be subdivided by measuring the lengths of its frontal, parietal, and occipital portions so that the relative proportions of these bones may be noted.

The *basinasal length* is the distance from the basion to the nasion.

The *basi-alveolar length* is the distance from the basion to the alveolar point.

The *dental length* is the distance, in the upper jaw, from the anterior surface of the first premolar to the posterior surface of the third molar.

The *total circumference of the cranium*, in the sagittal plane, may be obtained by adding together the longitudinal arc, the distance between the opisthion and the basion, and the basinasal length.

Reid's Base Line.—This is a line drawn from the auricular point to the lower margin of the orbit.

The *horizontal circumference* of the cranium is measured around a plane cutting the glabella anteriorly, and the maximum occipital point posteriorly.

In ascertaining the *maximum breadth of the cranium*, which is very variable in its position, it should be noted whether it is above or below the squamo-parietal suture.

The *length of the cranium* may be measured between a number of different points, as between the nasion, glabella, or ophryon anteriorly, and the maximum occipital point, or the inion posteriorly.

The *bistephanic width* of the cranium is the distance from one stephanion to the other in the horizontal plane.

The *biasterionic diameter* of the cranium is the distance, in the horizontal plane, from one asterion to the other.

The opisthion and the floor of the posterior cranial fossa occupy the same horizontal plane as the hard palate. The basion is a little higher than the opisthion. By consequence the plane of the foramen magnum in the higher races is oblique, being directed downward and slightly forward.

In order to describe the cranial peculiarities correctly and to have fixed coördinates to which the measurements can be referred, the skull should be placed, when studied, in the horizontal plane. Anthropologists are not agreed as to this initial plane. In Germany the plane in favor is one passing through the centre or top of the contour of the osseous external auditory canal and the inferior border of the orbit. In France and England Broca's alveolo condylean plane is adopted; this plane passes through the alveolar border of the superior maxilla and the condyles of the occipital bone.

Cranial Capacity.—The size of the brain cavity or the cranial capacity is estimated in various ways. Were it not for the fact that the brain cavity of the skull contains so many foramina which it is difficult to close, fluids would be the most accurate agents to use in ascertaining cranial capacity. But practically leaden shot, or seeds, or glass beads are the most serviceable. Cranial capacity is intimately correlated with the development of the brain, and, apart from individual variations and the proportion of head size to stature, it may be stated that the size of the cranium in highly civilized races is greatly in excess of that observed in the lower races.

For the purposes of comparison skulls are grouped according to their cranial capacity as follows: *megacephalic*, with a brain capacity over 1,450 c.c. (mixed Europeans, Japanese, Eskimaux); *mesocephalic*, with a capacity varying from 1,350 c.c. to 1,450 c.c. (some African Negroes, American Indians, Chinese); *microcephalic*, with a capacity below 1,350 c.c. (Veddahs, Australians, Andamanese, Bushmen).

The Cephalic Index.—Comparisons between crania may be made by *indices*. An index is the ratio between two dimensions that have a natural relation; the normally greater dimension is employed as a base and is assumed to be 100. The ratio is expressed as follows:

Greater dimension : lesser dimension :: 100 : index. Or,

$$\frac{\text{Lesser dimension} \times 100}{\text{Greater dimension}} = \text{Index.}$$

The cephalic index expresses the relation of the breadth to the length of the cranium and records the proportion of its maximum breadth to its maximum length (the latter being assumed to be equal to 100) in the following formula:

$$\frac{\text{Maximum breadth} \times 100}{\text{Maximum length}} = \text{Cephalic index.}$$

According to the amount of the cephalic index skulls are classified as follows: *Brachycephalic* index over 80 (American Indians, Malays, Andamanese), *mesaticephalic*, index varying from 75 to 80 (mixed Europeans, mixed Polynesians, Chinese); *dolichocephalic*, with an index below 75 (Australians, Zulus, Fijians, Kaffirs, Eskimaux).

The dolichocephalic skull is more primitive than the brachycephalic one. Generally tall men have long heads, while short men have short or rounded ones. The Norwegians are the tallest men as well as the largest-skulled nation in Europe, the Auvergnats are the shortest of European whites and possess the roundest heads.

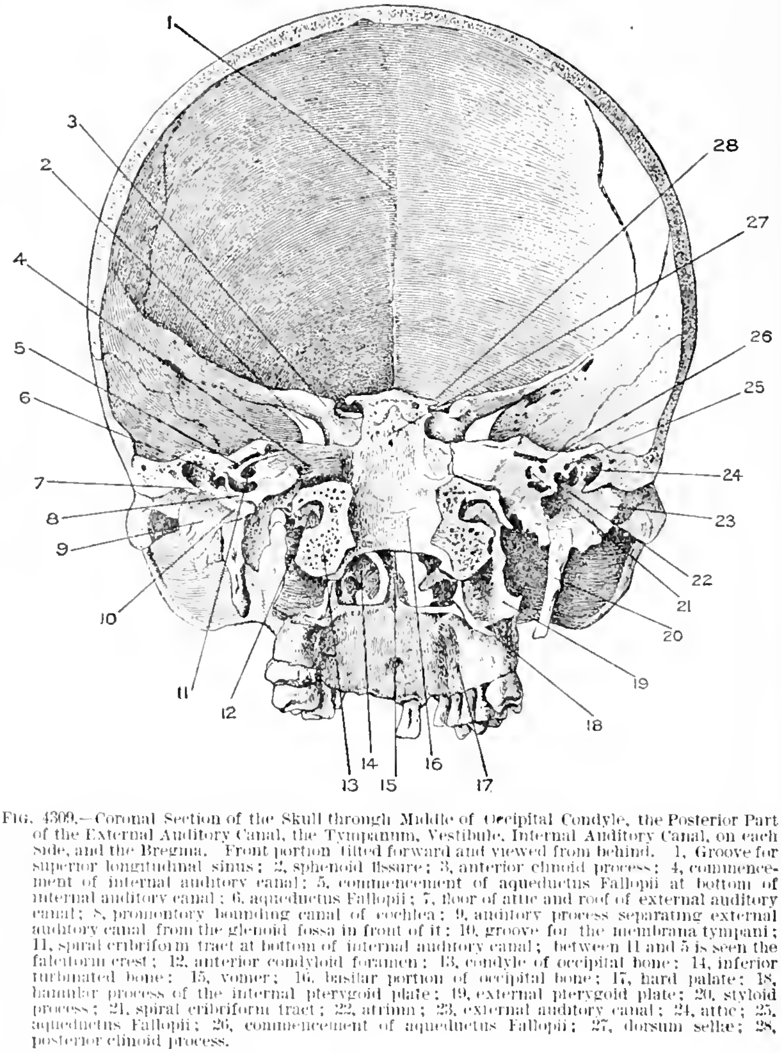

FIG. 4309.—Coronal Section of the Skull through Middle of Occipital Condyle, the Posterior Part of the External Auditory Canal, the Tympanum, Vestibule, Internal Auditory Canal, on each side, and the Bregma. Front portion tilted forward and viewed from behind. 1, Groove for superior longitudinal sinus; 2, sphenoid fissure; 3, anterior clinoid process; 4, commencement of internal auditory canal; 5, commencement of aqueductus Fallopii at bottom of internal auditory canal; 6, aqueductus Fallopii; 7, floor of attic and roof of external auditory canal; 8, promontory bounding canal of cochlea; 9, auditory process separating external auditory canal from the glenoid fossa in front of it; 10, groove for the membrana tympani; 11, spiral cribriform tract at bottom of internal auditory canal; between 11 and 5 is seen the falciform crest; 12, anterior condyloid foramen; 13, condyle of occipital bone; 14, inferior turbinated bone; 15, vomer; 16, basilar portion of occipital bone; 17, hard palate; 18, hamular process of the internal pterygoid plate; 19, external pterygoid plate; 20, styloid process; 21, spiral cribriform tract; 22, atrium; 23, external auditory canal; 24, attic; 25, aqueductus Fallopii; 26, commencement of aqueductus Fallopii; 27, dorsum sellæ; 28, posterior clinoid process.

The Height Index.—This index expresses the proportion of the height to the length of the cranium and is obtained by the following formula:

$$\frac{\text{Basiobregmatic height} \times 100}{\text{Maximum length}} = \text{Height or vertical index.}$$

According to the index skulls are divided into *hypsicephalic*, index 75.1 and upward; *orthocephalic*, index from 70.1 to 75; and *chamaecephalic*, index below 70.1.

The Nasal Index.—This index expresses the proportion of the maximum nasal width to the nasal height (measured from the subnasal point to the nasion) and is obtained by the following formula:

$$\frac{\text{Maximum nasal width} \times 100}{\text{Nasal height}} = \text{Nasal index.}$$

The form of the nasal aperture is of great value from an ethnic point of view, since it is so intimately associated with the shape of the nose in the living. According to the nasal index skulls are classified as follows: *Platyrhine*, with index above 53 (Australians, Negroes, etc.); *mesorhine*, index varying from 48 to 53 (Japanese, Chinese); and *leptorhine*, index below 48 (mixed Europeans, American Indians, ancient Egyptians).

The Orbital Index.—This index, though varying considerably in different races, is of much less value for purposes of classification than the nasal index. It expresses the proportion of the height to the width of the orbit. The orbital height is the distance, at its middle, between the lower and upper margins, while the width is measured from the dacryon to the most distant point on the anterior edge of the outer border of the orbit. The orbital index is obtained by the following formula:

$$\frac{\text{Orbital height} \times 100}{\text{Orbital width}} = \text{Orbital index.}$$

Skulls are divided, according to the index, into *megaseme*, index above 89; *mesoseme*, index between 89 and 84; and *microseme*, index below 84.

The Palatomaxillary Index.—This index is used to record the variations occurring in the form of the palate and dental arch. The width is measured between the outer surfaces of the alveolar borders immediately above the second molar tooth of each side, while the length is taken from the alveolar point to the mid-point of a line drawn from the posterior border of one superior maxilla to that of the other. The index is obtained by the following formula:

$$\frac{\text{Palatomaxillary width} \times 100}{\text{Palatomaxillary length}} = \text{Palatomaxillary index.}$$

According to the index skulls are classified as follows: *Brachyuranic*, index above 115; *mesuranic*, index between 110 and 115; and *dolichuranic*, index below 110.

The Dental Index.—From an ethnic point of view the proportion of the space occupied by the premolar and molar teeth (dental length), on one side, to the length of the basinasal line has been found to be a character of much value. The dental index is obtained by the following formula:

$$\frac{\text{Dental length} \times 100}{\text{Basinasal length}} = \text{Dental index.}$$

According to the index skulls are divided into *megadont*, index above 44 (Australians, Negroes); *mesodont*, index between 42 and 44 (Mongolians); *microdont*, index below 42 (Caucasians).

The Facial Index.—The characteristic features of the race are most readily noted in the face, and measurements of the skeleton of the face are of more value than those of the cranium, though more complex. As a general rule, to which there are many exceptions, it may be stated that a long or dolichocephalic cranium is associated with a long face, and a brachycephalic one with a shorter and rounder face.

There are two varieties of facial index, according to whether the mandible is included in the measurements or not. With the mandible present the measurement is taken from the nasion above to the mental tubercle below, and compared with the greatest bizygomatic diameter. This constitutes the *total facial index*, and is obtained by the following formula:

$$\frac{\text{Naso-mental length} \times 100}{\text{Bizygomatic diameter}} = \text{Total facial index.}$$

Since the mandible is frequently missing in skulls it is important to express the relation of length to the breadth of the face by the *superior facial index*, which can be obtained by the following formula:

$$\frac{\text{Naso-alveolar length} \times 100}{\text{Bizygomatic diameter}} = \text{Superior facial index.}$$

According to the facial index the following types of face are noted: *chamæprosopic* (broad or low face), *mesoprosopic* (medium size face), and *leptoprosopic* (high or narrow face). The terms *brachyfacial* and *dolichofacial* have also been employed to record the different faces observed. The proportion of the width of the face to that of the cranium is expressed by terms which indicate that the zygomatic arches are either concealed or observed when the skull is inspected from its norma verticalis. In the former case skulls are roughly described as *cryptozygous*; in the latter as *phænozygous*.

The Alveolar Index.—The degree of projection of the superior maxillæ, so characteristic of certain races, is most readily ascertained by the *alveolar index*. This expresses the proportion of the basi-alveolar to the basinasal length, the latter being equal to 100. The index is secured by the following formula:

$$\frac{\text{Basi-alveolar length} \times 100}{\text{Basinasal length}} = \text{Alveolar index}$$

According to the index races are classified into three groups: *prognathous*, index above 103 (Australians, various African Negroes, Melanesians, Tasmanians); *mesognathous*, index from 98 to 103 (Chinese, Eskimaux, Japanese, mixed Polynesians;) *orthognathous*, index below 98 (ancient Egyptians, mixed Europeans).

In calculating indices the *index calculator*, invented by Dr. Waterston, will be found of great service in saving time.

The amount of projection of the face may be measured by certain angles, the two most important of which are the following, viz., the facial and the maxillary.

The *facial angle* is that subtended by a line drawn from the most prominent part of the forehead above to the most projecting portion of the upper jaw below, and a second line drawn horizontally from the first through the centre of the aperture of the external auditory canal. The more acute this angle is, the smaller is the cranial capacity. The angle is 40° in the orang-outang, 70° to 75° in the African Negro, and 80° in the European whites.

The *maxillary angle* is subtended by lines drawn from the most projecting portion of the upper jaw to the most prominent points of the chin below and the forehead above. The more acute this angle, the more prognathic is the face and the less the chin. The angle is 110° in the orang-outang, 140° in the African Negro, and 160° in the European whites.

Sutures.—The lines of union or sutures between the several bones of the skull also give indications of great value in differentiating races. They are much simpler in the lower races than in the higher, and become obliterated earlier in life. Through this means the bones of the cranium unite into a compact mass and prevent the continued expansion of the brain cavity. Occasionally, in some races more frequently than in others, small distinct bones (Wormian bones) are observed in these sutures. One of these occurs so frequently in certain tribes of American Indians that it has been named the *Inca* bone. It is situated toward the back of the head.

The presence of inferior physical traits in certain races of men is either the perpetuation of the ape-like (pithecoid) characters of the lower animal, which was man's immediate ancestor, or they are atavistic.

As a very brief summary we may say that some of these inferior traits are a wide nasal aperture with synostosis of the nasal bones; simplicity and early union of the cranial sutures, with retarded union of the facial sutures; recession of the chin; prominence of the jaws; articulation of the temporal with the frontal bone; early appearance, large size, and permanence of the wisdom teeth.

In nearly all the black people (Soudanese, Australians, Melanesians, etc.) the wisdom teeth are ordinarily furnished with three separate fangs, while among the whites they decay early and have only two fangs.

It has been justly objected that ethnologists who are mere anatomists have claimed too much for craniology, and that they have given it a prominence which it does not deserve, too often applying it to the exclusion of other elements. The shape of the skull is no indication of race in the individual; only in the average of large numbers has it importance. Within the limits of the same race, as the Slavonians, the greatest variations in skulls are observed. Again the cranial indices were found to vary from 70 to 83 among the pure blooded natives of one of the small islands of the Pacific Ocean.

Nevertheless, employed with a due regard for all the ethnic elements, and in large averages, craniometry is extremely useful as furnishing additional data for comparison.

The cranial characters not only vary according to *race*, but also in each race there are other variations due to *age* and *sex*.

Age Differences in the Skull.—The skull of a new-born infant presents two striking peculiarities, viz., the great predominance of the cranial over the facial portion (8 to 1) (Fig. 4308, *C*) and its relatively large size in comparison with the body. The diminutive facial portion is due to the small size of the maxillary antrum, the undeveloped condition of the mandible and maxillæ, and the small size of the nasal fossæ which are as broad as they are high and almost filled with the turbinals. The parietal and frontal eminences are large and conspicuous, but the frontal sinuses and superciliary ridges are wanting. The bones of the vault are without any diploë, and therefore consist of a single layer. The sutures are absent in the cranium. Each angle of the parietal bone is undeveloped and in relation with a fontanel. The anterior fontanel is large and lozenge-shaped, the posterior small and triangular, and the lateral ones irregular in shape (Figs. 4310 and 4311).

The most striking facts about the base of the skull are the absence of the mastoid processes, the large angle formed by the pterygoid processes with the base, and the existence of the occipital condyles on the same level with the lower border of the symphysis menti. The frontal bones consist of two elements separated by a *metopic* suture.

The temporal bone consists of three parts, viz., the *squamosal*, *tympanic*, and *petrosal* (Fig. 4312). The squamosal has its postero-inferior angle prolonged downward into a *postauditory process*, which forms the outer wall

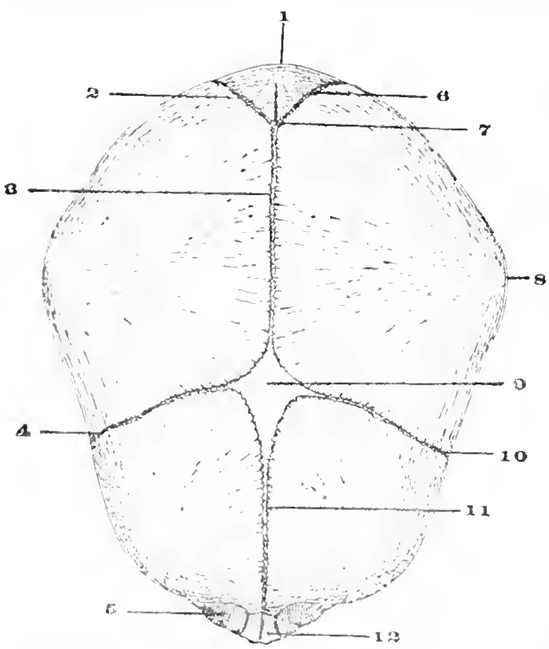

FIG. 4310.—Norma Verticalis of Infant. 1, Interparietal; 2 and 6, lambdoid suture; 7, posterior fontanel; 3, sagittal suture; 8, parietal eminence; 9, anterior fontanel; 4 and 10, coronal suture; 11, interfrontal metopic suture; 5, upper jaw; 12, nasal bone.

of the mastoid antrum. Its glenoid fossa is very shallow and has a relatively large post-glenoid tubercle.

The horseshoe shaped tympanic bone is attached to the inferior border of the squamosal by its anterior and posterior extremities. A striking feature of the norma lateralis is the absence of the bony external auditory canal. The petrosal presents a cartilaginous styloid process except for a minute nodule of bone (*tympano-hyal*) in its base. There are no mastoid sinuses, but a relatively large mastoid antrum; there is a large and conspicuous

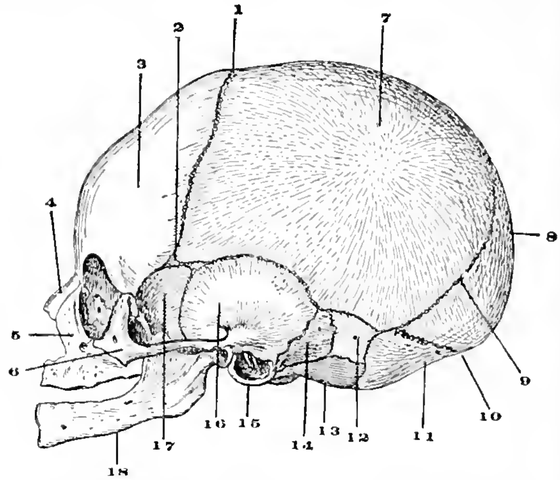

FIG. 4311.—Norma Lateralis of Infant. 1, Coronal suture; 2, antero-lateral fontanel; 3, frontal bone; 4, nasal bone; 5, superior maxilla; 6, malar; 7, parietal eminence; 8, interparietal portion of occipital bone; 9, lambdoid suture; 10, fissure between inter- and supra-occipital portions of occipital bone; 11, supra-occipital portion of occipital bone; 12, postero-lateral fontanel; 13, exoccipital; 14, petrosal; 15, tympanic plate; 16, squamosal; 17, alisphenoid; 18, mandible.

floccular fossa. The ossicles of the middle ear are about as large as in the adult. The processus gracilis may reach 2 cm. in length.

The occipital bone consists of four elements at birth, viz., *basi-occipital*, *exoccipitals*, and *squamo-occipital* (Fig. 4313). There are two deep fissures in the latter, separating it partially into a *supra-occipital* portion and an *interparietal* portion (the latter being a membrane bone). There is no jugular process or pharyngeal tubercle. The grooves for the lateral sinuses are lacking.

The maxilla presents on the oral surface of its palatine process the maxillo-premaxillary suture (Fig. 4306). The mandible at birth consists of two parts united by fibrous tissue in the line of the future symphysis menti.

The ethmoid presents three elements, viz., two lateral portions (*ectethmoids*) and a median portion (*ethmovomerine* plate). The uncinate process is undeveloped and the ethmoidal sinuses are represented by shallow depressions.

The sphenoid at birth consists of two lateral segments (*alisphenoids* with their pterygoid processes) and a composite median portion. This median portion is composed of the body of the sphenoid (ankylosed *presphenoid* and *postsphenoid*), the lesser wings of the sphenoid (*orbitosphenoids*), and the *lingulæ*. There is no foramen spinosum, and the future foramen ovale is merely a deep notch in the posterior border of the alisphenoid. The presphenoid is solid and gives no evidence of the sphenoidal sinuses which occupy this region in the adult. The Vidian canal of the adult occurs in the skull at birth as a *groove* between the lingula, the alisphenoid, and the internal plate of its pterygoid process. The sphenoidal turbinals lie in the perichondrium on either side of the ethmo-vomerine cartilage near its union with the presphenoid. They are two small triangular pieces of bone. The palate bones have their horizontal and vertical portions of the same length.

The vomer presents quite a different appearance from that in the adult.

The lachrymals are thin, delicate lamellæ. The inferior turbinal and the malar are relatively large. The nasals are broad and short.

From the above hasty survey of the skull of the new-born child it will be observed that there are many more bones than are present in the adult. At various periods in intra-uterine life the bones are still more numerous. With increasing age the bones are reduced in number through the ankylosis of two or more adjacent bony segments into composite bones. The child has fewer separate bones in his skull than the infant, the adult fewer than the child, and so on, more or less, until old age. These facts are the explanation of the occurrence of blood-vascular and nerve foramina in various parts of the adult skull.

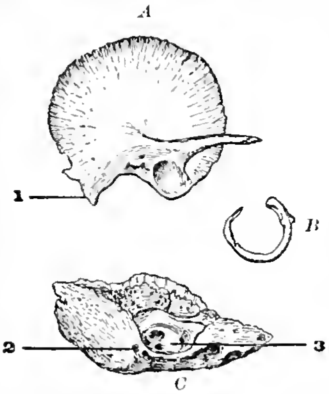

FIG. 4312.—Temporal Bone at Birth—the separate pieces. A, squamosal; B, tympanic or annulus; C, petrosal. 1, Outer wall of antrum (postauditory process); 2, stylo-mastoid foramen; 3, promontory on inner wall of tympanum proper or atrium.

The foramina and canals which transmit nerves have been subdivided into primary and secondary groups. *Primary foramina* occur at the points where the nerves leave the general cavity of the dura mater. In a morphological sense a nerve becomes extracranial where it perforates the dura mater, since this membrane largely represents the primitive connective-tissue cranium. Two illustrations of primary foramina are the *foramen magnum* and the *optic foramen*. The former is formed by four bones (the exoccipitals, the basi-occipital, and the supra-occipital) ankylosing around the medulla oblongata. The optic foramen is formed by the presphenoid and the orbitosphenoid ankylosing around the optic nerve.

Owing to the fact that human and other high vertebrate adult skulls have undergone, during the evolutionary process, complicated modifications, resulting in highly composite bones, it is observed that elaborate bony canals occur in these adult skulls that are not represented in the adult skulls of more primitive vertebrates, as the Elasmobranchs. In similar manner the adult skulls of high vertebrates contain foramina and elaborate tunnels that are not found in their embryonic condition. Such channels come under the category of *secondary foramina*. A few illustrations are as follows, viz.: the Vidian canal, to which reference has already been made; the anterior ethmoidal canal formed by bony ankylosis of the ecto-ethmoidal and the frontal bones around the nasal branch of the ophthalmic nerve; the *iter chordæ posterius* is a passageway for the chorda tympani nerve to enter the tympanum, and is formed by the ankylosis of the squamosal and tympanic bones around the nerve. The inferior dental canal of the mandible is formed by the ankylosis of several bony embryonic elements around a portion of the inferior dental nerve.

In the adult the face is at least one-half the size of the cranium. About the age of puberty the air sinuses, especially the frontal sinus, expand and develop, leading to characteristic alterations in face and head form. The age of the skull may be approximately estimated by several factors; for instance the eruption of the teeth in infancy and adolescence. When permanent dentition is completed the wear of the teeth may assist in hazarding an approximation. Complete bony union between the sphenoid and occipital bones is an indication of maturity. In old age the cranial bones become thinner and the whole skull lighter; also the condition of the sutures may guide us, since the sagittal and coronal sutures do not undergo synostosis until late in life; also at this period the obtuseness of the mandibular angle increases on account of the flattening of the vault of the hard palate, which is induced by changes in the alveolar borders of the mandible and maxillæ; for owing to the loss of the teeth in the aged, these borders become absorbed. Through this means is induced also a change in the relative position of the mental foramina.

SEXUAL DIFFERENCES IN THE SKULL.—It is always a matter of difficulty to determine with certainty the sex of a skull. The cranial capacity of the female skull is about a tenth less than the male of the same race; her skull is smaller and lighter; it has less prominent mastoid processes; it is smoother in consequence of the inferior development of the muscular ridges. The supra-orbital margin of the frontal bone is sharper and thinner in consequence of the less pronounced character of the superciliary ridges. For the same reason the frontal eminences are more conspicuous and the forehead more vertical. The parietal eminences are more prominent and the glabella less so in the female than in the male.

The edge of the tympanic plate of bone is more rounded and tubercular, whereas in the male it is sharp and divides to ensheath the styloid process. In the female the height of the skull is reduced in consequence of a more flattened vertex. No one of these sexual differences is characteristic, but taken together they enable us to arrive at a fairly accurate conclusion. It may be interesting to recall in this connection that Broca taught that if a skull rests on its mastoid processes it is almost certainly a man's.

PNEUMATIC SPACES IN CONNECTION WITH THE NASAL FOSSÆ AND THE NASOPHARYNX.—Connected either with the nasal fossæ or with the nasopharynx are the following air sinuses or pneumatic spaces, viz., the maxillary, frontal, ethmoidal, orbital, sphenoidal, and tubotympanic (Figs. 4314, 4315, 4316, and 4317).

The *maxillary sinus* or *antrum of Highmore* (Fig. 4314) occupies the body of the superior maxilla, and therefore is situated to the outer side of the nasal fossa on either side. It is a pyramidal cavity with its apex directed toward the malar bone and its base formed by the outer wall of the nose. Its walls are relatively thin and are directed forward to the face, inward to the nose, upward to the orbit, backward to the sphenomaxillary and zygomatic fossæ, and downward to the alveolar border. Portions of several bones assist in the formation of the thin osseous partition, which nearly, save for the small antral

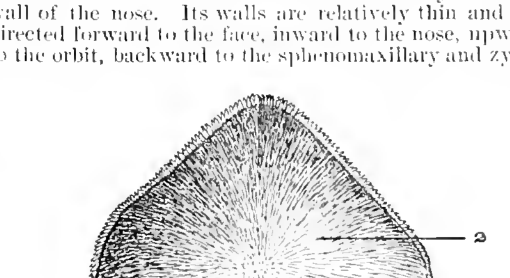

FIG. 4313.—Occipital Bone at Birth—Cerebral Surface. 2, Interparietal portion (develops in membrane); 4, supra-occipital portion (develops in cartilage); 1 and 3, infantile fissures, occasionally persists in adult; 2 and 4, form the squamo-occipital of the adult; 5, exoccipital; 6, basi-occipital.

orifices, separates it from the nasal fossa. These bones are the uncinate process of the ethmoid bone, the ethmoidal process of the inferior turbinated bone, a portion of the lachrymal, and the vertical plate of the palate bone. The floor of the antrum is separated from the roots of the molar and bicuspid teeth by bone of varying thickness. Ordinarily the floor of the antrum is on a level with the floor of the nasal fossa. But sometimes the floor of the antrum, when it is thin and devoid of spongiosa, sinks below the level of the fossa; under these circumstances suppuration at the roots of one or more of the teeth in this locality is very prone to extend to the antrum. Wide variations are noted in the size of the maxillary sinus. The cavity may be represented by a narrow cleft; more rarely it is entirely absent.

A large adult antrum will hold 32 c.c. The average capacity is 14.5 c.c. In a sinus of average dimensions the line of junction of its facial and nasal walls is indicated externally by the outer edge of the canine ridge.

Small recesses and pockets are frequently found on the inner surface of the walls of the sinus, thus favoring the collection of abnormal secretions. The sinus may rarely be completely subdivided into two compartments by a horizontal or vertical partition. In these circumstances both cavities may communicate with the middle meatus; or the superior or posterior compartment may communicate with the superior meatus, while the inferior or anterior one opens into the infundibulum. In the event of this anomaly, the surgeon might fail to find the source of suppuration in the superior or posterior compartment.

The antral orifice is unfavorably situated for natural drainage, since it is at the highest part of the antrum. It opens into the middle meatus of the nose through the posterior extremity of the hiatus semilunaris.

Ordinarily the antrum of Highmore is separated from the neighboring pneumatic spaces by thin bony partitions, and it communicates only with the nasal fossa.

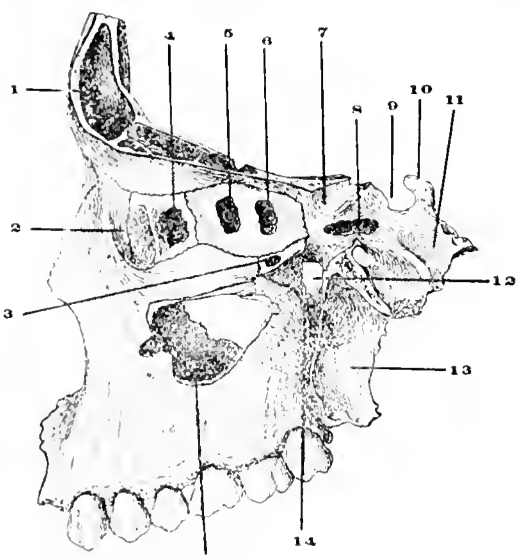

FIG. 4314. A Section of the Skull showing the Inner Wall of the Orbit and the Air Sinuses. 1, Frontal sinus; 2, lachrymal groove for the nasal sac; 3, orbital sinus; 4, infundibulum shown through opening in lachrymal bone; 5 and 6, anterior and posterior ethmoidal sinuses seen through openings in os planum of ethmoid; 7, optic foramen; 8, opening through body of sphenoid to show sphenoidal sinus; 9, pituitary fossa; 10, dorsum sellæ; 11, cavernous groove; 12, sphenopalatine foramen; 13, external pterygoid plate; 14, sphenomaxillary fossa; 15, maxillary sinus or antrum of Highmore revealed by removal of malar process.

Occasionally I have seen a direct, non-pathological channel of communication between the antrum and the anterior ethmoidal cells. In other specimens I have seen, as I explain below, a direct channel of communication between the antrum, the orbital, the posterior ethmoidal, and the sphenoidal sinuses.

At birth the maxillary sinus exists in a very rudimentary form, but reaches its full development about twelve years of age.

The opening through which the cavity may be evacuated and drained, in empyema of the maxillary sinus, may be made (1) through the canine fossa external to the canine eminence; (2) through the alveolus of the first or second molar or the second bicuspid tooth; or (3) through the lateral wall of the inferior meatus of the nose.

There are two principles that place the *canine fossa operation* at a great advantage in comparison with any other method of treatment. They are as follows, viz.: (1) by a free opening into the antrum of Highmore through the canine fossa the sinus can be carefully examined and its contents thoroughly controlled; (2) free drainage is established from the sinus into the nasal fossa and on a level with the floor of the sinus. When the bone is exposed by an incision made a few millimetres below the gingivo-labial furrow and extending from the level of the canine eminence to the first molar, the canine fossa (Fig. 4303, *32*) is broken down with mallet and chisel. The opening should be made well forward in order that it shall approach closely to the nasal wall of the sinus, and downward so as to be on a level with the alveolar floor of the cavity. An opening of this character is preferable because (1) it is most suitable for the further procedure of making the opening into the nasal fossa from the sinus; (2) it gives the best view of the sinus; (3) it is the most favorable situation for drainage. Care should be taken to avoid injury to the infra-orbital nerve. The margins of the opening should be made as smooth as possible. The mucoperiosteum should be injured as little as possible.

In creating a nasal opening from the antrum, blood should be prevented from escaping into the nasopharynx by inserting therein a small sponge attached to a tape. Prior to making the opening the anterior third of the inferior turbinal should be amputated. This gives free access to the naso-antral partition, which is to be broken through. This is done by mallet and chisel through the opening in the canine fossa. The operator should work as far forward as possible, keeping close to the antral floor. As soon as the chisel has penetrated the partition, a Krause cannula with probe-pointed trocar should be used to define and enlarge the opening. This opening should then be enlarged with mallet and chisel until the front third of the lateral wall of the inferior meatus has been removed. The opening should be large on account of the great tendency to after-contraction. During the operation care should be taken not to injure the nasal septum.

The *frontal sinus*, one on either side, lies between the outer and inner tables of the frontal bone over the root of the nose and extends outward under the superciliary ridges (Fig. 4314, *1*). The septum of bone which separates them is very seldom in the mesial plane. It may be so far removed from this plane that an opening made on one side of it may expose the sinus on the opposite side of the body. The sinus, on either side, communicates, through the infundibulum and front part of the hiatus semilunaris, with the fore part of the middle meatus of the nasal fossa. The sinus is smaller in young people and in women than in men. While there is no necessary correlation between a capacious frontal sinus and a prominent superciliary ridge, it may be stated as a general rule that there is a greater probability of the presence of a well-developed sinus where there is a prominent supra-orbital area (including a prominent superciliary ridge and nasal eminence). The outer table of the sinus is the thickest, but varies considerably in different skulls. Its average thickness is about 5 mm. It has a large amount of diploic tissue, which accounts for the possibility of septic infection when it is opened, and also for the hemorrhage that occurs from it. The inner table is thin and brittle. The floor of the cavity overlies the orbit, as well as the upper border of the lachrymal and the anterior part of the superior border of the lateral mass of the ethmoid. The floor is the thinnest wall, especially at the supero-internal angle of the orbit. Accordingly when there is empyema of the sinus the pus tends to point at the upper and inner angle of the orbit. This pneumatic chamber may extend upward on the forehead for 40 mm.; laterally as far as the external angle of the orbit; backward as far as the lesser wing of the sphenoid, on either side, thus separating the horizontal portion of the frontal bone (the roof of either orbit) into two tables, viz., orbital table and cerebral table. It may communicate by a large opening with a well-marked sinus in the crista galli.

The cavities are very unsymmetrical and irregular. They may be very small or altogether absent. The sinus may be present on one side and absent on the other. The sinus becomes funnel-shaped as it passes downward to the ethmoidal infundibulum. The ostium of the frontal sinus is found at a short distance from the septum and at the most dependent part of the cavity. It may be situated 28 mm. behind the outer table of the frontal bone. Incomplete trabeculæ of bone often divide the sinus into recesses of various sizes and shapes.

The frontal sinus is absent at birth. It appears about the seventh year and develops only slightly up to puberty, when it increases rapidly in size, reaching its maximum growth about the twentieth year.

When through empyema or other diseases of the frontal sinus it becomes necesary to open the cavity, there are several methods of procedure. 1 The infero-external wall (orbital surface) of the sinus may be opened at the upper and inner angle of the orbital fossa. The orbital surface of the sinus must be so freely removed that the little finger can be passed into the cavity after its contents have been thoroughly evacuated by syringing with an antiseptic solution. The little finger of the other hand should be placed in the corresponding nostril and pushed up to a point where the finger in the sinus can be felt. With a sharp gouge an aperture of considerable size should be made along the space between the two fingers. A serious objection to this operation is the almost certain injury of the pulley attachment of the superior oblique muscle and the production thereby of distressing diplopia. 2. A more satisfactory procedure, after exposing the bone by making an incision through the shaven eyebrow, is to open the cavity through the external table of the vertical portion of the frontal bone—that is, through the forehead. After the tissues have been raised and turned back sufficiently to expose the bone, the cavity is best entered just above the mesial or inner extremity of the supra-orbital margin, and slightly lateral from the median line of the forehead. On account of the very great variations of the shape and size of the sinus the safest procedure is to open its outer wall by a small drill run by an electric motor and controlled by a foot-switch, though the mallet and chisel are much used. The sinus can be explored with a probe through this opening and the relations of its walls and its size determined. Then a button of bone may be removed by a trephine, or a larger drill may be used, or the mallet and chisel. Care should then be exercised in securing a large opening into the nasal fossa in the same manner as indicated in the operation through the orbital surface. This operation not only avoids the possibility of injuring the superior oblique muscle, but facilitates direct inspection and treatment of the sinus.

Lothrop's observations on the cadaver have demonstrated—and the demonstration can be verified by any experienced anatomist in the dissecting-room—that it is impossible to pass a probe from the nose through the infundibulum into the frontal sinus in the majority of subjects. Much more difficult is the procedure in the living subject. In many cases the frontal sinus can be catheterized when free access to the infundibulum is secured by amputating the anterior end of the middle turbinal. The care with which catheterization of the frontal sinus should be carried out is best emphasized by citing the case recorded by Mermod, an experienced rhinologist. He observed a case in which a watery fluid was escaping from one nostril, and judged that it came from the corresponding frontal sinus. The attempt at catheterization induced so much pain that he was compelled to desist. The patient died some days later, and an autopsy showed the entire absence of any frontal sinus. The watery fluid which escaped through a small opening in the floor of the anterior cranial fossa was probably

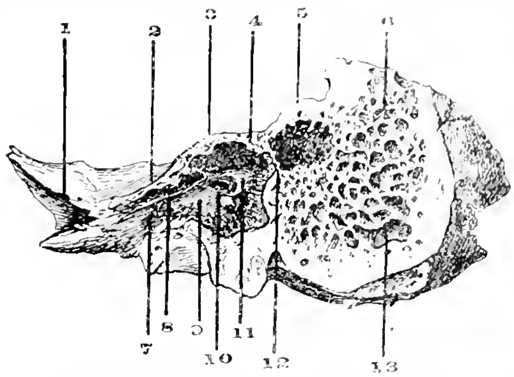

FIG. 4315.—Tubotympanic Pneumatic Cavity and Mastoid Sinuses, shown by removal of outer boundaries of the petromastoid portion of the temporal bone. 1, Carotid canal; 2, tegmen tympani over tube for tensor tympani muscle; 3, tegmen tympani over attic; 4, part of external wall of antrum; 5, tegmen tympani over antrum; 6, mastoid cells; 7, Eustachian tube; 8, processus cochleariformis; 9, promontory in atrium; 10, foramen ovale; 11, external horizontal semicircular canal; 12, part of external wall of antrum; 13, mastoid cells.

cerebrospinal fluid. Pyogenic infection was doubtless carried within the cranial cavity, although every antiseptic precaution had been observed in attempting to catheterize the supposed frontal sinus.

The *ethmoidal sinuses* (Fig. 4314, *5* and *6*) are placed between the cavities of the orbit and the supero-lateral part of the nasal fossæ, being separated from them by thin and papery walls. These pneumatic spaces are completed by the ethmoids articulating with the sphenoidal turbinate, palate, frontal, lachrymal, and superior maxillary bones.

The thin partitions are frequently absent at various points. For instance, some of the ethmo-maxillary septa may be absent, thus permitting the ethmoid cells to communicate directly with the maxillary sinus, as already mentioned; again the ethmo-frontal (orbital plate) partitions may be deficient so that a direct communication may exist between ethmoid cells; and, finally, a large sinus is sometimes present between the two walls of the orbital plate and extends well back toward the optic foramen.

The sinuses are separated into two groups by thin bony septa—an anterior and a posterior group. The anterior and sometimes a middle group of cells open either independently or through the ethmoidal infundibulum into the upper part of the hiatus semilunaris, and therefore into the middle meatus of the nasal fossa; the posterior ones open into the superior meatus. Ordinarily the ethmoidal cells are separated from the orbital cavity by the thin plate of bone called the *os planum*. Occasionally, as a result of arrest of development and in old people, the os planum may be defective in parts and the sinuses are then separated from the orbit only by membrane. A study of horizontal and coronal sections will disclose the fact that the pneumatic spaces increase in size from above downward, and from before backward.

The anterior ethmoidal cells ordinarily communicate, through the infundibulum, with the frontal sinus; occasionally they communicate directly with the maxillary sinus. The posterior ethmoidal cells occasionally communicate with the orbital sinus, and may through the latter communicate with the sphenoidal sinus or the antrum of Highmore, or with both the latter

The ethmoidal cells, on account of their irregular and complicated anatomical features and the importance of their topographical relations, deserve very careful study, with the help of both macerated and recent specimens. Empyema of the ethmoidal cells is frequently associated with pus formation in one or several of the other pneumatic spaces, and may lead to very grave complications involving vision or even life.

The ethmoidal cells are usually absent in infant skulls. They appear about the fourth year, and reach their full development about the twentieth year.

The only effective treatment of disease of the ethmoidal sinuses is to open them freely through the nasal fossa and then to curette them. As a preliminary step, however, the middle turbinal should be more or less extensively removed.

The *orbital sinus* is situated in the orbital process of the vertical plate of the palate bone (Fig. 4314, *3*). The orbital process, therefore, from an ophthalmological and rhinological point of view, is a very important structure, whose relative anatomy should be carefully studied. It presents five surfaces, three of which are *articular*, and two free or *non-articular*. The maxillary surface looks forward, outward, and downward, and articulates with the superior maxilla; the ethmoidal surface looks inward, forward, and upward, and articulates with the lateral mass of the ethmoid, helping to close in the posterior ethmoidal cells; the sphenoidal surface looks backward, inward, and upward, and articulates with the vertical portion of the sphenoidal turbinated bone. The zygomatic surface lies in the spheno-maxillary fossa, looking toward the zygomatic fossa. The orbital surface helps to form the floor of the orbital fossa at its apex. Ordinarily the orbital pneumatic space or sinus communicates with the sphenoidal sinus. Sometimes it communicates with the posterior ethmoidal cells. On several occasions I have seen it communicate not only with both of the above-mentioned pneumatic spaces, but also with the antrum of Highmore, so that there has been a direct continuity between the maxillary, orbital, posterior ethmoidal, and sphenoidal sinuses. Under these circumstances a severe empyema of these sinuses, leading to caries of bone, could produce grave complications, jeopardizing life through extension to the brain, or vision through extension to the orbit and its contents.

The *sphenoidal sinuses* (Fig. 4314, *8*), very variable in shape and size, are usually separated from one another by a sagittally placed bony septum. This septum is frequently displaced to one or other side, and may be more or less oblique. The sinuses are situated in the body of the sphenoid and often extend well down into the pterygoid processes and out into the bases of the great wings of the sphenoid.

In front and below they are bounded, in part, by the sphenoidal turbinated bone. Above the latter an irregular opening is left by which the sphenoidal sinuses communicate with the upper and back part of the nose in the region of the spheno-ethmoidal recess. Occasionally they communicate with the posterior ethmoidal cells.

One or both of the sinuses may be absent or replaced by diploë. The sphenoidal sinus is not present at birth. The time of its appearance is stated to be the third year (Steiner), seventh year (Laurent), or the twentieth year (Tillaux).

The location of the nasal opening into the sphenoidal sinus varies very much. In empyema of the sinus a probe, or the long, slender nozzle of a syringe, can sometimes be made to enter the cavity by passing it directly backward along the inferior margin of the middle turbinal. In other cases the sphenoidal opening is more laterally placed and on a higher level. Under these circumstances the probe must cross the posterior third of the turbinal and curve outward. Certain diseases of the sinus require that it should be freely opened. The distance of the anterior wall of the body of the sphenoid from the end of the nose should be ascertained and indicated on the drill. The anterior wall should then be drilled carefully and, sufficient allowance for the penetration of the wall being made, the surgeon knows precisely the distance beyond which the drill should not be passed. A sufficient opening having been made by the drill, the cavity is cleansed by curetting.

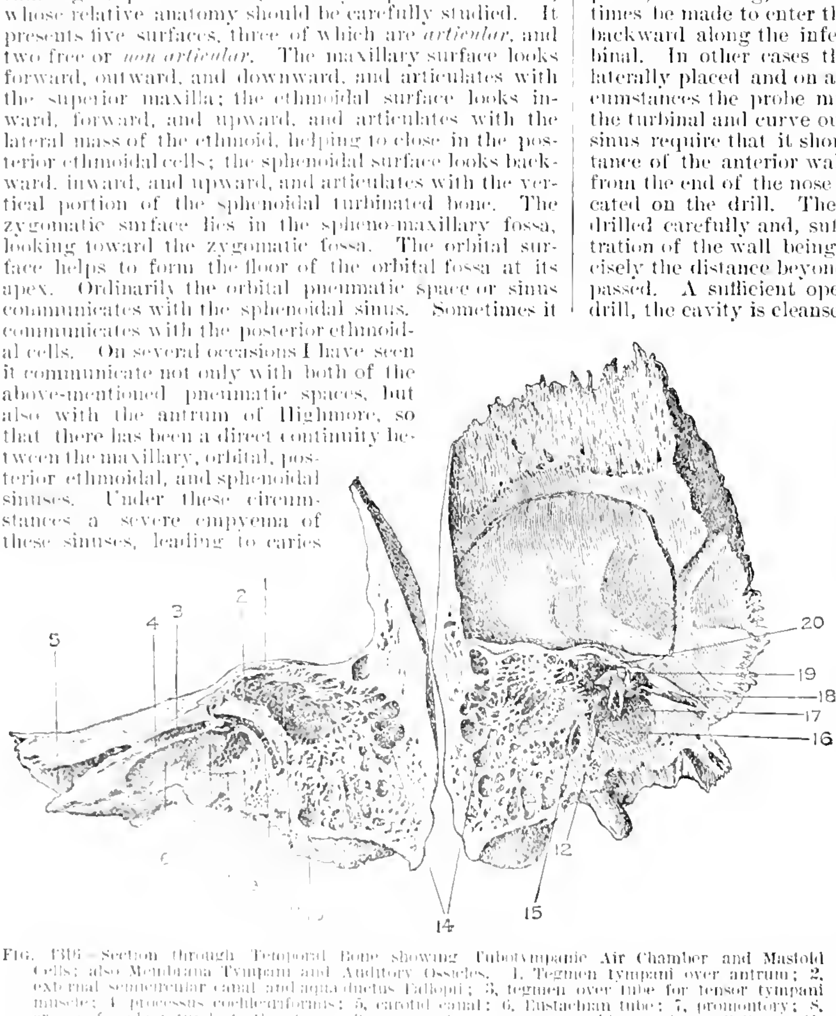

FIG. 4316.—Section through Petrous Bone showing Tubotympanic Air Chamber and Mastoid Cells; also Membrana Tympani and Auditory Ossicles. 1, Tegmen tympani over antrum; 2, external semicircular canal and aquæductus Fallopii; 3, tegmen over tube for tensor tympani muscle; 4, processus cochleariformis; 5, carotid canal; 6, Eustachian tube; 7, promontory; 8, crosses fossula rotunda to the stapes; 9, recessus hypotympanicus; 10, aquæductus Fallopii; 11, diploetic tissue at posterior part of atrium with the aquæductus Fallopii descending through it; 13, antrum; 14, mastoid cells; 15, aquæductus Fallopii; 12, body and short ramus of incus in the attic; 16, membrana tympani; 17, manubrium of malleus; 18, tensor tympani muscle; 19, head of malleus in the attic; 20, tegmen tympani roofing attic.

The Tubotympanic Cavity or Pneumatic Chamber (Figs. 4309, 4315, 4316, and 4317).—This cavity, though varying much in its dimensions in individual cases, is practically of full size at birth. From an anatomical and pathological point of view it is well to remember that the tympanum consists of three very important divisions, viz., the *mastoid antrum*, the recessus epitympanicus or *attic*, and the tympanum proper or *atrium* (Fig. 4315). The recessus hypotympanicus is an arbitrary subdivision of the atrium, interesting because of its relation to the jugular fossa. At birth the mastoid cells do not exist.

The *mastoid antrum*, like the other subdivisions of the tympanum, is practically of the same size at birth as in the adult. Its roof is formed by the thin *tegmen tympani*, and extends forward as the roof of the attic and tensor tympani canal. It communicates in front with the attic. In the rest of its course it is bounded by the diploëtic and pneumatic tissue of the bone. Its vertical measurement is about 7 mm.; the transverse measurement is about 9 mm. At birth the outer wall is bounded by a thin plate of bone belonging to the squamous portion of the temporal bone (squamosal) (Fig. 4312, *A*, *D*), and is only about 1 or 2 mm. thick, but it increases to about 10 mm. at the ninth year. Coincidently with the development of the mastoid process (which begins at the second year and reaches its maximum growth after puberty) the mastoid cells (Fig. 4315, *6* and *13*) develop backward and downward as radiate or racemose diverticula from the tabotympanic pneumatic space, especially from the antrum, and show in different skulls the greatest possible variations. Up to the second year the tiny mastoid contains only diploëtic structure, and in the developed bone this may never be wholly displaced. Randall states that in his study of a thousand bones he found scarcely two per cent. which could be classed as diploëtic, and only about ten per cent. revealed a notable amount of diploë combined with the pneumatic spaces. No mastoid is entirely pneumatic, though we may meet with a large, thin-walled, single pneumatic space occupying the greater part of the process in senile bones.

Through osteosclerosis a solid mastoid process may occasionally be seen. The pneumatic cells, when present, are not limited to the mastoid process, but extend upward toward the squama, forward over the roof of the external auditory canal, and may extend into the zygomatic process; some generally extend into the floor of the Eustachian tube lying in close relation with the carotid artery; others may extend inward toward the temporo-occipital suture, sometimes invading the pars jugularis of the occipital bone. While a dolichocephalic skull is more likely to present a pneumatic mastoid than a brachycephalic one, and while a prominent, large mastoid is more liable to be pneumatic than a small, ill-developed one, there is no method of determining beforehand the condition of the interior of the bone.

The antrum merges, anteriorly, almost imperceptibly into the attic through a triangular-shaped, hour-glass contraction called the *aditus*, made by the outward bulging, from the inner wall of the tympanum, of the horizontal semicircular and facial-nerve canals. The boundaries of the *aditus* (Fig. 4317, *1*, *2*, *12*) are very important surgically and are as follows, viz.: *above*, the base of the triangle is formed by the tegmen tympani; the *inner boundary* is formed by a prominence of compact bone containing the external semicircular canal, and below and in front of this is the portion of the aqueductus Fallopii winding above and behind the fenestra ovalis. The bony wall of the aqueduct at this point is very thin, and at times entirely lacking, so that an inflammation of the tympanum can readily extend to the facial nerve. The *outer wall* of the aditus is formed by the deepest part of the postero-superior wall (squamosal) of the bony external auditory canal. The *apex* of the triangular aditus is formed by the junction of the outer and inner walls in this region. Ordinarily the aditus will admit an instrument about 5 mm. in diameter.

The *attic* (Figs. 4315, *3*; 4309, *24*) is broadest above where it has as its roof the *tegmen tympani*, the latter extending backward as the roof of the antrum and forward as the roof of the canal for the tensor tympani muscle. It is about 7 mm. in its antero-posterior direction, about 5 mm. vertically, and 4 mm. in breadth. The roof, sometimes deficient to a varying degree, separates the tympanic cavity from the cranial cavity; it is limited externally by the *petrosquamous suture* (Fig. 4318, *A 1*, *B 1*). This suture may remain unossified for several years after birth or even permanently and thus afford a channel by which pyogenic infection may spread from the tympanum to the meninges and brain.

The attic overhangs markedly the inner end of the external auditory canal (Fig. 4309, *7*, *24*). It opens backward into the antrum and downward and inward into the *atrium* or tympanum proper. In the rest of its course it is surrounded by the diploëtic tissue of the bone. It contains, enveloped by mucous membrane, the head of the malleus, the body and the short process of the incus, the latter projecting into the aditus.

The *atrium* or tympanum proper (Fig. 4315, *9*) is that portion of the general tympanic cavity which is below the attic and internal to the membrana tympani. It is bounded externally by the tympanic bone or annulus and the membrana tympani, which is fixed in the tympanic groove of the bony ring.

On a level with the upper edge of the membrana tympani in front of the annulus is the tympanic end of the *Glaserian fissure* (remnant of the fissura petrotympanica). Close to the inner end of this fissure, and forming a division of it, is the commencement of the *iter chordæ anterius*, which transmits the chorda tympani from the tympanum.

It is bounded internally by the outer surface of the labyrinth or internal ear. It presents, in the macerated bone, (1) a reniform opening (*fenestra ovalis*) which leads into the vestibule of the labyrinth, but in the recent state of the bone this opening is closed by the foot of the stapes, surrounded by its *ligamentum annulare*. Below this is (2) a rounded eminence (*promontory*) due to the first turn of the cochlea. (3) Above and behind the fenestra ovalis is a portion of the *aqueduct of Fallopius* or canalis facialis. (4) In front of the fenestra ovalis is the *processus cochleariformis*, which here makes a sharp turn outward, and forms a pulley over which the tendon of the tensor tympani muscle plays. (5) A funnel-shaped recess (*fossula fenestræ cochleæ*) is situated at the postero-inferior part of the promontory, and is directed toward the *fenestra rotunda*, which in the macerated bone leads into the cochlea, but in the recent state is closed by a membrane (*secondary membrana tympani*).

The anterior wall of the atrium is narrowed vertically by the ascent of the floor and descent of the roof, and transversely by the approximation of the inner and outer boundaries of the cavity. At this point are two bony parallel canals separated by the bony *processus cochleariformis* and placed one above the other. The upper is the canal for the tensor tympani muscle, while the lower is the osseous Eustachian tube. The latter communicates with the nasopharynx through the membrano-cartilaginous Eustachian tube.

The posterior wall of the atrium presents from above downward the following: 1. A minute conical bony eminence (*pyramid*). The pyramid is hollow and contains the stapedius muscle. The tendon of the stapedius perforates the apex of the pyramid, and is inserted into the posterior surface of the neck of the stapes. The base of the pyramid communicates with the aqueduct of Fallopius by one or two small foramina for the passage of the nerve and vessels to the stapedius. 2. Immediately below the pyramid is the minute aperture of the *iter chordæ posterius*, which communicates with the aquæductus Fallopii and transmits the *chorda tympani nerve* from the facial nerve to the tympanic cavity. The chorda tympani, covered by mucous membrane, passes along the upper border of the drumhead between the handle of the malleus and the vertical ramus of the incus to enter the iter chordæ anterius. 3. There is sometimes seen below the aperture of the iter chordæ posterius a rounded eminence (*prominentia styloidea*) which is caused by the forward and upward prolongation of the styloid process. The aqueduct of Fallopius continues down from the posterior part of the fenestra ovalis through the diploëtic tissue of the posterior wall of the atrium to the stylomastoid foramen.

The front part of the *floor* of the atrium is in relation with the first bend or convexity of the carotid canal. At this point the bony septum may be absent and the artery separated from the tympanum only by membrane.

It may be well to state at this point that the outer wall of the carotid canal is in very close proximity to the bony Eustachian tube, and since dehiscence of the bony septum is here more frequent, the aural surgeon should always exercise great care in bougieing this passage.

The back part of the floor of the tympanum is in relation with the jugular fossa and presents small depressions separated by slight bony trabeculæ, thus producing an irregular region that has been called the *recessus hypotympanicus*. It is important because it is often quite encroached upon by the bulb of the internal jugular vein in the jugular fossa.

At times the lateral sinus is unusually large and arches far forward. Under these circumstances the bulb of the internal jugular is unduly large, and the jugular fossa which contains it may arch well up into the floor of the tympanum and be separated from the cavity by a thin and translucent septum of bone, or even the bone may be dehiscent. In such cases as this the bulb of the internal jugular has been wounded in performing a paracentesis of the tympanic membrane or drumhead.

In the antero-posterior direction the atrium measures about 12 mm., of which 9 mm. is bounded by the membrana tympani; from the floor of the atrium to the commencement of the attic is about 10 mm.; the narrowest part of the atrium, 2.5 mm., is caused by the outward projection of the promontory and the inward traction of the centre of the membrana tympani (*umbo*). Owing to the great obliquity of the drumhead the handle of the malleus is very obliquely placed in the drum; also the long ramus of the incus is quite oblique. The stapes, since it is placed at a right angle to the tip of the long ramus of the incus, passes upward and inward very obliquely toward the fenestra ovalis. The atrium is placed in the midst of the temporal bone, about 20-35 mm. from the entrance of the external auditory canal.

BONY LANDMARKS OF THE SKULL (Figs. 4303, 4304, 4305, 4319).—Among the many landmarks of the skull the following can readily be palpated, viz.: the inion, lambda, glabella, nasion, mastoid process, the supramastoid crest, suprameatal spine, nasal spine, osseous anterior nares, the bridge of the nose, the superciliary ridges, the external and internal angular processes of the frontal bone, the infra- and supra-orbital margins, the supra-orbital notch, the malar bone, the anterior part of the temporal crest, the region of the canine fossa of the superior maxilla, the lower portions of the borders of the ramus, the angle and mental tubercle of the mandible, and the zygomatic arch.

The *inion* is about 50 mm. above the spine of the axis or second cervical vertebra and 25 mm. below the posterior pole of the cranium. The inion not being developed in the child, its position is defined by taking a point at the junction of the middle and upper thirds of a line drawn from the spine of the axis to the posterior pole of the cranium.

The *lambda* can generally be felt through the scalp and is situated about 63 mm. above the inion. The parieto occipital fissure, in the adult, lies opposite, or a few millimetres in front of, the lambda; in the child the fissure may be as much as 25 mm. in front of it.

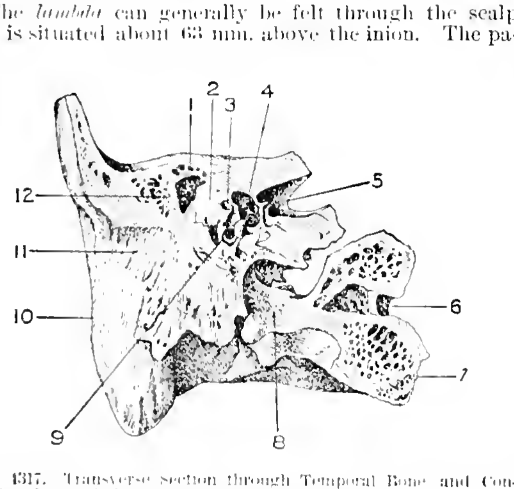

FIG. 4317. Transverse Section through Temporal Bone and Condyle of Occipital Bone, showing especially the *Aditus*. 1, Tegmen tympani roofing in the aditus; 2, inner wall (external semicircular canal) of the aditus; 12, outer (squamosal) wall of aditus; 3, aqueductus Fallopii; 4, vestibule; 5, internal auditory canal; 6, part of anterior condyloid foramen; 7, condyle of occipital bone; 8, jugular foramen; 9, pyramid with foramen at apex for exit of tendon of the stapedius muscle; 10, mastoid portion of temporal bone; 11, external auditory canal.

The *bregma*, in the child, is occupied by the anterior fontanel; in the adult it is about a third of the distance from the nasion to the inion.

The *zygomatic arch* is a very important landmark. In the natural position of the head it is horizontal, and is on the same level as the inion and the infra-orbital margin. Its upper border about indicates the level of the lower lateral margin of the cerebral hemisphere. By tracing the upper border of the zygoma backward we shall find that it passes immediately above the tragus and the external auditory canal to become continuous with the *supramastoid crest* or posterior root of the zygoma (posterior portion of the temporal crest).

If a line is carried in a vertical coronal plane from the *pre-auricular point* on one side to that on the other, it will pass through the bregma. The *lower end* of the fissure of Rolando is situated 50 mm. vertically above the pre-auricular point.

The *pterion* cannot be felt, but may be located two fingers' breadth (37 mm.) vertically above the middle of the zygomatic arch. It locates the *Sylvian point*—the point where the fissure of Sylvius divides into its three branches; it overlies also the anterior branch of the middle meningeal artery.

The posterior extremity of the *left* inferior frontal convolution (*Broca's convolution*) is situated about three fingers' breadth (56 mm.) above the middle of the left zygomatic arch.

The junction of the motor areas for the face and arm is situated at the junction of the lower and middle thirds of the Rolandic area, which is indicated by the highest part of the *temporal crest*.

The *parietal eminence* overlies the supramarginal convolution of the brain, and therefore also the terminal part of the posterior horizontal limb of the fissure of Sylvius.

The *frontal eminence* overlies the middle frontal convolution of the cerebrum.

Slightly above the outer canthus of the eyelids is located the *fronto-malar suture*, directly above which is the *external angular process* of the frontal bone. The lower lateral margin of the frontal lobe of the cerebrum is situated 12 mm. above the tip of the external angular process. About 12 mm. below the process is a small *tubercle* on the posterior border of the malar bone; a line drawn from this tubercle to the lambda overlies the superior temporo-sphenoidal fissure (*parallel fissure*) and corresponds to the descending horn of the lateral ventricle. That part of the temporal crest which extends between the external angular process and the coronal suture is located a little above the level of the inferior frontal fissure.

Situated at the junction of the inner and middle thirds of the supra-orbital margin is the *supra-orbital notch*. A line carried downward from this notch to the lower border of the mandible and crossing the interval between the lower bicuspid teeth will pass over the *infra-orbital* and *mental* foramina, the latter being situated about midway between the upper and lower borders of the mandible, while the former is about 12 mm. below the infra-orbital margin. These foramina furnish the guides for the operation of neurectomy to relieve neuralgia of the trifacial nerve.

On a level with the crown of the last molar tooth and midway between the posterior and anterior borders of the ramus of the mandible the inferior dental nerve enters the inferior dental canal on the inner surface of the ramus of the mandible. Consequently neurectomy of this nerve can be performed by trephining the corresponding outer surface of the ramus. Since the lingual nerve lies a little anterior to the inferior dental nerve, it can be exposed through the same opening.

A landmark of interest to ophthalmic surgeons is the *lachrymal tubercle*, which is situated at the junction of the infra orbital margin belonging to the body of the superior maxilla, and the anterior border of the lachrymal groove on the nasal process of the superior maxilla. In the operation for lachrymal fistula it serves as a guide to the position of the lachrymal sac.

The lachrymal groove is a bony groove situated between the crest of the lachrymal bone and the nasal process of the superior maxillary bone. It contains the lachrymal sac, which is the most important part of the lachrymal apparatus, since it is the seat of very disfiguring diseases. The lachrymal groove is directly continuous with the nasal duct. The latter passes downward and slightly backward and outward to open, under cover of the anterior extremity of the inferior turbinated bone, into the inferior meatus of the nose, at the junction of its anterior fourth with its posterior three-fourths, at a distance of from 30 to 35 mm. from the posterior boundary of the nostril.

The general direction of the duct is best expressed by a line extending from the inner canthus of the eye to the interval between the premolar and the first molar tooth of the upper jaw.

The sac measures from 12 to 15 mm. in length, from 4 to 5 mm. in breadth, and about 7 mm. antero-posteriorly. It is narrowest at its termination in the nasal duct.

The nasal duct has a diameter of 3 or 4 mm., and averages about 18 mm. in length. The duct is somewhat narrower near its middle than at its lower or its upper extremity.

On the living subject by drawing the lids outward, the *internal palpebral ligament* (tendo oculi) is made tense, and can be felt as a narrow tense band passing inward transversely, and in front of the lachrymal sac, to be attached to the nasal process of the superior maxillary bone. The ligament passes a little above the centre of the lachrymal sac, and is a guide to its position. Spontaneous rupture of an abscess of the lachrymal sac almost invariably takes place just below the internal palpebral ligament. In opening a lachrymal abscess in this the best location, the incision should be made a little external to the angular artery.

The position of the mastoid antrum is represented by Macewen's *suprameatal triangle*, situated a little behind and above the bony external auditory canal. This triangle is bounded by the postero-superior segment of the bony external auditory canal below, by the supramastoid crest above, and by an imaginary line joining the above boundaries. According to Macewen, if the aperture of the bony external auditory canal be bisected horizontally, the upper half would approximately be on a level with the mastoid antrum. On bisecting this upper segment vertically its posterior half would correspond roughly to the junction of the antrum and the attic, and immediately behind this is the suprameatal triangle.

Macewen states that the level of the base of the brain will be 1 or 2 mm. above the supramastoid crest and about 5 or 6 mm. above the roof of the osseous external auditory canal.

The supramastoid crest, which indicates the roof of the antrum as well as the floor of the middle cranial fossa, may vary as much as 20 mm. down or up. Measurements on large numbers of skulls show that the middle cranial fossa is never 10 mm. below the supramastoid crest. But the crest is sometimes imperfectly developed and cannot be relied upon as a landmark.

The *suprameatal spine* is situated at the postero-superior portion of the aperture of the bony external auditory canal, and has the suprameatal triangle or fossa back of it (Fig. 4304, *28 a*). This spine can almost invariably be recognized as indicating the postero-superior portion of the opening of the bony meatus. Randall states that he has found the floor of the middle cranial fossa as low as this spine only five times in one thousand bones. It averages about 6 mm. above the spine. The suprameatal spine is a safer guide for avoiding the middle fossa of the cranium than is the supramastoid crest.

In opening the mastoid sinuses it should be borne in mind that the *mastoid foramen*, extending from that portion of the groove for the lateral sinus called the *sigmoid fossa*, and terminating on the exterior at or near the occipito-temporal suture, is very variable in size. It usually transmits a small emissary vein from the lateral sinus to the occipital vein. Sometimes the foramen may be so large as to transmit all the blood from the lateral sinus to the external jugular vein.

The sigmoid fossa, and consequently the lateral sinus, varies very much in its outward curving; it may even project to the external cortex or table of the mastoid process.

In operating upon the mastoid antrum the surgeon chisels away the bone immediately behind and above the postero-superior quadrant of the osseous external auditory canal and endeavors to avoid the *middle fossa* of the cranial cavity by keeping below the suprameatal spine. In opening the mastoid cells he hopes to avoid the *lateral sinus* by chiselling obliquely to the surface and keeping parallel with and close to the external auditory canal. He avoids the *descending portion* of the *facial nerve* by not encroaching upon the lower half of the deepest portion of the posterior wall of the osseous canal.

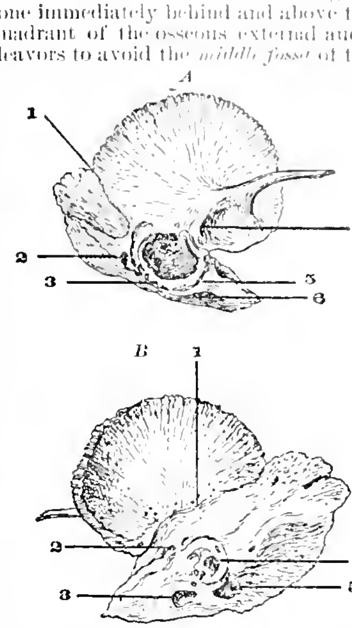

FIG. 4318.—Temporal Bone at Birth. *A*, Outer view. 1, Petrosquamous suture; 2, stylomastoid foramen; 3, tympanic plate; 4, postglenoid tubercle; 5, petrotympanic suture; 6, carotid canal. *B*, Inner view. 1, Petrosquamous suture; 2, hiatus Fallopii; 3, internal auditory canal; 4, floccular fossa; 5, aquaeductus vestibuli.

On account of the non-development of the mastoid process and the tympanic plate in the infant the stylomastoid foramen is situated upon the *lateral surface of the skull* instead of at its base (Fig. 4318, *A*, *2*). Hence the facial nerve emerges from the foramen immediately behind the annulus, and is unprotected. Therefore in infants the incision through the integument and subjacent soft parts, for the purpose of reaching the cranial wall, should not extend too far forward and downward, otherwise the facial nerve will be severed.

CRANIO-ENCEPHALIC TOPOGRAPHY (Fig. 4319).—In the study of what is commonly called *cranio-cerebral* topography, it should be clearly understood that we are to deal not only with the cerebrum, but also with the cerebellum, the ganglia of Gasser, and the brain's meninges or coverings; and the dura mater contains the middle meningeal arteries, and those venous channels called lateral sinuses and superior longitudinal sinus, not to mention other structures of less conspicuous importance from the point of view of applied anatomy. Also in relation with the arachnoid mater is the *cisterna magna*, the largest of the subarachnoidan spaces.

It would seem that the use of the term *cranio-encephalic* topography would be more conducive to accuracy than the more commonly employed expression craniocerebral topography. It may not be amiss to recall the fact that cranio encephalic topography must not be confounded with the cranioscopy of the phrenologists, a pseudo science founded by Gall. Gall quite arbitrarily localized the different intellectual faculties in various parts of the brain, and attempted to establish a relation between certain irregularities or bumps on the surface of the skull and the parts of the brain in which were resident the intellectual faculties. It is now known that the irregularities and bumps of the external table of the cranial walls have no relation whatever with the inequalities of the internal table, and still less have they anything in common with the configuration of the brain's various components.

The human skull varies greatly, in the details of its conformation, according to race, age, sex, and even stature, not to mention pathological variations. In no two individuals of the same race, age, sex, and stature are the skulls ever precisely alike; nor, under such circumstances, are the fissures and convolutions of the brain ever identical in pattern. The relations of the brain's convolutions and fissures to definitely chosen anatomical points on the surface of the skull or scalp vary in individuals of the same race, etc. Lastly, as the convexity or surface area of the brain is always less than the outer surface area or convexity of the skull, and still less than the surface of the scalp, lines drawn on the scalp cannot always correspond exactly to the fissures and convolutions of the brain.

In view of the preceding facts the well informed anatomist knows that the anatomical lines used in cranio-encephalic topography to locate fissures, convolutions, and areas of the brain are simply approximations—approximations that have been correlated from examinations of many brains and skulls. Fortunately, these approximations are found to be exceedingly useful as reliable guides in surgical anatomy. Practically, the surgeon uses the lines and points correlated by the anatomist, and overcomes the difficulties due to variations in individuals, by removing a greater area of the cranial wall than that indicated to him by the anatomist's lines and points as corresponding to the portion of the encephalon which he desires to expose. The brilliant results of modern cerebral surgery clearly proclaim the practical utility of the anatomist's approximations in cranio-encephalic topography.

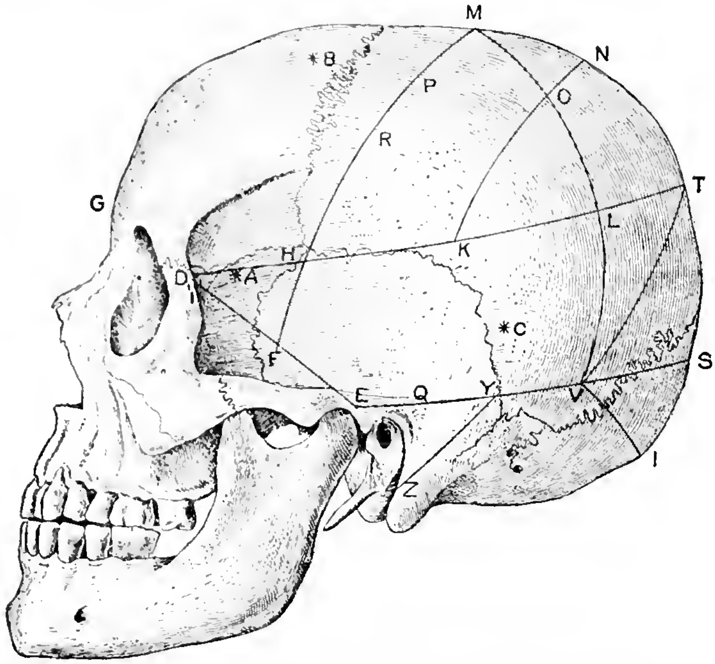

FIG. 4319.—Chiene's Guiding Lines in Cranio-Encephalic Topography. *G*, glabella; *I*, inion and indicates site of torcular Herophili; *M*, mid-point between *G* and *I*; *T*, three-quarter point between *G* and *I* and overlies parieto-occipital fissure; *S*, seven-eighth point between *G* and *I*; *E*, pre-auricular point on root of zygoma; *Q*, post-auricular point on supramastoid crest; *Y*, a finger's breadth behind *Q*; *V*, mid-point of line *E S* and marks highest convexity of lateral sinus; *Z*, near tip of anterior border of mastoid process; *D*, external angular process of frontal bone; *F*, mid-point on line *D E* and overlies point of bifurcation of middle meningeal artery; *H*, Sylvian point located by intersection of the Sylvian line *D T* and the line *F M*; this Sylvian point overlies the Sylvian point of the fissure of Sylvius and also the anterior division of the middle meningeal artery; *L* indicates angular gyrus and extremity of parallel fissure and is located by the intersection of line *D T* and line *V M*; *K*, mid-point of line *H L*; *H M*, precentral line and overlies precentral fissures; *K N*, line drawn from *K* to median sagittal plane parallel with *H M* and is the postcentral line; *H A*, anterior horizontal limb of the Sylvian fissure; *H K*, posterior horizontal limb of the Sylvian fissure; *O K L*, triangular area indicating parietal eminence, supramarginal convolution, and terminal part of Sylvian fissure; *R*, at the level of the temporal crest and on line of inferior frontal fissure; *P*, on line of superior frontal fissure; *T V* courses a little in front of the lambdoid suture; *T V I*, triangular area indicating occipital lobe of cerebrum; *I V Y Z*, guiding lines for lateral sinus; below *I V Y Z* is the region of the cerebellar hemisphere; *F E V L H*, pentagon indicating temporal lobe of the cerebrum except the apex which projects a finger's breadth downward, forward, and inward from *F*; *H K N M*, parallelogram indicating cortical motor area (Rolandic area); *A, site for opening subarachnoid space; *B, Kocher's point for tapping the lateral ventricle; *C, Keen's point for tapping the lateral ventricle; *Y Z*, indicating anterior limit of lateral sinus.

Many methods have been devised for mapping out the relations of the scalp to the cranial contents. From a clinical point of view, that introduced by Professor John Chiene, of Edinburgh, is a very simple and useful one (Fig. 4319). His method is as follows, viz.: The head being shaved, the *mid-point* (*M*) is located in the sagittal plane of the vertex from the glabella (*G*) to the inion (*I*); then the *three-quarter point* (*T*); and then the *seven-eighth point* (*S*). Next locate the *pre-auricular point* (*E*) on the root of the zygoma, and the *external angular process* (*D*) of the frontal bone. Having located these points join *D T*, *E S*, and *D E*. Bisect *E S* at *V* and *D E* at *F*. Draw the line *F M* and also the line *V M*. Bisect *H L* at *K* and draw a line from *K* to *N* parallel to *H M*. Trisect *H M* at the points *R* and *P*. Draw a line from *T* to *V* and another from *V* to *I*. A finger's breadth (18 mm.) posterior to the *post-auricular point* (*Q*) is the point *Y*; at the tip of the anterior border of the mastoid process is the point *Z*. A line drawn from *Y* to *Z* indicates the anterior border of the mastoid portion of the *lateral sinus*. The line *H M* corresponds to the *precentral fissures*, and may be called the *precentral line*. The points of its trisection correspond to the posterior extremities of the *superior* (*P*) and *inferior* (*R*) *frontal fissures*. The line *D T* is called the *Sylvian line*; it intersects the precentral line at the point *H*, which corresponds to the *Sylvian point* of the fissure of Sylvius, and also to the *anterior division* of the middle meningeal artery. *H A* corresponds to the anterior horizontal limb of the Sylvian fissure, and *H K* indicates the posterior horizontal limb of the fissure of Sylvius. This posterior limb of the Sylvian fissure terminates at the parietal eminence in the triangle *K O L* at the level of the temporal crest, indicating the position of the supramarginal convolution. The point *T* is the termination of the Sylvian line, and is somewhat in advance of the *parieto-occipital fissure*. The triangle *T V I* corresponds to the outer surface of the occipital lobe of the cerebrum. The line *I V* about corresponds to the tentorium cerebelli and the upper margin of the *lateral sinus*, while the line *V T* is a little above the *lambdoid suture*. The upper portion of the line *K N* corresponds to the *superior postcentral fissure*, but the lower part of the line is somewhat behind the *inferior postcentral fissure*; the line *K N* may be called the *postcentral line*.

The parallelogram *H K N M* overlies the ascending parietal and ascending frontal convolutions separated by the *central fissure* (fissure of Rolando), and hence corresponds to the cortical motor area (*area of Rolando*). The pentagon *F E V L H* outlines the *temporal lobe* of the cerebrum, except the apex; the latter is directed forward, downward, and inward about 18 mm. (a finger's breadth). About 18 mm. below the line *H L* is the superior temporal fissure (*parallel fissure*), which turns upward and terminates at L, thus indicating the position of the *angular gyrus.*

By drawing a line on the scalp from a point 12 mm. behind the mid-sagittal point (M) downward and forward for 8.5 cm. and at an angle of 67° to the sagittal line, the *fissure of Rolando* will be mapped out.

The inion I corresponds to the *torcular Herophili* and thus overlies the point of junction of the superior longitudinal, straight, lateral, and occipital sinuses. The groove for the lateral sinus may be mapped out by drawing a line from a point 1 or 2 mm. above the inion, in a slightly curvilinear direction with the convexity upward, to the point V at the postero-inferior angle of the parietal bone. The point V forms the highest part of the convexity of the sinus. From this point the upper margin of the sinus follows the line $E V$ for 25 mm.; it then curves forward and downward to a point 18 mm. below and behind the centre of the external auditory canal. The anterior border of the mastoid portion is indicated by the line $Y Z$.

The groove for the superior longitudinal sinus extends from the glabella to the inion. It increases in size from before backward and usually becomes continuous with the right lateral sinus. The edge of the trephine should be maintained at least 18 mm. from the mesial plane when the skull is opened over the posterior part of the vertex.

After the *middle meningeal artery* enters the middle cranial fossa through the foramen spinosum it runs outward and forward for about 37 mm. to the point F, which is located about a finger's breadth (18 mm.) above the mid-point of the zygomatic arch. It here divides into anterior and posterior divisions. The anterior division passes, with a slight convexity forward, across the pterion upward and slightly backward behind the coronal suture. It gives off branches which ascend over the Rolandic area corresponding to the parallelogram $H K N M$. This anterior branch corresponds to the lower two-thirds of the precentral line $H M$. In trephining over the lower part of the Rolandic area, especially over the cortical motor centres for the face and tongue, this anterior division will be encountered.

The *posterior division* of the middle meningeal artery passes backward almost horizontally toward the postero-inferior angle of the parietal bone. It may be indicated on the exterior of the cranial wall by drawing a line backward from the point F (which is 18 mm. above the mid-point of the zygomatic arch) parallel to the line $E V$.

When the calvarium is removed in the recent state the meningeal arteries will be found intimately adherent to the dura mater. The middle meningeal artery is the only one of them that is of surgical importance. In fractures of the skull the artery is frequently ruptured; the extravasated blood will generally be found between the cranial wall and the dura mater, and beneath the clot will be found the bleeding point of the artery.

To expose the anterior division of the artery the point of the trephine should be applied over the Sylvian point H.

To expose the posterior division of the artery the point of the trephine may be applied a finger's breadth (18 mm.) above the zygomatic arch and the supramastoid crest between the points E and V.

To expose the main trunk of the meningeal artery between the foramen spinosum and the point of bifurcation at F, the trephine is applied immediately above the mid-point of the zygomatic arch. When the anterior division of the meningeal vessel is ruptured the extravasated clot presses upon the temporo-parietal portion of the cerebrum and induces motor symptoms through pressure upon the centres for the face and arm; when the *frontal* branch of the meningeal's anterior division is wounded, the clot of blood is in the temporo-frontal region of the cerebrum and produces pressure symptoms in the motor area for the face, and in addition, on the left side, involves Broca's convolution. Wounds of the meningeal's posterior division involves the occipito-parietal region and the pressure symptoms are sensory.

To reach the lateral hemisphere of the cerebellum the point of the trephine is placed over the mid point of a line drawn from the inion to the tip of the mastoid process. In turning down the flap for this operation the mastoid emissary vein and the occipital vessels will be divided.

To tap the lateral ventricle at the commencement of its descending horn the point of the trephine should be placed a finger's breadth (18 mm.) below the mid point of the line $K L$; in this operation only 1 cm. of brain tissue is penetrated through the posterior half of the first temporal convolution.

The asterisk at C overlies the site chosen by Keen for tapping the lateral ventricle; he makes an opening through the cranial wall 31 mm. above Reid's base line and the same distance behind the external auditory canal; he then passes the instrument into the brain tissue toward the summit of the auricle on the opposite side. The undistended ventricle will be reached at a depth of 5 cm. from the surface.

The asterisk at B indicates the site selected by Kocher for draining the lateral ventricle. He makes an opening two fingers' breadth (31 mm.) in front of the point P, the instrument being directed backward and downward through the superior frontal fissure for a depth of 4 or 5 cm.

The asterisk at A overlies the site at which the point of the trephine is entered for draining the subarachnoid space; a small trephine should be used and the operator should be careful to keep in front of the middle meningeal artery.

The cisterna magna is reached by trephining a little above the foramen magnum and a little to one side of the external occipital crest so as to avoid the occipital sinuses.

Daniel Kerfoot Shute.

SKULLCAP.—(*Scutellaria*, U. S. P.). The dried herb, *Scutellaria lateriflora* L. (fam. *Labiatæ*). This genus consists of bitter perennials, nearly destitute of the aromatic properties found in most species of this large family, and further distinguished by a peculiar helmet-like development of the upper sepal, to which it owes its name. Calyx two-lipped, persistent; closed-in fruit until maturity, when it splits and opens widely. Corolla bilabiate, ascending; stamens four, also ascending, and under the upper lip of the corolla; lower anthers one-celled. Leaves opposite, petiolate; flowers axillary, usually solitary, sometimes in apparent spikes or racemes. There are nearly two hundred species, forming a very distinct and natural genus, distributed over nearly the whole north temperate zone. There are about a dozen in the United States, and several of them are used like the official, from which they are distinguished in trade by the appellation "Western skullcap."

The official drug is thus described:

Dark green, smooth, or slightly puberulent on the younger portions, the branches elongated, slender, sharply quadrangular; leaves opposite, exstipulate, shortly petioled, the blades rarely exceeding 8 cm. (3 in.) long and about a third as broad, ovate, rounded or truncate at the base, acuminate, obtusish or acutish, shortly and obtusely serrate, thin, veiny; flowers in axillary, peduncled, mostly simple and secund racemes, nearly sessile, about 6 mm. (¼ in.) long, the calyx bilabiate, in fruit becoming closed and developing a large helmet-shaped crest, the corolla deep blue, bilabiate, the stamens didynamous; fruit of four depressed, globose, papillose nutlets.

So called "Western scutellaria," more or less rough gray-hairy and with much larger flowers, in terminal panicles, is not of this species.

Skullcap contains a very little volatile oil, and its bitter principle has been called *scutellarin*.

The Scutellarias have had from time to time some transient or popular reputation in medicine for the cure of mad-dog bites, chorea, epilepsy, or other nervous diseases; also as tonics, antiperiodics, etc. The official species is considerably used by the eclectic school of practitioners and in home medication. It is reputed to be antispasmodic, anticonvulsant, etc., and is given for restlessness and wakefulness. It certainly possesses bitter tonic and mildly laxative properties.

W. P. Bolles.

SLEEP. See *Drowsiness.*

SLEEP. DISORDERS OF. See *Insomnia.*

SLEEPING SICKNESS.—DEFINITION.—Sleeping sickness, or negro lethargy, is a disease of the central nervous system—a meningo encephalomyelitis—endemic in Western equatorial Africa; characterized by gradually increasing drowsiness and lethargy, both mental and physical; and, after a period of about a year, terminating in death.

SYNONYMS.—Negro Lethargy, Sleeping Sickness of West Africa, Sleeping Sickness of the Congo, Congo Sickness, African Lethargy, Sleeping Dropsy, Lalaregolo, Lalangolo, Manungina, Nélavane, Ntolo, Dâdane, Somnolenza, Hypnose, Hypnosie, Maladie du Sommeil, Maladie des Dormeurs, Die Schlafkrankheit der Neger, Enfermedad del Sueno.

GEOGRAPHICAL DISTRIBUTION.—This disease is endemic on the western coast of Africa, between the River Senegal in the north and Loando in the south, a distance of about fifteen hundred miles. It is found on the coast, inland, and on the islands; how far inland it spreads has not been ascertained, but it may be safely said to be endemic in the whole of the region drained by the Senegal, the Niger, and the Congo. Outside of this region it has never been known to originate. Those who have resided within this area, and have left it, are liable to be attacked by the sleeping sickness at any time within six or seven years, so long is the latent period that has been assigned to this disease. Those cases of sleeping sickness that have been reported from other parts, as the Bahamas, Brazil, British Guiana, the French West Indies, etc., either have been imported from the endemic region or else are not sleeping sickness at all, but most probably ankylostomiasis. Thus "Guérin in an experience of one hundred and forty-eight cases at Martinique never saw the disease in a negro who had not been imported from Africa, nor in one who had been resident on the island for more than ten years" (Manson, in "Allbutt's System of Medicine"). Within the area of its endemicity sleeping sickness rages in certain places and at certain times as an epidemic. The spots thus unfortunately visited are selected with a capriciousness that defies all explanation. Settlements, villages, or garrisons are suddenly attacked with the epidemic; all who can, leave the infected place; the others remain—and die. Other spots in the neighborhood are passed by, at any rate for the present; later on their turn comes, and another district is desolated and decimated. Further, some districts are constantly attacked; and others, in fairly close proximity, as constantly and inexplicably escape. Epidemics are very frequent in the Lower Congo region, while at Stanley Pool and at the mouth of the Congo they are almost unknown. From recent accounts it would seem as if the disease was spreading. Dr. Cook (*Jour. of Trop. Med.*, iv., p. 236) reports cases occurring at Uganda on the Upper Nile; and Dr. Castellani has witnessed it raging among the natives in the Victoria Nyanza district. According to this observer, fifty thousand natives died of this disease in one year (see also the London *Hospital* of December 27th, 1902). Sleeping sickness is almost entirely confined to the negro race; the mulatto and the Moor have been attacked, but it has not yet been observed in a European. Whether this is due to hygienic precautions and conditions, or to something inherent in the disease, is at present unknown, and is likely to remain so until the etiology of sleeping sickness is settled.

ETIOLOGY.—The cause of sleeping sickness is not known. The disease has, in turn, been attributed to a variety of causes, some of which need only be mentioned to be rejected. For example: 1. *Sunstroke* has been put forward as the cause; but whether the sun was hotter or the negro's skull thinner in the endemic region was never explained; nor were the peculiar epidemic outbreaks so characteristic of the disease. If sunstroke had been the exciting cause, sleeping sickness would have had a much wider area of distribution. 2. Various *foods* and *intoxications*, as fungus, hemp, maize, the bitter manioc or cassava. When properly cooked these are said to be non-injurious; but when eaten raw it is claimed that they are liable to produce the disease. But these plants are found outside of this region, and are just as liable to be eaten uncooked in other districts; hence as an etiological factor they have not much value, although some analogy may be claimed to pellagra and lathyrism. 3. *Emotional causes*, such as nostalgia, pining under ill-treatment when away from home; and yet it has never been asserted, much less proved, that the negro from western equatorial Africa was either worse treated than others, or that he was more tender-hearted than his brother from other parts. 4. Various *microbes* have, of course, been suggested, but, unfortunately, the observers do not agree among themselves.

Bettencourt thinks that the cause of the sleeping sickness is a micrococcus; Cagigal and Lepierre did not find the micrococcus, but report a bacillus; Dr. Broden also found a bacillus. Marchand thinks that the disease is due to the pneumococcus; Drs. Mott and Bulloch found no micro-organisms at all; but, of course, this does not preclude the possibility of the disease being due to a specific organism, for, as in the case of syphilis, the organism may be there, but so far may have eluded the bacteriologists.* 5. Among the *parasites* that have been put forward as the probable cause are *Filaria perstans* (Manson), *Rhabdonema strongyloides* (Le Dantec), and *Ankylostomum duodenale* (Ferguson). Of these, Manson's suggestion of the Filaria perstans is by far the most probable. Manson has shown that the geographical distribution of the Filaria perstans is the same as that of the sleeping sickness; and further, the Filaria perstans has been found in an exceedingly large proportion of the cases in which any proper examination has been made; the latent period and the peculiar endemicity are both capable of explanation on this theory. Probably there is something else requisite besides the Filaria perstans, for many negroes have this latter and yet escape the sleeping sickness; so far, Manson only puts it forward as a hypothesis, but it is quite the most reasonable that has appeared. 6. "Like all tropical pathological puzzles, sleeping sickness has been attributed to *malaria*—that blessed cloak for ignorance—but there are none of the clinical or pathological marks of malaria about the disease" (Manson, *Jour. of Trop. Med.*, i., 125). 7. Dr. Andriezen has pointed out how very similar the symptoms of sleeping sickness are to those produced by destruction of the pituitary gland. Whether the pituitary gland is a causative factor in sleeping sickness is not known. 8. Crombie suggests that the deep cervical glands, which receive the lymph from the brain, may, by becoming obstructed by the Filaria perstans or its ova, cause sleeping sickness. 9. The virus, whatever it may be, is said to be conveyed by the saliva, the negroes using their fingers to eat with out of a common dish.

SYMPTOMS AND COURSE OF DISEASE.—Before describing the symptoms of sleeping sickness it may be well to remember that the negro is naturally prone to sleep. To those who have lived for any length of time in the tropics, the following quotation from Scheube's "Diseases of Warm Climates" will appear to be a remarkably mild statement of fact: "The negro works—when forced to—but with frequent interruption; he eats and drinks, sings, laughs, perspires; he capers and dances with ex-

* As this goes to press, Dr. Castellani, an Italian physician residing at Uganda, claims to have discovered the microbe of the disease, viz., a new variety of streptococcus. This same observer has since reported the finding of a species of Trypanosome in the blood and cerebro-spinal fluid of patients suffering from sleeping sickness. This has also been verified by Colonel Bruce, who found a trypanosome in the blood of twelve out of thirteen cases of sleeping sickness, and in the fluid obtained by lumbar puncture in every one of thirty-eight cases. ("Brit. Med. Jour.," 1903, i., 617 and 1218.)

Sleeping Sickness.

treme gayety—or he sleeps. When unemployed he cannot keep himself awake without a noise. It is therefore customary in the negro schools of the West Indies to oblige the unemployed half of the scholars to sing hymns while the other half receive instruction. If this were not done half of the scholars would be asleep" (Junker von Langegg). Neither *sex* nor *occupation* has any influence either as regards liability to the disease or immunity from it; all *ages* are susceptible to it, chiefly the young and vigorous adult from about fifteen to twenty years; in infants, and in those over forty years of age, the disease has not been noted.

Sleeping sickness begins very gradually with general weakness and languor, enfeebled powers of endurance, debility both muscular and intellectual, a more than ordinary disinclination to work coupled with an almost irresistible longing to doze or sleep, and this latter shows itself not only during the hours of labor, but even at meal-times. With this muscular fatigue and weakness there is also a corresponding mental dulness and vacuity, so that in place of his usual vivacious disposition the afflicted negro gets morose and silent, does not initiate conversation and talk for the mere love of talking as is his wont; but at first he will only answer questions, then only in monosyllables and when pointedly and repeatedly interrogated; later on, it is only after considerable lapse of time that an answer can be extracted from him, thereby showing the slowness and impairment of the mental processes. Headache is often one of the prominent early symptoms, though it is by no means an invariable one; when present, it is generally occipital.

Vertigo is often present. The patient has a shuffling, staggering gait, as if half asleep. The face is puffy; the upper eyelid droops, though whether as the result of drowsiness or from paralysis of the levator palpebræ superioris is not known. The lower lip also droops, showing the lower teeth and allowing the saliva to dribble and almost flow out of the mouth. The state of torpor increases, sometimes punctuated by brief snatches of seeming improvement which are not only short-lived, but generally lead to worse relapses, so that work of any kind becomes absolutely impossible and the patient does little but sleep; food is taken if brought to the patient, and if he is kept awake while eating it; otherwise he is very liable to fall asleep while a bolus is making its way from his tongue to the œsophagus. He lies around anywhere and in any position, even the most uncomfortable, and sleeps. If left alone now he would starve. Even now under proper care and attention it is more than probable that nutrition will fail, bedsores form, and diarrhœa and epileptiform seizures come to add to his generally miserable condition. The skin is generally cold, though the temperature may rise to 101° or 102° F., or even higher. There is enlargement of the lymphatic glands, chiefly the cervical; but the supraclavicular and occipital glands are often noticeable too. These enlarged glands vary in size from a small bean to a walnut, are tender on pressure, are discrete, do not adhere to the skin, and have no tendency to suppurate. The skin suffers from loss of the peculiar gloss and lustre which is noticed in health; it is also liable to be covered with an eruption, either papular, vesicular, or pustular; sometimes it may have the appearance of an exanthem. Such eruption is most common on the chest and abdomen. There is a very pronounced pruritus, and the consequent scratching leaves whitish lines of abraded epithelium on all accessible parts of the skin. Muscular tremors and light fibrillar twitchings are noticed.

Sensation is not much affected, except toward the end of the disease, when it may be diminished. The secretions are fairly normal, except the saliva, which constantly flows or dribbles out of the mouth; but whether it is a hypersecretion or inability of the patient to swallow, is not settled. Insanity is apt to supervene before the end. The superficial reflexes are normal and the knee-jerk is normal or increased. Choreic attacks have been observed, with tonic or clonic convulsions, and in severe cases epileptiform attacks. Muscular spasms are most apt to affect the flexors of the limbs and the sterno-cleido-mastoid. The above are the chief symptoms that have been noted, but it must be understood that no case presents *all* the symptoms, and there is considerable variation in their presentation.

Duration.—The disease may last anywhere from three months to three years; about one year is the average time.

Diagnosis.—There ought to be but little difficulty in diagnosing sleeping sickness; the geographical distribution, the progressive somnolence and bodily weakness, and the pruritus present a complex that is not afforded by any other disease. It has been confounded with beriberi, but the following table, compiled from Manson (Allbutt's "System of Medicine"), will show the differences:

Sleeping Sickness.	Beriberi.
1. Diseases of the central nervous system.	1. Disease of the peripheral nerves.
2. Progresses slowly.	2. Progresses rapidly.
3. Nearly always fatal.	3. Rarely fatal.
4. Limited endemic distribution.	4. Extensive distribution.
5. Not a peripheral neuritis, and not associated with marked œdema, although in the earlier stages there may be puffiness of the face, and in the later stages puffiness of the feet.	5. Has all the signs of a peripheral neuritis, and generally is accompanied with more or less œdema.
6. Muscular atrophy of rapid development, palpitations, abolished knee-jerk, and hyperæsthesia of muscles not found.	6. Torpor, tremor, insanity, and itching papular eruption not found.

Prognosis.—The disease is almost invariably fatal. Guérin reports 148 cases with 147 deaths; Gore 179 cases with 132 deaths; Forbes 13 cases with 11 deaths (and the termination of the other two not known).

Pathology and Pathological Anatomy.—Although sleeping sickness has been known for a little over a century, it is only in the last few years that anything has been learned about its pathology. Among the few notices that make any direct reference to the pathological anatomy, there is one that stands quite alone for its completeness and utility; this is a report of two cases (including autopsy) by Dr. F. W. Mott, director of the Pathological Laboratory of the London County Asylums. We here quote from his report in the *British Medical Journal* for 1899, i., p. 1108:

"The brain and spinal cord, pituitary body, and spinal ganglia were examined. To the naked eye the tissues in Case I. presented but little change beyond some slight thickening of the pia-arachnoid. The cerebral convolutions were complex and not atrophied; the brain weighed fifty-four ounces. The two hemispheres were of equal weight and there was no excess of fluid. In Case II. (the younger patient) the dura mater was found adherent to the calvaria. A considerable quantity of cerebrospinal fluid was present. The pia-arachnoid was somewhat thickened and opaque over the convolutions. The base of the brain likewise showed thickening and opacities of the pia-arachnoid. The weight of the brain was thirty-six ounces. Neither of the brains showed flattening of the convolutions, erosions on stripping the membranes, or dilated ventricles with granular ependyma. The nervous tissues before mentioned were removed so soon after death as to avoid post-mortem fallacies. Portions of different parts of the hemispheres, cerebellum, pons, medulla, and cord, as also the spinal ganglia, were stained by the Nissl, Marchi, and Marchi-Pal methods after suitable fixation. The microscopical examination of these sections exhibited in both instances similar conditions. There was a leptomeningitis and an encephalomyelitis. Throughout the whole central nervous system, but especially in the medulla and base of the brain, sections showed all the perivascular limits distended with mononuclear leucocytes. . . . Sections were also stained for micro organisms by Gram's, Pfeiffer's, and other methods, but with negative results. . . . The general and special appearance of the nerve cells was as follows: In Case I. the outline of the nerve cells and their arrangement appeared fairly normal; neither was it considered that the neuroglia cells were markedly increased. The columns of Meynert in the cortex cerebri were distinctly evident, thus contrasting with the appearance of the brain in general paralysis. The cells themselves throughout the whole nervous system showed a uniformly dull, diffuse, staining reaction, and in none of the cells were the Nissl granules evident. This change was undoubtedly due to the hyperpyrexia during the last hours of life. In Case II. the cells for the most part presented a normal outline and exhibited Nissl granules on the dendrons and in the body of the cell. In the medulla, however, a considerable number of cells showed chromolytic changes, and to a less degree changes were found in the motor cells of the anterior cornua The cells in the left hemisphere showed degenerative changes in sections of the motor area, Meynert's columns were not distinctly visible, and many of the cells seemed atrophied and broken up. Fibres: Sections of the brain and cord were stained by Marchi and Marchi-Pal methods. Nothing abnormal was found in Case I. except perhaps that the tangential fibres were not so numerous as in the normal cortex cerebri. In Case II. there was obvious wasting of the tangential fibres in both hemispheres, but especially of the left. There was slight sclerosis of the crossed pyramidal tracts of the cord, more marked on the right side, and also a number of recently degenerated fibres were exhibited by the Marchi method. The arteries of the central nervous system exhibited no trace of endarteritis. In the choroid plexus there were numerous microscopical psammomata. The central canal of the spinal cord was filled up with proliferated glia tissue. The posterior spinal ganglia showed the same appearances around the vessels, but the ganglion cells in Case I. only showed the diffuse staining of hyperpyrexia, and in Case II. exhibited a fairly normal appearance. . . . The symptoms which were, however, present in both patients, and characteristic of the disease—namely, progressive drowsiness and lethargy, and the progressive weakness in body and mind, without any distinct paralysis or mental disability—could best be accounted for by supposing that the metabolism or functional activity of the neurons as a whole was affected injuriously by some toxic product either circulating in the blood or existing in the cerebrospinal fluid; that this toxic agent, whatever it might be, occasioned great proliferation of mononuclear leucocytes beneath the pia-arachnoid and in the perivascular lymphatics. It might, however, be supposed that the functions of the nervous system were affected by an interference with their nutrient lymph supply, owing to the perivascular lymphatics being filled with leucocytes. The liver, kidneys, lungs, pituitary body, spleen, lymphatic glands, and duodenum were also examined. The results were for the most part, with the exception of the duodenum and lymphatic glands, negative. The lymphatic glands were much enlarged owing to great increase of lymphocytes. Sections of duodenum showed a large number of lymphocytes, and a proliferation of the same in the lymphoid nodules."

In addition to the above, Dr. Mott furnished a much fuller report, with illustrations, to the *British Medical Journal* for December 16th, 1899. To this the reader, in search of further details, is referred

TREATMENT.—This has, so far, been most unsatisfactory Purgatives, tonics, quinine, and arsenic have all been tried, but without much effect on the death rate. Among the newer suggestions are: (1) Hypodermic injections of testicular extract; (2) venesection of about one-fourth of a litre per week, followed by injection of an artificial serum, the object being gradually to free the blood from the Filaria perstans; (3) thyroid extract; (4) electricity over the spine. Probably the best that can be done will be found along the lines of hygiene, nursing, and feeding. *R. J. E. Scott.*

SMALLPOX.—DEFINITION.—Smallpox is an acute, contagious, febrile, exanthematous malady, characterized by an eruption which passes through four stages of development, *i.e.*, macule, papule, vesicle, and pustule. The initial symptoms are, ordinarily, chill, fever, headache, lumbar pain, and vomiting. The fever disappears when the eruption appears, and recurs when the latter has reached the pustular stage. The period of incubation varies from seven to twenty-one days.

HISTORY.—Though an ancient disease, its origin is unknown. DeHaen, Willan, Moore, and Barron contend that it was known to the ancient Greeks and Romans; Friend, Mead, Good, and Adams deny this assertion. Rhazes, an Arabian physician, who practised medicine about the year 910 A.D., was one of the most celebrated of the earlier writers on smallpox. When we consider the date of his writings and the state of medical knowledge at that time, it will be seen that he delineated the natural history of the disease with remarkable accuracy. Rhazes contends that Galen was familiar with the malady, and cites extracts from his first, fourth, ninth, and fourteenth books as evidence of the fact. He also mentions Ahrún, of Alexandria, and Mesue, of Bagdad, among the other early writers on variola. It is, however, commonly agreed among historians of medicine that this disease cannot with certainty be traced to a period anterior to the Christian era. Since smallpox first attacked mankind it has never wholly disappeared, and from Europe and Asia has been carried all over the world. It appeared in England in the first part of the thirteenth century, and in Germany in the latter part of the fifteenth. It was imported into the United States soon after the discovery of America. It reached Mexico in 1527. Smallpox is a malady to which the human race is wellnigh universally susceptible, probably not more than one in a thousand persons being naturally immune. In consequence of the universal susceptibility of unvaccinated persons, and the neglect of vaccination in almost all communities, smallpox smoulders in different localities, and at varying periods breaks loose from these endemic foci and assumes epidemic proportions in municipalities, States, and nations.

Like all other contagious maladies epidemics of smallpox differ markedly one from another, not only in the amount and character of the eruption, but in the character and intensity of symptoms, and in mortality as well. For centuries prior to Jenner's discovery of vaccination (1796) smallpox was regarded as the king of fatal diseases. M. de La Condamine, writing of this malady, says that it was the cause of one-tenth of all the deaths among mankind. He also says: "Among those who outlive it, many, either partially or totally, lose their sight or hearing; many are left consumptive, weakly, sickly, or maimed; many are disfigured for life by horrid scars, and become shocking objects to those who approach them. Immense numbers lose their eyesight by it." Black, Frank, and other reputable writers on this disease state that it caused half a million deaths annually in Europe prior to general resort to vaccination. The great English historian Macaulay, in speaking of this malady in England, says: "The havoc of the plague had been far more rapid, but the plague visited our shores only once within living memory, but the smallpox was always present, filling the churchyards with corpses, leaving on those whose lives it spared the hideous traces of its power, turning the babe into a changeling at which the mother shuddered, and making the eyes and cheeks of the betrothed maiden objects of horror to her lover."

Rosen says that one-tenth of the deaths in Sweden resulted from smallpox. Simon says that this disease concurred with fire, and sword, and famine to depopulate St. Domingo.

In an epidemic of smallpox in Mexico in the sixteenth century 3,500,000 of the inhabitants died in a few years, leaving in some places scarcely enough people alive to bury the dead. Prescott ("Conquests of Mexico," vol. vi) describes this epidemic as "sweeping over the land like fire over the prairies, smiting down prince and peasant, leaving its path strewn with the dead bodies of natives who perished in heaps like cattle stricken with the murrain." Smallpox invaded Brazil in 1653, and in some instances whole races of men died of the malady.

In a few years the Province of Quito lost 100,000 of her Indian population by this disease. Iceland had been invaded by smallpox seventeen times prior to 1707, and desolation and ruin followed in its wake for years, causing in the year 1707 the death of 18,000 out of a total population of 50,000. The terrible fatality of the disease in Greenland in 1707 is evidenced by the following extract from Crantz's "History of Greenland": "Empty, depopulated houses and unburied corpses, some within and some without the houses, were commonly encountered. In one island they found one girl with the smallpox on her, and her three little brothers; the father, having first buried all the people in the place, had laid himself and his smallest sick child in the grave, raised with stones, and ordered the girl to cover him." In 1734 Greenland lost two-thirds of her population from smallpox. From authentic sources it is learned that in one epidemic of this malady one-sixth part of the inhabitants of Ceylon died. Siberia had a similar experience, and Kamchatka has suffered in like manner. Captain Cook ("Voyages to Pacific Ocean," 1785), speaking of the first appearance of smallpox (1767) in Kamchatka, describes it as "marking its progress with ravages not less dreadful than the plague, and seeming to threaten their extinction." M de La Condamine says that prior to vaccination one-tenth of all the deaths in France were from smallpox. In 1805 M. Laborde says: "I had been a witness of the variolous epidemic which had, in 1792, swept off one-fourth of the population of the Isle of France." North America has been fearfully scourged by smallpox; whole tribes of our Indian population were almost literally extinguished by it. McKenzie says of the disease among the Indians: "It was as a fire consuming the dry grass of the field. The infection spread with a rapidity which no flight could escape, and with a fatal effect which nothing could resist." Godfrey says that 2,000,000 of the inhabitants of the Russian empire died of smallpox in a single year. Sir Gilbert Blaine says: "When there was no vaccination in our navy, one-fifth of all the men enlisted died of smallpox." Mr. Makena describes an epidemic of this disease in the Argentine Confederation from 1846–48, as "sweeping with the wings of death over that enormous tract of country from the seaboard of the Atlantic on the East to the cordillera of the Andes on the West." Alexander Wheeler, of England, an ardent antivaccinist, says: "In 1875 smallpox carried off 101,397 inhabitants of India." Hirsch says that between 1866 and 1869 smallpox killed 140,000 natives in Bombay and Bengal. In the whole of India (1873–74) 500,000 inhabitants died of this disease.

An exhaustive account of the various epidemics of smallpox is, of course, not to be expected in a limited article. The instances above quoted are presented in order to show how malignant smallpox commonly was in prevaccinal times, as well as the present, in a population unprotected by vaccination. The instances cited are entirely authentic, and justified Macaulay in styling smallpox "the most terrible of all the ministers of death." It, however, would be wholly erroneous to contend that all epidemics of smallpox had been as pernicious as the ones above cited. It is an incontestable fact that throughout the entire written history of this malady individual epidemics have differed markedly one from another, not only in mortality, but in the quality and quantity of the eruption and the other attendant symptoms. In some epidemics a large percentage, and in others the largest percentage, of cases of smallpox were of the mildest type—varioloid as it is called—and this resulted, not, as some text-writers assert, in consequence of previous vaccination or a prior attack of smallpox, but from an inexplicable partial natural immunity of populations more general at one period than at another, for this disparity of different epidemics as to mortality, quality, and quantity of eruption, and other symptoms was noted prior to vaccination. I cite three instances from a number at hand. George Cleghorn, M.D., in his book on the "Epidemic Diseases of Minorca," says: "The smallpox were twice epidemical in Minorca while I resided there, viz., in 1742 and 1746. About the middle of March, 1742, the smallpox broke out in Minorca, to the great consternation of the natives who had not seen them since the year 1725, but well remembered the destruction which they then occasioned. During the first six or eight weeks (1742) the distemper was favorable and seldom proved fatal; but its virulence increased with the heat of the weather, so that in June and July it was not uncommon, both at Mahon and Ciudadella, to bury ten or twelve a day. Nevertheless, in proportion to the numbers not many died, and what mortality there was happened chiefly among children at the breast and the common soldiers." Of the epidemic of 1745–46 he says: "Then they (the smallpox) travelled northward to Ciudadella, and disappeared in the spring, having carried off almost all of the children who survived the chincough and the summer fevers. It was, however, very remarkable that the longer the infection continued in the island the milder it became, so that there was much less mortality in the northern part than in the southern, where it first broke out." He then cites the fact that in 1846 at St. Phillip's Castle three-fourths of the smallpox patients died.

In the early part of 1898 smallpox appeared in several of the Southern States. The first case in this city (Augusta, Ga.) was detected May 5th, 1898 the patient having contracted the disease in South Carolina. The malady spread from one State to another until it invaded all sections of the United States. The disease is said to have been brought to this country from Cuba, it having been prevalent there during the Spanish-Cuban war. In a large number of communities it assumed epidemic proportions by reason of the fact that physicians failed to recognize its nature until it had attacked a large number of the inhabitants. Cases of the disease were observed by me in citizens of twelve counties in Georgia and four counties in South Carolina. In each and all of the communities in which I encountered the disease it was, in my experience, unprecedentedly mild and irregular both as to constitutional symptoms and quantity and quality of eruption, and equally strange was the further fact that while perhaps one-sixth of the cases were either confluent or semiconfluent in type, the vast majority of discrete and semiconfluent cases went on to and through the purulent stage without secondary or maturation fever. This fact was ascertained by repeated daily observations with the thermometer. Again, not more than five per cent. of confluent cases terminated fatally. In the confluent and semiconfluent cases pitting of the face was in about the percentage usually attendant on severer epidemics. The disease was confined almost exclusively to the unvaccinated. No one of the four hundred and twenty-nine cases coming under my observation during the last four years had a typical vaccine scar. Ten of them had a scar, and claimed to have been vaccinated from ten to twenty years previously, but in no one of them could I say from the cicatrix that the patient had undergone vaccinia.

The initial symptoms of the malady were headache, lumbar pain, chill, fever, and vomiting, and these symptoms were as commonly complained of by those having the disease mildly as by those who had the severer types. In those who had the disease mildly, *i.e.*, about two-thirds of the cases, the constitutional symptoms disappeared wholly when the eruption appeared, and these patients then went to work or visited their friends. I found a large per cent. of them at work in the fields, shops, and other industrial pursuits while the eruption of smallpox was in full bloom on them. Two of these patients after remaining at home three days resumed their work of delivering ice to our citizens. Others were apprehended on the public thoroughfares or in houses where they were visiting. These individuals claimed that their disease was chickenpox, and in not a few instances had been so informed by their physicians. In one case the total number of pustules on the patient's body was six, yet this patient gave rise to an epidemic of smallpox in the jail in our city. Another patient had only twelve pustules, another twenty-four, another thirty-five, another forty-four, others had from fifty to sixty, others from seventy-five to one hundred, while still others had several hundred.

The disease attacked entire unvaccinated families, and it was a common experience to find all numerical grades of eruption from fifty to one hundred on to discrete, semiconfluent, and confluent cases in one unvaccinated family. Several of the confluent and semiconfluent cases were in direct traceable connection with those who had respectively six, twelve, thirty-five, and fifty pustules. That the disease in America has been for the last four years unprecedentedly mild, when judged by fatality, is shown by the statistics of the United States Marine Hospital Service. The reports of this service show the following facts: 1899, total number of cases of smallpox 11,136, deaths 553; year 1900, cases of smallpox 20,362, deaths 819; six months ending June 13th, 1901, cases 28,257, deaths 486; from December 28th, 1901, to June 13th, 1902, cases 36,373, deaths 1,154. While the statistics above quoted are imperfect in that they do not represent the total number of cases nor the total mortality occurring in America, they are valuable in that they are made up from data furnished from all parts of the United States, and accurately show the mortality rate in the various localities from which these reports were obtained. The report of the Marine Hospital Service shows that for the term ending June 13th, 1902, smallpox was in existence in forty-three States and Territories in the United States. Of the 129 cases which occurred in this county during the last four years only 6 resulted fatally.

That the course of the disease was altogether atypical is shown by the fact that the initial symptoms constituted the major part of the attack of smallpox in nine-tenths of the cases observed by me. Other atypical manifestations of the malady were noted as follows: In not a few cases the eruption remained globular throughout its entire course, umbilication being wholly absent. In a still greater percentage of cases, although umbilication was present, a large per cent. of the eruption continued globular through its entire course. Not uncommonly, in discrete cases, the vesicles were observed to have changed into pustules on the fourth day, and then rapidly desiccated, and in a few additional days began to drop from the body. In some instances semiconfluent cases did likewise, while in other instances, in both semiconfluent and confluent cases, the course of the eruption was as prolonged as that in severer epidemics. In semiconfluent and confluent cases pitting of the face was about in the percentage observed by me in former years, though in some cases of both of these varieties the eruption ran an exceedingly rapid course, desiccated and soon dropped off in large patches, leaving no sign of pitting. In a large proportion of the mild cases the exanthem did not pass through the various stages usually observed in the disease, but after developing in an abortive form promptly retrograded, leaving warty excrescences on the face which after several months disappeared and left no trace of disfigurement.

My experience with smallpox during the last four years may be summed up by saying that the cases of the disease varied from one another—from those showing the extreme limits of the severest and fatal types to the very mildest forms of varioloid in which but a few pustules evidenced the fact that I was dealing with smallpox. The variations in types of the malady were rarely ever sharply defined amidst the group of variolous affections ordinarily described in the books, but were rather a direct or an indirect change from one type to another, ofttimes so gradual as to be diagnosticated by general outlines rather than by sharply defined outward appearances.

Morbid Anatomy.—The only characteristic pathological lesion of smallpox is the exanthem. This passes through four stages, *i.e.*, macule, papule, vesicle, and pustule. In the white subject the macules consist of small, non-elevated red spots, which within forty-eight hours become elevated into papules, then develop into vesicles, and later into pustules. In the negro the exanthem follows a similar course except as regards the redness of the macules and papules. In the hemorrhagic variety hemorrhage occurs in the skin, in the exanthem, in the mucous and serous membranes, and in the viscera. The eruption of variola appears on the skin and on the mucous membrane of the nose, mouth, pharynx, œsophagus, the genitalia, and occasionally of the larynx and trachea. If the suppurative process of the eruption does not invade the true skin, pitting will not result; if, however, it be involved, scarring of the part is inevitable. The morbid changes in the viscera of the smallpox patient show nothing peculiar to this disease, but are such as are common to most of the zymotic affections—*i.e.*, congestive, inflammatory, and degenerative changes.

Etiology.—Smallpox is contracted by breathing a confined atmosphere infected with the virus of the malady and by contact mediate or immediate, with an infected person, clothing, bedding, etc. It is a disease *sui generis*, and therefore can be propagated only by its own specific virus. (In regard to the nature of this, consult the article on *Protozoa* in Vol. VIII.) The contagious element is given off from the infected body by the breath, exhalations, secretions, and exanthem. Attempts to produce the malady by inoculations with the blood and secretions of smallpox patients have in some instances resulted negatively. The disease is, however, transmissible by inoculation of an individual with the contents of the pustule, yet this virus may be rubbed upon the skin with impunity unless the skin be abraded. If it comes in contact with the mucous membrane of an unvaccinated individual variola results. It has been claimed that smallpox is transmissible through the atmosphere. From long experience with the disease I am convinced that it never is air-borne. Our smallpox hospital has been for years located within one thousand feet of two populous blocks of our city, yet we have had but one case of the disease develop on these two blocks, and it was traced to an extraneous source. I am convinced that in every instance where it has been claimed that smallpox was disseminated through the atmosphere, it resulted from infected fabric having been scattered from time to time through the community, or from contact with individuals having the malady so mildly as to escape detection. I recently intercepted an individual having an extremely mild case of smallpox in the pustular stage, who, the whole night previous to his detection, had attended a ball. These extremely mild cases are frequent sources of dissemination of the disease. The virus of smallpox is tenacious of life when attached to fabrics, and when these have been packed away it has been known to retain its vitality for a year or more. It is therefore portable. Indeed, infected clothing, bedding, and other fabrics are frequent sources of extension of the disease. The contagion of smallpox infects an individual by passing into the system through the respiratory tract.

The character of an attack of variola as to lightness or severity varies with the then constitutional condition or degree of susceptibility of the individual. If an unvaccinated person be exposed to varioloid so mild that there may not be more than six pustules on the body, he may contract malignant smallpox therefrom, while, on the other hand, one who had never been vaccinated may be exposed to a malignant case of variola and only contract varioloid. This inequality of individual predisposition has been observed from the earliest period embraced in the recorded history of the disease. A fractional part of mankind seems to be wholly insusceptible to smallpox. I have met with two physicians who had never contracted the disease, although repeatedly exposed to it, and they possessed equal immunity to vaccination, as shown by failure of repeated efforts to inoculate them with vaccinia. These individual instances of immunity to smallpox and vaccinia are among the rarest of medical experiences, are in fact clinical curiosities, for it is a proven fact that susceptibility to both infections is well-nigh universal in man. Occasional instances are met with demonstrating that some individuals possess remarkable susceptibility to smallpox. I have encountered seven instances of second attacks of this malady. Three of them were cases of recrudescence; in the other four, all of whom were pockmarked by the first attack, a long number of years intervened between the attacks of smallpox, and two of these patients died. I have a photograph of one of the cases of recrudescence plainly showing the marks of the first attack while the pustules of the second infection were still adherent to the body of the patient. Second attacks of variola are, however rare, though a few cases are on record in which physicians have reported cases of third and even fourth attacks of the malady in the same individual.

A successful vaccination in the vast majority of instances is protective against smallpox during life, though in a minority the protective effect of vaccination decreases, and in some cases wholly disappears, in from ten to twenty years after it was done. I have never observed a case of smallpox or varioloid in a person with a typical scar of vaccination made within ten years, and I have carefully searched for such instances. The wife and six children of the superintendent of our smallpox hospital were successfully vaccinated, and though in constant contact with the patients they have never contracted smallpox. No vaccinated employee or officer of our hospital has ever contracted variola in any of its forms. In my experience a recent successful vaccination (*i.e.*, one made within five years) is as fully protective against smallpox as a previous attack of this disease is against a second one. If vaccination be done in infancy and repeated at puberty, such patient will prove immune to smallpox, though it would only be prudent for such a one to be promptly revaccinated if directly exposed to the former disease. I was vaccinated in infancy, and though I have repeatedly in the last thirty years made attempts at revaccination of myself, every such effort has failed.

Incubation.—The period of incubation varies from seven to twenty-one days. Ordinarily it is about twelve days. I have, however, repeatedly observed it to be as long as eighteen and twenty-one days. This latter fact is important in that it demonstrates the necessity of detaining suspects in isolation for a period of twenty-one days.

Types of Smallpox.—The Chinese described forty varieties of this disease. While the eruption of smallpox shows itself under a number of modifications from the several types ordinarily described by modern writers, it is not deemed necessary to describe the twenty or more varieties presented by the old writers. I shall describe the following types of the disease:

Discrete Smallpox.—*Symptoms and Course.*—The initial symptoms of this variety are chill, fever, vomiting, headache, and lumbar pain. Ordinarily the temperature reaches 102° or 103° F. on the first day of the attack, 103° or 104° F. on the second day, and on the third day it may be 105° or more. With the elevation of temperature the pulse becomes full and frequent, beating 120, 140, or even 160 per minute. Photophobia and sore throat now set in. The patient becomes restless or even delirious in consequence of the febrile movement and other constitutional disturbance. Convulsions are of frequent occurrence in children. The face becomes flushed, the conjunctivæ congested, and the carotids throb. Redness and swelling of the tonsils and soft palate take place at the end of the second day; this may extend to the larynx and cause hoarseness, and a shrill, harsh cough. At the end of the third day the fever and other constitutional disturbance have attained their maximum. At this time the eruption appears, and, as a rule, the fever and pulse-beats fall to the normal. The initial symptoms are usually quite severe, though their intensity is not always indicative of the grade of the attack, for it is frequently observed that the initial symptoms of extremely mild cases are of considerable intensity. At this stage of the disease no symptoms are present by which it may be diagnosticated. The severe lumbar pain is, however, so characteristic that its presence should lead the physician to suspect the nature of the disease.

Stage of Eruption.—At the end of the third day of the fever the eruption commences on the face, scalp, neck, and wrists. When it first appears it is macular, *i.e.*, consists of red spots which simulate the exanthem of measles, and at this stage cannot be diagnosticated from measles. During the succeeding day it spreads over all parts of the body. It commences on the mucous membrane of the throat before it attacks any other part of the body, but it is rarely first detected in this situation owing to the slight local disturbance which it causes in its incipiency. On the third day the macules have changed into papules. The papules on the surface of the body impart to the sense of touch a feeling similar to that of shot beneath the skin. If the efflorescence be copious in the mouth it causes increased flow of saliva; in the pharynx it causes difficulty in swallowing; in the larynx, hoarseness and cough; on the conjunctivæ, lachrymation and photophobia. The papules persist for two days and, by elevation of the epidermis over the site of each papule, develop into vesicles. The individual vesicles are about the size of a split pea, contain a lactescent fluid, and become umbilicated. On the sixth day of the efflorescence the vesicles begin to lose their umbilicated appearance, rapidly assume a globular shape, and by the eighth day have changed into pustules. The skin surrounding the pustules becomes red, swollen, and œdematous, each pustule has a broad base, and in cases of confluent or semiconfluent smallpox is closely set against or runs into its fellows. During this stage, in a full case of discrete smallpox, and in all cases of the confluent and semiconfluent varieties, the patient suffers from profuse salivation, swallowing is accomplished with great difficulty, the nose is filled with pustules, the voice is husky or inaudible, the cough croupy and distressing; the eyes are red, discharge a muco-purulent matter, and are extremely sensitive to light. When the exanthem covers the face, as it not infrequently does when the eruption is discrete on all other parts of the body, the face is swollen into a shapeless mass, the eyes are closed, and the features are so distorted as to render it impossible to recognize the patient. Secondary fever sets in upon the stage of pustulation being reached, a chill having preceded the fever. The fever is distinctly remittent in type, reaching its acme in the evening. The temperature in this stage is higher than in the initial fever, not infrequently reaching 106° F. when the fever is at its highest point. The pulse increases in frequency simultaneously with increase of temperature, ranging from 120 to 140 or 160 beats per minute. At this stage the patient is in the most critical period of the disease. The fever and other constitutional perturbation continue until the stage of desiccation has been completed. A subsequent marked elevation of temperature is suggestive of some complication, and its cause and significance should be promptly ascertained.

Stage of Desiccation.—The process of desiccation ordinarily commences on the twelfth day of the efflorescence, and follows in the order in which the eruption appeared. The desiccative process usually occupies from eight to fourteen days, the length of time being governed by the extent and degree of pustulation. The desiccative process on the palms and soles in some instances extends from four to six weeks. Just prior to or at the commencement of the desiccative process many of the pustules rupture and the exuded fluid dries into a yellowish or brown crust. As desiccation advances the swelling of the skin decreases and the constitutional disturbance abates. Cicatrization advances beneath the pustules or crusts, and ordinarily when these are thrown off there remains at the site of each pustule a reddish-brown or violet color in white subjects, and a white or black spot on negroes, with elevated margins and depressed centre. If only the superficial layer of the skin has been invaded these blotches sooner or later wholly disappear; if, on the other hand, the true skin has been invaded by the suppurative process the face will be permanently pockmarked. This description is an outline of discrete smallpox as it is ordinarily encountered among unvaccinated patients. Individual cases, however, present the widest differences in severity and character under different constitutional conditions of patients, and in numerous instances during every epidemic the malady is so light in the amount of eruption and character of the symptoms that those suffering from it present but few if any of the typical symptoms of the malady, and may not even suspect the true nature of the disease. If such patients perchance consult a physician, he, unless practised in smallpox, diagnosticates the malady to be chickenpox or some other light affection, and the patients continue to attend to business throughout the entire course of the disease, and thus scatter it abroad in the community.

Confluent Variola.—This type differs from the discrete in that the eruption and constitutional symptoms are much more severe than in the latter. The initial fever is more intense and of shorter duration, usually lasting not more than two days. The initial fever frequently reaches 106° F. and then falls to 103° or 104° and continues at this height until secondary or maturation fever occurs. The fever of confluent smallpox is of the remittent type, and when the suppurative process is reached, not infrequently registers 107° or 108° F. The development of the eruption in this type occurs from twelve to eighteen hours earlier than in the discrete variety, and spreads over the body more rapidly, frequently appearing simultaneously on the face, trunk, and limbs. In the severest cases the eruption is so thickly set upon the entire body that each vesicle coalesces with its fellows. The skin is intensely swollen and the eruption may cover the entire body as a mask. Suppuration rapidly ensues in the vesicles, and the eyes, lips, nose, cheeks, ears, scalp, hands, feet, and genitalia present one horrid mass of deformity. Ordinarily, however, where there is a complete coalescence of the exanthem on the face it is semi-confluent on the other parts of the body. It may be stated as a rule that pustulation on more than one-half of the body results fatally. Confluent variola is a formidable malady, the mortality ranging from fifty to seventy-five per cent. In its onset, and throughout the entire course of the disease, the confluent type shows a marked difference from the discrete variety in intensity and character of all of the symptoms. In addition to the more violent fever and delirium the nervous and muscular systems show greater depression of vitality. The mucous membrane of the air tracts is attacked with greater severity, the eruption in the mouth and throat is confluent, and frequently a diphtheritic exudate covers the soft palate, tonsils, pharynx, and nasal cavities. The larynx is occasionally invaded by the exanthem and the severity of this invasion is not infrequently evidenced by the occurrence of submucous abscesses, necrosis of the cartilages, or œdema glottidis. The eyes, too, are more severely affected in this type; the eruption usually invades the ocular conjunctivæ, giving rise to inflammation of the lids, and frequently results in keratitis with perforation and loss of eyesight. In the mouth the severity of the disease is manifested by profuse salivation, by great difficulty in swallowing, and not infrequently by inflammation of the parotid glands. Confluent variola is prone to a number of complications, such as bronchitis, pneumonia, pleurisy, pericarditis, diarrhœa, albuminuria, abscesses, etc. So intense is this variety of variola that some patients die before the eruptive period has arrived, but the majority of those who die survive until the stage of desiccation has been reached, death resulting at this time usually from exhaustion, or from one of the numerous complications which beset this type of the disease. In those who survive, the process of desiccation is slowly accomplished, often extending over a period of four or five weeks. In this variety but few patients escape permanent disfigurement of the face from pockmarks. Convalescence, too, is quite slow, the patient often being troubled with boils and abscesses for several weeks after the exanthem has been thrown off.

Hemorrhagic Varioloid.—The difference between this and the other types of smallpox consists mainly in the character of the eruption, the spoliation of the blood, the course of the fever, and the constitutional symptoms. It is simply a modification of variola vera. The hemorrhage into the eruption takes place under various circumstances. In some cases the exanthem becomes hemorrhagic upon the appearance of the papules, in others when the vesicular stage is reached, and in still others only when the pustules are fully formed. In some cases the entire exanthem is hemorrhagic, while in others one-half or even a very small portion of it is hemorrhagic. As a rule it begins in the eruption on the lower extremities. Petechiæ and ecchymoses usually appear between the efflorescences, and livid spots or patches are to be found on the mucous membrane of various parts of the body, particularly in the mouth and throat. Diphtheritic exudates frequently form on the tonsils, pharynx, and nasal cavities. The gums become spongy and bleed as in scurvy. Hemorrhages occur from the nose, stomach, lungs, kidneys, rectum, or uterus. The amount and persistency of the hemorrhage vary in different cases. There is no means of diagnosticating this variety of variola until the hemorrhage has occurred. The initial fever is ordinarily mild, and throughout the subsequent course of the disease the temperature rarely exceeds 102° F. When the hemorrhage has been profuse the temperature falls to or below the norm. There is a marked contrast between the temperature and the pulse rate. While the temperature is but slightly above, at, or below the norm, the pulse is beating from 120 to 160 per minute. The breathing is rapid, the countenance pinched and sunken, and occasionally there is delirium, though as a rule the intellect remains clear. This is a very fatal form of the disease; fully ninety-five per cent. of the cases end in death.

Modified Variola.—Under this head are embraced all varieties of smallpox which depart materially from the course pursued by variola vera. These departures from type may consist in variations in the character and course of the eruption, or in the symptoms of the malady, or in both; in a word, it embraces all abortive forms of smallpox. These varieties are usually designated varioloid. Varioloid may be defined smallpox modified by a previous attack of the disease, by a previous attack of vaccinia, or by an unusual degree of personal insusceptibility. There is no ground whatever for the old claim that varioloid is essentially different from variola vera. Varioloid, it is true, is milder in its course and shorter in duration than variola vera, and presents many striking departures from the ordinary course of the latter disease. That it is, however, the same disease as variola vera is constantly being demonstrated by the fact that individuals contract all other grades and varieties of smallpox by contact with individuals affected with varioloid. The duration of the initial fever of the latter variety is rarely beyond two days and the temperature seldom exceeds 102° F., falling, as a rule, to the norm at the end of the second day. With the disappearance of the initial fever the patient is convalescent and generally able immediately to return to business. In rare instances the initial fever is as high as in variola vera, yet it persists for only two days. Secondary fever is extremely rare, and when present seldom continues beyond twenty-four hours. The eruption differs in its character and development from that of unmodified smallpox. In varioloid the efflorescence appears simultaneously on all parts of the body, and it rarely passes through all the stages characteristic of variola; it may not go beyond the vesicular stage and then rapidly desiccate. Not infrequently the eruption goes on through the pustular stage, but the pustules are dwarfed, and while they are surrounded by a red areola the skin is neither tense nor swollen, and the pustules rapidly dry up and fall from the body. Desiccation usually commences from the fifth to the seventh day of the eruption. Pitting is rare in varioloid, but in some instances the face is left pockmarked. When the eruption of varioloid passes through all the stages of variola it is differentiated from the latter by the milder constitutional symptoms and by the smaller number and abortive forms of the pocks of varioloid. Varioloid is devoid of fatality.

Several other varieties of varioloid are encountered in every epidemic of smallpox. These are mainly: (1) Variola verrucosa. In this variety the eruption does not go on to well-formed pustules of smallpox, but stops with the development of solid papules with a vesicle at their summit, and on the site of each of which, after desquamation, a warty elevation of the skin is left. (2) V. pemphigosa. In this type the exanthem progresses regularly to the vesicular stage, when the vesicles become irregular bullæ with sero-purulent contents. (3) V. miliaris. In this form, while a portion of the eruption is that of regular and fully developed smallpox, the largest part consists of vesicles slightly larger than millet seeds. These vesicles, which are filled with a yellow fluid, progress no further than the vesicular stage, dry up and fall off. (4) V. siliquosa. In this variety the eruption develops regularly to the pustular stage, when the contents of the pustules are absorbed, leaving them with the appearance of empty shells. This variety is less often encountered than the three previously described.

Curschman, in discussing varioloid, has summed up the philosophy of the matter as follows: "It is generally conceded at the present time that varioloid is nothing more than a form of smallpox with a milder course and shorter duration, and, this view being accepted, it is readily seen that between varioloid and variola vera no absolute line of distinction can be drawn. During every epidemic of any considerable extent a number of cases are found which show a transition from one to the other form, and which, when we have followed their entire course, leave us in doubt as to whether we shall call them cases of variola or varioloid. The quantity or quality of the eruption is as far from being a good criterion in determining the nature of the affection as the presence or absence of the suppurative fever, which some consider decisive in this respect. This latter does not even depend entirely upon the intensity of the disease, but upon personal peculiarities, and particularly upon the sensibility of the person attacked. As regards the peculiar conditions under which varioloid occurs, it is important in the first place to observe that many persons who have never had smallpox nor have been vaccinated are only attacked by this form, on account of a natural slight susceptibility to the smallpox contagion. We accordingly find frequent mention made of cases in which the disease runs an extremely mild course."

Differential Diagnosis.—In diagnosticating smallpox in any of its varieties time is an important factor. The chill, fever, headache, vomiting, and lumbar pain constitute a group of symptoms which should put the prudent physician on his guard when smallpox exists in the locality, yet the occurrence of this symptom complex would not justify him in committing himself unqualifiedly to the diagnosis of smallpox, even though it were known that the patient had never been vaccinated and had been exposed to the disease. Under such circumstances he should make a provisional diagnosis, isolate the patient, and await the development of the disease to a stage at which it can be diagnosticated, *i.e.*, the vesicular stage. The wisdom of this course is attested by the experience of all hospital physicians. Marson, of the London Smallpox Hospital, says on this subject: "Upward of twenty diseases have been mistaken within the last few years, in the early stage of the disease, for smallpox, and the patients have been sent as having smallpox to the smallpox hospital." Under such circumstances the physician is guilty of malpractice, and can be held liable for damages. Such mistakes show ignorance or carelessness on the part of their authors. When the characteristic exanthem of smallpox has appeared, there are but few diseases liable to be confounded with it. These are chickenpox, pustular syphilis, pemphigus, impetigo contagiosa, and measles.

Diagnosis of Smallpox from Chickenpox.—A few modern writers contend that variola and varicella are one and the same disease, yet in the whole domain of medicine no proposition is better established than that each of these is a disease of its own kind, having its own specific cause. By reason of the frequency of atypical cases of variola the differential diagnosis of such cases from varicella is at times quite difficult, and in all cases demands the exercise of prudence and judgment. While they are essentially different diseases they generally prevail simultaneously, and the vesicles of each counterfeit those of the other, yet when judged in connection with the symptoms and course peculiar to each disease they can be differentiated readily by one familiar with them. Smallpox is generally ushered in with a chill; varicella is not. Varicella is ordinarily unattended by an initial fever, and when it occurs it is very slight and disappears in twenty-four hours; but in variola, even in the lightest and most atypical cases, the fever reaches 102° F. and persists for two days. The initial stage of smallpox is attended by intense pain in the lumbar region; in varicella it is absent. Vomiting is a constant symptom in the early part of the attack of smallpox, and is rarely, if ever, present in varicella. It is, however, in the character of the eruption that the difference between these two diseases is most strikingly manifested. The smallpox eruption passes through four stages, *i.e.*, macule, papule, vesicle, and pustule; the macule persists for from twenty-four to forty-eight hours before being converted into a papule; the papule remains as such for forty-eight hours before being converted into a vesicle; the vesicle continues to retain this form for four or five days prior to becoming a pustule. In varicella the eruption is fully vesicular within twenty-four hours after the efflorescence first manifests itself. The vesicles of smallpox contain a lactescent fluid and appear to be deeply seated in the skin; those of varicella contain a serous-looking fluid and appear to be quite superficial. Indeed they present the appearance of having been produced by spattering hot water on the skin. In smallpox all of the pocks have a prominent red base, while in varicella the red base is slight if at all present. All smallpox vesicles develop into pustules, whereas in cases of chickenpox not more than one in fifty or one hundred does so. Umbilication occurs in the vast majority of smallpox vesicles, while but a small percentage of vesicles of varicella become umbilicated. Some text-book writers contend that umbilication never occurs in varicella. This is a mistake. Of the hundreds of cases of chickenpox observed by me I have never encountered one case in which a fractional part of the vesicles were not umbilicated; on the other hand, I have encountered cases of smallpox which never at any stage of the disease became umbilicated. Some writers contend that chickenpox never attacks an adult. This, too, is a mistake. I have repeatedly observed undoubted chickenpox in adults. I have, however, never known chickenpox attack a whole family of adults. This is an important diagnostic point in differentiating modified smallpox from chickenpox. Again, the eruption of chickenpox appears in several successive crops, while in smallpox there is but one. In varicella the major part of the eruption is upon the body, the back particularly, while it is sparse on the face and limbs. This rule is reversed in smallpox. It is well, however, to remember just here that in rare instances chickenpox is observed to be copiously scattered over the entire body. A few months ago I saw in consultation a case of chickenpox in a child about six years old in which the eruption was semiconfluent over every part of the entire body except the palms of the hands and soles of the feet; these were devoid of eruption. All of the children of this family had been vaccinated the previous year, and all of the others had light cases of varicella.

Diagnosis of Smallpox from Syphilis.—Occasionally it becomes necessary to differentiate smallpox from syphilitic eruptions. As health officer of this city (Augusta, Ga.) I have repeatedly been called upon to discharge this duty. With care and patience these diseases can be readily separated. Papular, vesicular, and pustular syphilides counterfeit the exanthem of smallpox. In either of these varieties of syphilitic eruption fever may coexist. Papular syphilides are devoid of the shotty feel of variola. I have encountered a syphilitic vesicular eruption which was distributed over the surface of the body; a portion of the vesicles were umbilicated, and they closely simulated variola in the vesicular stage. I have also observed pustular syphilides which bore a close resemblance to the pustular stage of smallpox. Such cases are to be differentiated from smallpox by the following points: (1) None of them commence with the symptom complex of smallpox, *i.e.*, chill, fever, vomiting, headache, and lumbar pain. In each of these varieties of syphilides, if fever be present, as it not infrequently is, it persists beyond the appearance of the efflorescence, while in smallpox the fever disappears immediately after the exanthem appears. Pain may be a prominent symptom of syphilis, but it is never confined to the lumbar region as in smallpox. In any and all forms of syphilitic exanthem it will be found that the syphilides, whether papular, vesicular, or pustular, have persisted as such far beyond the time limit of either variety of the smallpox eruption. Again, the eruption in any variety of smallpox is of uniform size, while in syphilis it is of various sizes. The eruption of smallpox consists of one crop, while that of syphilis is commonly observed to be in various stages of development, thereby showing a succession of crops. In doubtful cases the diagnosis is easily cleared up by isolating the patient and awaiting the development of the exanthem.

Diagnosis of Smallpox from Pemphigus.—When pemphigus is scattered over the body it may for the first few days simulate the vesicles of smallpox. Pemphigus commences as minute red spots upon which vesicles form. The vesicles present a clear citrine or yellow color, in whites, owing to the fact that the translucency of the epidermic covering allows their serous contents to shine through it. When fully developed the vesicles are tense and firm to pressure. The fluid in them changes from a serous to a milky color. In some instances the exanthem attacks all parts of the body, but ordinarily it is confined to the limbs. The palms and soles are rarely invaded. When the eruption reaches the vesicular stage the vesicles are of uniform size, about the size of a split pea, though at a later stage a majority of the vesicles develop into bullæ of sizes varying from that of a chestnut to that of a split walnut. By reason of the thinness of their covering the vesicles and bullæ easily rupture and fold over on the adjacent sound skin, leaving a superficial raw surface on the site of those which have been broken. The major part of the eruption does not rupture, and the walls of the unbroken ones become progressively shrunken and flattened until the tops of the vesicles and bullæ sink down on the underlying layer of skin. The exanthem develops in crops and sooner or later all sizes of vesicles and bullæ will be represented. Pemphigus pursues a chronic course. Pitting does not occur in this malady. The eruption may attack the mucous membrane of the mouth, conjunctivæ, and genitalia. Fever attends the majority of cases of pemphigus in which the eruption is extensive. As a rule the fever will be in proportion to the extent and intensity of the exanthem. Four years ago I attended a case of pemphigus in which the eruption was scattered over all parts of the body. When I saw this patient the case was in the acute stage. For the first two days the vesicles counterfeited those of variola, but on the third day many of them formed bullæ varying in size from that of a chestnut to that of a guinea egg. The fever ranged from 105° to 108° F., and continued until the death of the patient on the eighth day after I was called to see him. This case in its eruption pursued the typical course of pemphigus. In cases of pemphigus which in their incipiency simulate smallpox, the diagnosis is arrived at by the following points of difference: Pemphigus is devoid of the symptom complex of smallpox, *i.e.*, chill, fever, headache, vomiting, and lumbar pain. The vesicles of pemphigus do not umbilicate; umbilication is common in variola. When fever attends pemphigus it persists for days after the eruption has appeared; this rule is reversed in smallpox. The exanthem never, in pemphigus, goes through the four stages of macule, papule, vesicle, and pustule common to variola.

Diagnosis of Smallpox from Impetigo Contagiosa.—Inasmuch as many physicians claim that the recent epidemic of smallpox was impetigo contagiosa, I give the following sketch of the malady. It is a contagious disease occurring mostly among children, and at times as a quasi-epidemic. The initial symptoms are malaise, chilliness or chill, and fever, though not infrequently these symptoms are absent. As a rule the eruption commences on the face around the mouth, on the chin, cheeks, alæ nasi, forehead, and about the eyes. The exanthem commences as small vesicles, which soon contain a turbid serum; the exanthem then extends peripherally, and assumes the character of flat, somewhat flaccid bullæ containing a sero-purulent fluid, and surrounded by an inflammatory areola of greater or less intensity. As the bullæ expand and flatten, the contained fluid dries, and in a few days a yellowish-green or straw-colored crust covers each bulla. This crust becomes dry and of a papery consistence, and has the appearance of having been stuck on its site. When it becomes detached at its margins it curls up and finally falls off; the underlying site seems superficially excoriated. After desiccation a shiny epithelium of a pinkish-red color is left on the site of the eruption, but this gradually fades to the normal color of the skin. The fully formed bullæ vary in size from that of a split pea to that of a silver three-cent piece. The eruption lacks uniformity in size, and commonly appears in small crops. After the exanthem has gradually developed over the face it attacks the abdomen and extremities in successive limited advances. As a rule the force of the disease is expended on the face, only a few scattered spots appearing on the other parts of the body. To the physician practised in smallpox it is readily seen that impetigo contagiosa bears no resemblance of any kind whatsoever to any variety of smallpox, and that these two diseases ought never to be confounded by any physician who has even a limited acquaintance with smallpox.

Diagnosis of Smallpox from Measles.—Up to the vesicular stage of smallpox its eruption simulates that of measles so closely that it is impossible positively to differentiate these diseases prior to the appearance of the vesicles of variola. If the physician awaits the vesicular stage of variola, as he should invariably do before committing himself unqualifiedly to the diagnosis, he will have no difficulty whatever in separating these two diseases. The catarrhal symptoms of measles should put the physician on his guard as to the probable nature of the malady, and the fact that the fever persists after the eruption has appeared, while it disappears in smallpox, gives added strength to the probability of the case being one of measles. Yet these two points in diagnosis, together with the difference in the initial symptoms of each malady, do not justify the physician in committing himself to a positive opinion as to the disease, inasmuch as neither these two nor all of the symptoms are pathognomonic. His duty to the public will be fully discharged by isolating the patient until the time has passed for the appearance of the vesicular stage of the exanthem. If the patient presents the initial symptoms of smallpox, has never been vaccinated, and is known to have been exposed to the former disease, the physician is justified in making a provisional diagnosis of smallpox and reporting the case as a suspicious one, reserving the right to amend his opinion thereon should the course of the disease demand it. Suit for damages has been sustained in a number of instances in which physicians reported the disease as smallpox, the patient on this diagnosis having been sent to the smallpox hospital and subsequent events having demonstrated that the diagnosis was erroneous.

Diagnosis of Smallpox from Febrile Lichen.—Febrile lichen bears a close resemblance to the efflorescence of variola in the papular stage. The exanthem of the former appears as small, slightly red papules, ordinarily of the size of millet seeds. In differentiating these two maladies time is an important factor. The eruption of lichen follows within twenty-four to forty-eight hours after commencement of the initial symptoms, and it never passes through the four stages characteristic of smallpox. In lichen the eruption is practically devoid of fluid contents, and even when it is present it is so unlike that of variola that after the vesicular stage of the latter has appeared it is impossible for the trained observer to mistake the one disease for the other.

Finally it may be said that the eruption of smallpox is the only one of all the various eruptions which passes through the four successive stages of macule, papule, vesicle, and pustule. This, then, is a crucial test of smallpox.

PROGNOSIS.—The type of the disease largely determines the rate of mortality. If a large number of cases extending over a period of many years be taken, so that epidemics of mild and severe types shall be represented, the mortality from the several more important types will be about as follows: Hemorrhagic, 95 per cent.; confluent, 50 per cent.; semiconfluent, 10 per cent.; discrete, 7 per cent.; varioloid, 0. In individual epidemics characterized by marked virulence of the disease the mortality will greatly exceed that above given, while in epidemics of marked mildness, like the one in this country for the last four years, the mortality will fall below it. Marson, from the records of the London Smallpox Hospital from 1836 to 1851 inclusive, reports that of the 2,654 cases of confluent, semiconfluent, and discrete types of variola there were 996 deaths, being a mortality of 37 per cent. Welch, from the records of the Municipal Hospital of Philadelphia, Pa., shows that from 1870 to 1894 the total number of cases of smallpox was 5,000; total number of deaths, 1,562; mortality per cent., 31.24. So much for general considerations. Several other circumstances must be considered in estimating the result in individual cases. They are mainly as follows:

Vaccination.—In the vast majority of individuals vaccination performed in infancy confers immunity from smallpox during the remainder of life, yet it is a proven fact that in some persons the protective power of vaccination decreases after a greater or less number of years, and thereby fails fully to protect these individuals from smallpox. It is also a demonstrated fact that even in those cases in which vaccination fails wholly to protect against variola, it markedly decreases the mortality from this disease. The mortality from post-vaccinal smallpox varies with the length of time intervening between the attack of vaccinia and that of variola. Marson, of the London Smallpox Hospital, claims that the mortality in post-vaccinal smallpox is greatly influenced by the number of insertions of the vaccine virus. After examining into 4,896 cases of post-vaccinal variola he says that the percentage of mortality was as follows: Having one vaccine cicatrix, 7.73 per cent.; two vaccine cicatrices, 4.70 per cent., three vaccine cicatrices, 1.95 per cent.; four or more vaccine cicatrices, 0.55 per cent.

My experience does not agree with that of Marson. In this locality vaccination is made by only one puncture, and I have never observed a fatal case of variola in a patient having a typical vaccine scar. Marson shows by elaborate statistics that the death risk from smallpox in the unvaccinated is as three to one compared with the most defective vaccination, and as seventy to one after the best vaccination.

Constitutional Condition.—The constitutional condition of the patient markedly influences the prognosis in this disease. Intemperate and debilitated patients show a greater mortality than those who are in full health and of robust constitution.

Age and Sex.—The age of the patient influences the prognosis. Among infants the mortality often reaches ninety per cent., and the same is true of those at the other extreme of life. Sex has no influence on the mortality of smallpox except in cases of pregnant females in whom abortion or miscarriage results during the attack of variola.

Complications.—The complications of this disease will be referred to under the head of treatment.

TREATMENT.—The treatment of variola embraces two important though widely divergent indications, viz. (1) Prophylaxis. (2) Therapeutics.

Prophylaxis.—In the whole range of preventive medicine prevention and control of smallpox can be more certainly accomplished than in any of the other contagious diseases, provided measures for the attainment of this end are wisely planned and faithfully executed. Vaccination, isolation, and disinfection constitute the measures necessary to be applied in prevention and control of this malady.

Vaccination.—No fact is better established than that vaccination, when duly and efficiently performed, is a full and efficient preventive of smallpox. It is equally true that vaccination, properly performed and properly cared for, is devoid of danger to health or life. In the twenty thousand vaccinations made by me, or under my personal supervision, no one of these individuals ever had any trouble other than the mild fever and pain in the arm which constitutes the vaccine disease, except a small number who contracted erysipelas or developed an abscess at the point of insertion of the vaccine virus. In every instance in which erysipelas or an abscess complicated the vaccine disease it was due to lack of care to prevent infection of the vaccinal site, and in nowise to vaccination. The subject of vaccination has been assigned to another writer, and therefore I will dismiss the subject with the following general statement: In view of the prophylactic power of vaccination every citizen should be vaccinated, and it should be deemed a solemn duty on the part of authorities of cities, counties, and States continuously to provide gratuitous vaccination for indigent citizens. When smallpox threatens a community the authorities should resort to universal vaccination, and, in needful cases, to revaccination. Every unvaccinated person is liable to contract variola if exposed to it; therefore all such persons should be excluded from schools, hospitals, asylums, and other public institutions. The same rule should be applied to all employees in business enterprises wherein large numbers are assembled. Compulsory vaccination should be resorted to where citizens are known to have been exposed to smallpox.

No matter how absolute the protection conferred by vaccination, there will always be great and insurmountable difficulties in the way of enforcement of this measure in America, where individual ignorance and prejudice are allowed to contravene public welfare, and for this reason isolation and disinfection must be added to vaccination. If a case of smallpox be introduced into a community it cannot be disseminated if the patient be promptly isolated and all infected materials disinfected.

Whenever a case of variola is encountered the patient should be promptly isolated and provided with an immune nurse if the case is not to be moved to hospital. All unvaccinated persons in the domicile, together with all outsiders who have been in contact with the patient, should be immediately vaccinated. If any of them have been previously vaccinated the procedure should be repeated. The patient should be removed to hospital, unless he can be isolated in perfect safety to the inhabitants of neighboring houses and unless the necessary nurses, guards, and medical service can be provided. When a patient is allowed to remain at home the sanitary authorities should, at the patient's expense, furnish reliable guards to compel isolation of the patient and household and compliance with all necessary sanitary precautions. When a case of smallpox is moved to hospital, all fabrics of every kind whatsoever should be thoroughly disinfected, together with the entire domicile. The fabrics in the patient's room should be taken to the public disinfection station for treatment, and, after having been thoroughly disinfected, they should be returned to the owner. It is indispensable in waging warfare against smallpox that every community should be provided with a properly located and equipped hospital, detention buildings, and a disinfection room located on the same premises. Persons who have been directly exposed to the disease should be taken to the detention building, vaccinated, and kept there for twenty one days, and at the expiration of this time they should be sent home if free of smallpox. A community which attempts to treat smallpox without a hospital and detention buildings will do so in a haphazard manner, and thereby prolong the existence of the disease among its citizens. A suitable detention building is as necessary as a hospital in attempts to stamp out smallpox in a community. Of the three hundred and seventeen persons who were taken to the detention apartments after they had been exposed to smallpox, fifty nine contracted the disease and were transferred to hospital. But for the prompt removal of these suspects to detention buildings, they would have constituted that additional number of centres of smallpox in our community The fabrics of smallpox suspects should be disinfected as carefully as if it were known that their owners were affected with the disease. Smallpox patients and their fabrics should be taken to hospital in a closed conveyance used exclusively for that purpose.

The origin of every case of smallpox should be vigilantly traced. It is equally important to ascertain the name and residence of every person who has been in the presence of the patient or has entered the house. Every such individual should be promptly apprehended and vaccinated, forcibly if necessary Those who have been in only momentary contact with the disease can, after being vaccinated, be detained at home until the period of incubation of smallpox has passed; in the mean time a sanitary officer should visit and inspect every suspect every second day in order promptly to detect any who may fall ill of variola Suspects detained in their homes should undergo detention for three weeks

Among our servant class of population (negroes) it is necessary to exercise the closest possible supervision, inasmuch as they habitually conceal the disease in their families. They also commonly go from their infected houses to their duties in the families of their employers, while others of them carry on their work in the household, as washer-women, during the full bloom of variola, and deliver this washing without the owners suspecting that their clothing had been in the midst of the disease and was being returned without being disinfected. In scores of instances I have found the clothes of white families being done in a room occupied by a patient in the full bloom of smallpox.

Disinfection.—The contagious element of smallpox resides in the eruption, exhalations, secretions, and excretions of the patient. These contaminate the sick room and adhere to all fabrics therein. The vitality of the poison of variola persists for a long time when contained in fabrics which are laid away in closed receptacles. By intelligent use of germicidal agents every particle of contagion in houses and fabrics can be destroyed. To do this the germicide must be used in sufficient quantity, and of sufficient potency, and the fabrics must be opened so that the disinfectant can come in immediate contact with every particle of the contagion. Fabrics in bundles cannot be disinfected even by boiling. Gaseous disinfectants are to be relied upon only for surface disinfection. Every discharge which passes from the patient's body, mouth, nose, kidneys, or bowels must be received in suitable receptacles containing a potent germicidal solution The discharges from the nose and mouth are best disposed of by being received upon bits of old cloth, which should be burned as soon as soiled. Every handkerchief, towel, every article of bed or body linen, should be thoroughly saturated in a germicidal solution prior to being sent from the patient's room. All articles of crockery and utensils of every kind whatsoever used in the sick room must be disinfected before being sent from it. In order, as far as possible, to confine the contagion to the patient's room, all communicating doors, except the one leading to the hall, should be securely sealed by pasting paper over all joints, and a sheet saturated with a germicide should be hung on the hall side of the door. The nurse should wear a washable suit, and the physician should put on a linen duster which covers his entire body when he enters the room. The patient should be detained in isolation until desquamation has been completed on every part of the body. The epidermis being thicker on the palms and soles, desquamation is slower on these parts than on the remainder of the body.

After desquamation has been completed the patient should be given a general sponge bath charged with creolin or carbolic acid, and then, dressed in a fresh suit of clothes, just brought into the room, may be allowed to mingle with the household. The nurse should take similar precautions as to bath and fresh clothing before leaving the room. As soon as the room has been vacated, it, with its contents, should be disinfected. The first step is to stop up all openings in the apartment, then to open and hang all unwashable fabrics on furniture or wires, and fumigate it with sulphur or formaldehyde. Formaldehyde fumigation is preferable by reason of its greater convenience and economy and because it does not injure household articles. Sulphur fumigation is, however, equally efficacious. After fumigation the room should remain closed for twenty-four hours, when all fabrics which are washable should be wrung out in a hot germicidal solution and subsequently boiled for half an hour. It is extremely difficult, if indeed it be possible, to disinfect pillows and mattresses except by placing them in a chamber and subjecting them to superheated steam. Inasmuch as few municipalities are provided with this apparatus, it will be found cheapest and safest to burn such articles. All stuffed furniture in the infected room should be stripped and the stuffing burned. If a carpet is on the floor it should be thoroughly scrubbed with a solution of bichloride of mercury (1 to 5,000), then removed from the floor and hung in the air for a week or more. All unwashable fabrics, after having been fumigated, should be hung in the open air for several days. After the room has been fumigated and the carpet and other fabrics have been removed therefrom, the floor and woodwork should be scrubbed with a germicidal solution, the walls carefully swept, and the apartment thrown open for atmospheric disinfection for a period of two weeks, after which it may be safely reoccupied. Where mattresses, pillows, and other articles belonging to citizens are destroyed, they should be replaced at public expense, inasmuch as they were destroyed for public protection.

It should be remembered that it is impossible to disinfect an inhabited room, and that there should be no such thing as partial disinfection. Disinfection must be perfect in all of its details or it will prove a failure. To demonstrate that disinfection can be made a perfect success, I cite the fact that the fabrics of fully eight hundred smallpox patients and suspects have been disinfected, as above outlined, in Augusta, Ga., and in no instance have these fabrics spread the disease after having been so treated by our chief sanitary inspector

In fatal cases of smallpox the body should be thoroughly washed in a strong disinfectant solution and subsequently enveloped in a sheet charged with a solution of chloride of zinc, bichloride of mercury, or undiluted commercial formaldehyde. Under no circumstance should public burial be permitted, nor should the corpse be transported in a public conveyance. The body should be carried to the grave in the smallpox ambulance, but if no such conveyance is available, the vehicle in which the corpse is so transported should be disinfected under the supervision of the sanitary authorities immediately after it has been used.

Therapeutics.—There is no known curative treatment of smallpox. It is wholly symptomatic and must be adapted to the case in hand with a view to mitigate the severity of the symptoms Vaccination, if successfully performed within three days after exposure to smallpox, will in some cases prevent, in others abort, and in still others markedly modify the course of smallpox. In a number of instances I have vaccinated individuals from three to five days after they had been exposed to smallpox, and these individuals failed to contract the disease notwithstanding the fact that they continued to occupy the room of the smallpox patient. Some of them continued to sleep in the same bed with a case of the disease, yet remained immune. I have known five infants to be successfully vaccinated three days after the eruption of variola commenced on the mothers, and although they continued to nurse the breast of these mothers, they nevertheless remained free from the disease. I recall three instances of individuals who had been vaccinated five days after exposure to smallpox, and who had continued to nurse relatives affected with the disease. In each of these individuals, who in due time contracted smallpox, the disease was ushered in with a severe chill, high fever, vomiting, headache, and lumbar pain, and from the severity of the initial symptoms I expected them to develop severe cases of variola, yet the entire crop of eruption consisted of one vesicle. In other instances, under like circumstances, I have counted only ten or twelve vesicles on the entire body. In still other cases I have seen the vaccine disease and smallpox affect the patient at the same time, neither malady at first seeming to interfere with the other, but in whom at a later period the eruption rapidly dried up and the crusts soon dropped from the body. On the other hand, I have observed several cases in which individuals, who had been known to be exposed to smallpox, were vaccinated for the first time after such exposure and promptly developed vaccinia; then, twelve days after this exposure to smallpox, they contracted the disease, and the two diseases, smallpox and vaccinia, pursued typical courses, apparently travelling together in the patient's system as harmonious companions. That vaccination, even after persons have been exposed to smallpox, has a marked power to prevent the latter disease is shown by facts observed in the smallpox hospital of Augusta. Within the last four years three hundred and seventeen persons, who had never previously been vaccinated, but who were known to have been exposed to smallpox, were vaccinated and taken to the detention hospital, and yet only fifty-nine of them contracted variola. It would not, in my judgment, be fair to claim that this favorable result was wholly due to vaccination, inasmuch as a certain number of these individuals—exactly how many cannot be determined—doubtless escaped because they were separated at an early moment from the smallpox patients. I regard smallpox as but slightly contagious up to the vesicular stage. It is most actively contagious in the pustular stage. In view of the proven fact that vaccination, done even a few days after exposure of individuals to smallpox, has the power to prevent, abort, or mitigate the latter disease, it is important that every such exposed person should be promptly vaccinated. The character of the vaccine virus is a matter of importance. The vaccine should be used in that form which will most promptly and certainly produce vaccinia. Glycerinized lymph possesses both of these requisites. In my hands glycerinized lymph from approved propagators has succeeded in producing typical vaccine vesicles in from ninety-five to ninety-nine per cent. of primary vaccinations; and the vaccinia appeared from two to four days earlier than when dry lymph on points was used. In my experience glycerinized lymph in capillary tubes is infinitely superior in all respects to dry lymph on points. I have used glycerinized lymph in vaccinating about ten thousand individuals.

As soon as the patient has contracted smallpox he, if he is to remain at home, should be isolated in a well-ventilated room, preferably on the upper floor of the house. All unnecessary clothing, bedding, furniture, carpeting, and other household effects should be immediately removed from the room, disinfected, and stored away. In the winter season the temperature of the sick-room should be maintained at or near 72° F. When the patient has a chill he should be warmly covered, and a mustard plaster should be applied to the spine for twenty minutes. When the fever is high it should be treated by hot foot baths and if need be by general warm baths, repeated as indicated. The fever being the result of the toxins of the smallpox infection in the patient's system, the chief indication for treatment of the pyrexia will be met by opening up the emunctories of the body. This is to be accomplished by administering such agents as will induce free diuresis, diaphoresis, and catharsis, as indicated by the case in hand. It should be remembered that children are liable to convulsions during the febrile period of smallpox, and when they are so threatened hydrate of chloral and bromide of potassium should be administered in suitable doses. After the eruption has appeared the initial symptoms disappear. As a rule, fever returns when the pustular stage of the malady is reached. This is best combated by general warm baths followed by enveloping the patient in blankets in order to induce free sweating. In treating fever on the above plan, the warm baths, besides producing active diaphoresis, will induce free action of the kidneys and allay the patient's restlessness. The exanthem in the mouth and throat causes discomfort and difficulty in swallowing. To alleviate these symptoms glycerinized astringent gargles are indicated. The diet of the patient should consist mainly of milk, soup, eggs, beef-tea, gruel, oatmeal, stewed fruit, etc., during the early course of the disease; while in the later part of the attack the food may consist of almost anything which the patient's appetite may call for. In severe cases of smallpox the patient's strength will be severely taxed, and for this reason it is important that suitable food should be freely administered. In these severe cases the conjunctivæ are commonly invaded. The lids become swollen from the eruption on them, and not infrequently purulent conjunctivitis sets in, the secretion causing temporary adhesion of the eyelids, which necessitates their forcible opening so that the pent-up secretion may be removed and the eyes treated. If this be not done a diffuse keratitis may set in, and it may go on to ulceration and perforation of the cornea. In cases attended with intense swelling of the eyelids the vesicles thereon should be emptied immediately upon their reaching that stage. The lids must be frequently opened and the eyes wiped out with absorbent cotton, and at least every six hours a suitable astringent solution should be instilled between the lids. In all cases the physician must carefully watch for iritis, keratitis, and ulceration. As soon as the inflammation appears atropine should be instilled into the eyes, and iced compresses applied over the lids.

The eruption on the surface of the body is often the source of extreme discomfort. This may be alleviated by brushing it over several times daily with a solution of two grains of carbolic acid to an ounce of glycerin or linseed oil. Various plans of treatment looking to prevention of pitting of the face have been advocated. I have tried all of them and have found them to be utterly useless. If, as previously stated, only the superficial layer of the skin be involved, the patient will escape being pockmarked. If, on the other hand, the true skin be involved, pitting is inevitable. I have encountered cases of all varieties of variola unattended by pitting, although no local treatment had been used.

In some cases of variola sleeplessness is a prominent and distressing symptom. This should be overcome by the use of morphine or of a mixture of chloral and bromide. In cases of variola attended by profuse expectoration opiates should be given with caution. Constipation should be overcome by saline purgatives. When diarrhœa is present it should be controlled by astringents and careful feeding.

Abscesses not infrequently form in the subcutaneous tissues during the course of smallpox. The scalp is a favorite seat of these abscesses, and when they first appear they are of small size, but they continue to enlarge and show but little disposition to point. Whenever they form they should be promptly laid open. As soon as it is known that a patient has smallpox the hair on the scalp ought to be shaved, inasmuch as the eruption is commonly copious on the head, and if this be not done the hair will become matted and the mass putrescent. Boils over various parts of the body are of common occurrence, and these frequently terminate in foul ulcers.

Boils should be promptly lanced and both they and the abscesses should be carefully watched and treated. Wherever suppuration is present it calls for treatment with quinine, iron and strychnine, wine, and full nourishment.

Complications such as erysipelas, laryngitis, pleurisy, pneumonia, nephritis, etc., are to be treated on general principles.

In severe cases of smallpox the heart muscle usually undergoes fatty and parenchymatous changes. This fact suggests the necessity of guarding the patient against heart-strain by rest in bed and, when needful, by the administration of cardiac tonics, such as strychnine and alcoholic stimulants. Delirium, restlessness, weak and rapid pulse, shrunken features, with great prostration, demand free, even bold administration of alcoholic stimulants and strychnine. The amount of alcoholics and strychnine to be administered in adynamic states of smallpox must be decided by the degree of vital depression to be combated. Convalescence is protracted in those who have had a severe type of smallpox. During this period marked benefit will be derived from taking Aitken's pills of arsenic, iron, strychnine, and quinine, with full feeding and alcoholic stimulants in moderate doses.

Eugene Foster.

SMELL, SENSE OF. See *Olfactory Nerve.*

SNAKEROOT, CANADA, or *Wild Ginger*, is the rhizome of *Asarum Canadense* L., and that of *A. reflexum* Bicknell has probably been more or less used for and with it. These plants are natives of rich woodlands in the Northeastern United States. The rhizomes lie very near the surface of the soil, may become a foot or more in length, branch rather freely, and bear few coarse roots. The leaves are long petioled, kidney-shaped, and sometimes reach a breadth of six inches. The solitary flower is terminal, cup-shaped, three-lobed, about an inch broad, and of a deep purple color. The dried rhizomes are quadrangular or two-edged, longish-jointed, deep-purple, lightly curved, and about as thick as matchsticks. The odor and taste remind one strongly of ginger. With some resin, starch, gum, and sugar, Canada snakeroot contains an unknown bitter principle and 1.5 to 3.5 per cent. of a volatile oil. An alkaloid is also thought to be present. It is an excellent aromatic bitter, the aromatic element predominating, and a carminative and diaphoretic. The dose is from 1 to 2 gm. (gr. xv.–xxx.), the tincture being the preferable form of administration. The volatile oil is also known to commerce. Its active constituent is *asarol* ($C_{10}H_{16}O$). Under the name "*asarabacca*," the rhizome of *A. Europæum* L. has long been employed similarly. It is now very little used. Its oil contains *asaron* instead of asarol, and it is distinctly emetic, or even purgative in the dose above specified for the other species. Its ordinary dose is only one-tenth as large.

Henry H. Rusby.

SNAKEROOT, VIRGINIA, OR TEXAS.—(*Serpentaria*, U. S. P.; *Serpentariæ Rhizoma*, B. P.) The dried rhizome and roots of *Aristolochia Serpentaria* L. (True Virginia Snakeroot or Serpentaria) or of *A. reticulata* Nutt. (Texas Snakeroot or Serpentaria) (fam. *Aristolochiaceæ*). These are perennial herbs, a foot or so high, from knotty, horizontal, aromatic rhizomes; stems slender, flexuose, branching at the base; leaves of various shapes between ovate and narrowly lanceolate, with heart- or halberd-shaped base, petiolate, entire; flowers lateral, on slender, straggling, crooked peduncles in the axils of bracts near the surface of the ground, about an inch long, consisting of a dull-purple, single perianth (calyx), whose curved tube has a wasp-like constriction near the middle, and a very oblique, spreading, three-lobed border; stamens six, short, connected with the style in three pairs; ovary three-celled, many-ovuled, inferior. The first named is a native of the Eastern United States, especially of Pennsylvania, Virginia, and Kentucky, where much of the drug is collected. The second named, of Texas and the adjacent region, is somewhat larger and coarser.

FIG. 4320. Virginia Snakeroot. About one-half natural size. (Baillon.)

DESCRIPTION.—*Virginia Serpentaria.*—Rhizome of oblique growth, 1 to 3 cm. (⅖ to about 1 in.) long and 1 to

2 mm. ($\frac{1}{25}$ to $\frac{1}{12}$ in.) thick, crooked and somewhat branched, bearing on the upper surface approximate, short stem bases, and underneath a dense tress of long, thin, branched roots, which are straightish, except as they are bent and doubled by pressure; dull yellowish-brown, internally whitish, the wood-rays of the rhizome longest in the lower side; fracture of both rhizome and roots weak; odor strong, aromatic, and camphoraceous; taste warm, aromatic, bitter.

Texas Serpentaria is larger, coarser, of a more gray color, and the roots are fewer.

CONSTITUENTS.—Serpentaria owes its aromatic properties to a volatile oil, existing to the extent of from one-half to one per cent., of which *borneol* is the important constituent. Associated with this is five or six per cent. of resin, the greater portion of it soluble in petroleum ether. Tannin, starch, gum, and sugars also occur. The bitter principle is not well known, but is believed to be, in part at least, a very small amount of the alkaloid *aristolochine*, extracted by Hesse from *A. Argentina* Griseb. The amaroid *clematitin* ($C_9H_{10}O_6$), obtained from *A. Clematitis* L., is believed to be identical with a constituent of serpentaria which has been called *aristolochin*, also *serpentarin*, and which is poisonous; but the relationship of these to the alkaloid named above is not known. Hesse also describes *aristinic*, *aristidinic*, and *aristolic acids* from *A. Argentina*, and these are believed also to be present in serpentaria.

ACTION AND USE.—Although aristolochin has been found, as stated above, to be poisonous when pure, it is present in the drug in such small amount that the latter is not poisonous in any ordinary doses. Neither has serpentaria any specific properties, although such have been ignorantly ascribed to it. Its action is merely that of an excellent aromatic bitter and its antiperiodic and antirheumatic reputation is doubtless due entirely to its indirect effects as a general tonic. The dose of serpentaria is 1–4 gm. (gr. xv.–lx.); of the official fluid extract, 1–4 c.c. (♏xv.–lx.). The Pharmacopœia provides also a ten-per-cent. tincture, of which the ordinary dose is 4–16 c.c. (fl. ʒ i.–iv.). Like other bitter stomachics, serpentaria is far better taken in small doses, of the weaker preparations, a short time before eating.

The genus contains a large number of species, many of which have been similarly used in their own homes. Some of them are far more active than serpentaria, large doses acting as emetico-cathartic poisons.

Henry H. Rusby.

SNAKES AND SNAKE-POISON. See *Poisonous Reptiles*.

SOAP.—When natural fats or oils are decomposed by treatment with salifiable bases, they split up into the alcoholic body *glycerin* on the one hand, and a series of *acids* on the other—principally oleic, palmitic, and stearic acids, in varying proportions, according to the nature of the fat, which acids then unite with the base used in effecting the decomposition of the fat, to form salts—oleates, palmitates, or stearates, or all combined, as the case may be. Such salts are generally called *soaps*, but in common parlance the name soap is applied only to the fatty salts of the alkali bases—potassa, soda, and ammonia—which, in contradistinction to the soaps derived from earthy and metallic bases, are soluble in "soft" water and in alcohol. Of the alkali soaps, furthermore, ammonia soap is used only in the preparation called *ammonia liniment*, or *volatile liniment* (see *Ammonia*), so that the soaps in common use as such are narrowed down to soda and potassa soaps.

Between soda soaps and potassa soaps, as distinct classes, the broad distinction is that soda soaps tend to be comparatively hard, and potassa soaps soft, so that the phrase *hard soap* is applied generically to soda soaps, and *soft soap* to potassa soaps. But the consistence of soaps is also markedly affected by the nature of the fat used in the manufacture, in the way that fats rich in olein, as is the case with oils, tend to yield softish soaps, whereas those rich in stearin and palmitin, typified by the solid fats, such as tallow, furnish soaps of greater consistence.

Soaps are bodies of a well known characteristic odor and disagreeable alkaline taste. They dissolve in alcohol and in "soft" water, but in "hard" waters they suffer decomposition by the calcic salts present, and the resulting lime soap floats in insoluble flocculi on the surface of the water. Soaps are, in general, decomposed by acids, by earthy bases and salts of the earths, and by the heavy metals. The useful property of soaps is that they attack grease, dirt, and dried animal débris, probably by virtue of their free alkalinity, and so affect those substances as to render them soluble in water, and thus readily removable.

The kinds of soap official in the United States Pharmacopœia for use in technical medicine are as follows: Under the simple title *Sapo*, Soap, is recognized "soap prepared from soda and olive oil." Such a soap corresponds to what is commercially called *Castile*, or *Spanish*, soap, and is an opaque, white substance, hard, but when fresh easily to be cut. It has the simple, characteristic smell of soap and an unpleasant alkaline taste. It dissolves readily in water and in alcohol. If the soap, as first separated in the making, be not purified, it presents a marbled appearance from contaminating streaks of an insoluble iron soap. This unpurified soap is stronger than the purified, white soap, since in the process of purification the soap combines with more water.

Castile soap is locally detergent, and, by virtue of its free alkalinity, mildly irritant to tender surfaces. Taken internally, it is innocent in moderate quantity, and tends only to relax the bowels and neutralize acid in the *primæ viæ*. Locally, free ablutions of soap and water are beneficial in certain forms of skin disease, such as acne, and, as regards internal giving, the principal application of soap is as a ready and innocent alkali to administer in cases of poisoning by any of the strong acids. A strong aqueous solution—one part of soap to four or five of water—should in such cases be very freely administered pending the arrival of more powerful and appropriate alkaline antidotes. Soap and water is also much used as a cathartic enema, but in sensitive conditions of the rectum may irritate. Pharmaceutically, soap is much used as an excipient in pill composition, but due regard must be paid to its chemical susceptibilities, as above detailed. From Castile soap are made the following official preparations: *Emplastrum Saponis*, Soap Plaster, is compounded of soap, one part, and lead plaster, nine parts, mutually incorporated when in the fluid condition, and the product evaporated to the proper consistence. Soap plaster is a feebly active plaster, devoid of specific medicinal properties. *Linimentum Saponis*, Soap Liniment, is compounded of soap and camphor with a little oil of rosemary, made into a liniment with dilute alcohol. This preparation makes an excellent gently stimulant embrocation, and takes the place of the *camphorated soap liniment*, or so-called *opodeldoc* of older revisions of the Pharmacopœia, an article substantially the same in composition as the present, but prepared from the common white soap made of animal fat, instead of from Castile soap.

The second variety of official soap is entitled *Sapo Mollis*, Soft Soap, and is made from potassa and linseed oil. It is a soft, unctuous substance of a brownish-yellow color. "*Green soap*" or "*German soap*" is a soft soap made in Europe and formerly imported into America. Its greenish color is due to impurities in the oils from which it is made.

Soft soap is more strongly alkaline, and therefore more detergent on the one hand, and more irritating to sensitive tissues on the other, than the hard soda soaps. Severe pain is easily excited upon tender surfaces, such as that of an eczematous patch of skin, by applications of soft soap. The medicinal use of the soap is as a detergent and "alterative" application in certain forms of skin disease, notably in *eczema rubrum*. The part is com-

monly washed with the soft soap, and afterward dressed with some bland substance, such as ointment of zinc oxide.
Edward Curtis.

SOAP BARK.—(*Quillaia*, U. S. P.; *Bois de Panama*, Codex Med.) The dried inner bark of *Quillaia Saponaria* Molina (fam. *Rosaceæ*). This bark is derived from a large evergreen tree, native and abundant in Chili. After the removal of the corky layer, the bark is usually flattened out and pressed tightly into bales, in which form it reaches the market. It is imported in considerable quantities for various purposes connected with manufacture—sizing, cleansing, etc.—and has found a not very commendable place in syrups for aërated waters, and in beers, to make them hold their froth.

Description.—In large, flat pieces, 3-8 mm. ($\frac{1}{8}$–$\frac{1}{3}$ in.) thick; outer surface brownish-white, often with larger or smaller patches of the dark brown outer layer adhering, otherwise smoothish or lightly striate; inner surface pale yellowish or whitish, nearly smooth, or often with longitudinally elongated blister-like elevations; fracture tough and strongly splintery, the laminæ oblique to each other; transverse section checkered with pale brownish bast fibres embedded in the white tissue; inodorous, but the powder highly sternutatory; taste persistently acrid. The infusion foams like soap water.

The active constituent of soap bark is saponin (from eight to ten per cent.), which is in turn resolvable into several distinct substances, all of them poisonous. Sapotoxin, the more important of these, is soluble in water but not in alcohol, and is precipitated by basic lead acetate. It is the principal irritating constituent. Quillaic acid is soluble in alcohol and water, not in ether, and is precipitated by the neutral as well as the basic lead acetate.

Uses.—Soap bark, or an infusion or tincture made from it, is useful as a detergent in washing fine linens, laces, etc., cleaning the surface of paintings, and other fine work of that kind. It is also an ingredient of some cosmetic preparations—lotions, hair washes, etc. Its use in syrups has been referred to; it has been further employed to a small extent as an emulsifying agent. Physiologically it is a pretty active substance, paralzying voluntary muscles with considerable rapidity, and producing local anæsthesia. It is also a local irritant. These properties have not, however, been put to therapeutic use. As an expectorant, in small doses, it has been recommended, also as an alterative in place of sarsaparilla, but its value is at least doubtful.
Henry H. Rusby.

SOAP ROOT.—*Soapwort.* "Bouncing Bet." (*Saponaria officinalis*, Cod. Med.). The dried root of *Saponaria officinalis* L. (fam. *Caryophyllaceæ*). This plant is a well-known European perennial herb, freely naturalized in North America, and often a troublesome weed around the edges of gardens, along roadsides, and in rich waste places. It is about two feet high, with ovate, opposite, usually sessile, three- or five-nerved leaves, and cymes of large whitish or pink flowers terminating the branches. All parts of the plant, but especially the roots, contain saponin in large amount, and its properties are very similar to those of soap bark, considered above, though it is scarcely so active as that drug. It is commonly employed in the household in the form of a viscous, suds-like solution for washing or sizing. It is also more or less employed, though less than formerly, as a stimulating expectorant, like senega, or as an alterative, like sarsaparilla. The ordinary dose is from 2 to 8 gm. (ʒ ss.–ij.) and it is mostly employed in the form of the decoction, one ounce to the pint.

Levant soap root, from various species of *Gypsophila*, of the same family, occurs in pieces of a large root, often two inches in thickness, of a pale yellowish- or brownish-white color. Its constituents, as well as its properties and uses, are similar to those of the ordinary soap root. It is rather more active, however, than the latter. Many other related plants have a similar composition and use.
Henry H. Rusby.

SODIUM.—I. General Medicinal Properties of the Compounds of Sodium.—From the close chemical alliance between sodium and potassium, theory would assign to compounds of sodium physiological properties similar in kind to the corresponding potassic compounds, but less strongly pronounced. The prediction is true in that the sodic effects, such as they are, are potassic effects weakened; but an inference that all the potassic effects, in kind, will be reproduced to some degree in the action of sodium, will not hold. The notable potassic effects are irritation, catharsis, cardiac paresis, general motor paresis, oxidation quickening, and, toxicologically, general toxæmia. Sodium, in comparison, is irritant, salt for salt, in decidedly less degree; is purgative in only slightly less degree; paralyzes heart and motor function so very little that the action appears only at all in excessive dosage in animal experimentation; scarcely seems to quicken oxidation at all, nor, even in high dosage, to impoverish the blood after the manner of potassium. So far, however, as concerns those compounds of sodium that are alkaline in reaction, or which, as in the case of citrates, acetates, and tartrates, are converted into an alkaline compound in the blood, the degree of alkalinity is but little less than that of the analogous potassic compounds, and hence the effects that follow simply from the fact of such alkalinity are, with sodic compounds, well pronounced. But yet, therapeutically, so far as constitutional alkalizing is concerned, the diseases calling for alkaline medication are also specifically benefited by the specific potassium effects, so that in their case sodic salts, though strongly alkaline, still cannot compete in curative power with their potassic rivals.

II. The Compounds of Sodium Used in Medicine.—As in the case of potassium, those compounds only will be discussed here whose effects are either *sui generis* to the compound, or are determined mainly by the basic radical. Such salts, official in the United States Pharmacopœia, are the following: *Hydroxide* (hydrate), *carbonates*, normal and acid, (pyro-) *borate*, *acetate*, *potassio-sodic tartrate*, *sulphate*, *phosphate*, *pyrophosphate*, *nitrate*, and *chlorate*. Of these the potassio-sodic tartrate (Rochelle salt) will be found discussed under the title *Potassium*. Other sodic salts, whose properties are derived mainly from the acid radical of the composition, are treated of under the title of such radical. Such pharmacopœial salts are the following: *Arsenate*, see *Arsenic*; *benzoate*, see *Benzoic Acid*; *bromide*, see *Bromides*; *chloride*, see *Chlorides*; *hypophosphite*, see *Hypophosphites*; *hyposulphite*, see *Sulphites*; *iodide*, see *Iodides*; *nitrite*, see *Nitrites*; *salicylate*, see *Salicylic Acid*; *silicate*, see *Silicates*; *sulphite*, see *Sulphites*; *sulpho-carbolates*, see *Sulpho-carbolates*.

Sodium Hydroxide (Hydrate): NaOH.—This substance, commonly called *Caustic Soda*, is official in the United States Pharmacopœia, in solid condition, under the title *Soda*, Soda, and in about five-per-cent. aqueous solution, as *Liquor Sodæ*, Solution of Soda. Soda is a white, hard, opaque substance, occurring either in lumps or in moulded cylindrical pencils. It is odorless, but has an intensely acrid, caustic taste. It deliquesces in moist air, but becomes dry and effloreseent in dry air. It dissolves freely in water and alcohol. It should be kept in well-stoppered bottles made of hard glass. Soda is commonly made by evaporating an aqueous solution of the substance, until the water is driven off and the hydroxide remains in a state of fusion, and then either pouring the viscid fluid into cylindrical moulds or allowing it to harden *en masse*. Solution of soda may be made by dissolving soda in water, but is commonly prepared from the carbonate by decomposition with lime in the presence of water. Calcium carbonate precipitates, and the solution of soda, clarified by straining and settling, is separated by siphonage. Solution of soda is "a clear, colorless liquid, odorless, having a very acrid and caustic taste, and a strongly alkaline reaction. Specific gravity about 1.059" (U. S. P.). The solution should be kept in green glass bottles, glass stoppered, and the stoppers should be coated with vaseline or paraffin.

Soda and its solution are powerfully alkaline and caustic, like potassa, but to a somewhat inferior degree. Soda is available as a caustic, to be used after the manner of potassa, but potassa, being the stronger agent, is generally preferred. Solution of soda is possible as a local alkali for the skin or the stomach, but the carbonates are almost always used in preference. If given internally, the dose of solution of soda would range from 1 to 4 gm. (♏ xv.-lx.), largely diluted. In considerable quantity, undiluted, solution of soda would prove a caustic poison, with symptoms generally similar to those of poisoning by potassa.

Normal Sodium Carbonate: $Na_2CO_3.10H_2O$.—Sodium carbonate in crystals or effloresced powder is official in the United States Pharmacopœia as *Sodii Carbonas*, Sodium Carbonate; and the effloresced powder, baked at a temperature of about 45° C. (113° F.) until its weight is reduced to a fixed standard, is also official under the title of *Sodii Carbonas Exsiccatus*, Dried Sodium Carbonate. Sodium carbonate is the salt commonly called *sal soda* or *washing soda*, and is obtained in part from natural deposits—"native soda," so called—in part from the ashes of certain plants growing in or near the sea, the impure yield of which constitutes *barilla* or *kelp*, and in part by artificial making from sodium chloride, sodium sulphate, or the mineral *cryolite*. Sodium carbonate occurs as large, colorless, monoclinic crystals, which effloresce in dry air and fall into white powder. The salt has no odor, but has a harsh, alkaline taste. It dissolves freely in water, but is insoluble in alcohol. The dried salt of the Pharmacopœia, a fused mass as first prepared, finally presents itself as a white powder. Both forms of the carbonate should be kept in well-stoppered bottles.

Sodium carbonate combines, very purely, strong alkalinity with absence of specific qualities of any kind except the irritation or even causticity in concentrated application which is inherent in a powerful soluble alkali. Its uses are solely those of a local alkali, and are practically confined to external employment in lotion or ointment in skin affections. Lotions average two per cent. in strength, and ointments between two and ten, the basis being lard. For internal use, the acid carbonate, next to be described, is preferred, because of its more agreeable flavor and milder action. In considerable quantity and strong solution the normal carbonate is a corrosive poison.

Acid Sodium Carbonate: $NaHCO_3$.—This salt, the well-known *cooking soda*, so called, occurs in two grades of purity. One, corresponding to 95 per cent. of the pure salt, is the commercial *bicarbonate of soda;* the other, purified to represent 98.6 per cent. of the pure salt, is what is used in medicine, and is official in the United States Pharmacopœia under the title *Sodii Bicarbonas*, Sodium Bicarbonate. This salt is a white powder, permanent in the air, without odor, and of a not unpleasant taste, cooling, mildly saline and alkaline. It dissolves in 11.3 parts of cold water (15° C. = 59° F.), but is decomposed by hot water, losing carbon dioxide, and becoming the normal carbonate. It is insoluble in alcohol.

Sodium bicarbonate is purely alkaline, like the normal salt, but to a less degree, and by reason of that fact is far less irritant. In all ordinary dosage it is indeed practically free from danger. Its taste also is mildly mawkish only, instead of harshly alkaline. For these various reasons this salt is a favorite one for stomachic alkalizing, as in acid dyspepsia or diarrhœa. It is also much used to make alkaline lotions for the skin. Internally from 1 to 4 gm. (gr. xv. to lx.) may be given at a dose in water, and externally washes or ointments may be made in the same manner and of the same strengths, as in the case of the normal carbonate. Both of the carbonates are incompatible with acids and acidulous salts, lime water, ammonium chloride, and salts of the metals and metals of the earths.

Troches of the bicarbonate—*Trochisci Sodii Bicarbonatis*—are official in the United States Pharmacopœia, each troche containing 0.20 gm. (gr. iij.) of the salt. The salt is also an ingredient of the pharmacopœial preparations, *Mistura Rhei et Sodæ*, for which see *Rhubarb*, and *Pulvis Effervescens Compositus* (Seidlitz powder), for which see *Potassio-Sodic Tartrate*, under *Potassium*.

Sodium (Pyro-) Borate: $Na_2B_4O_7.10H_2O$.—This salt—the familiar substance *borax*—is official in the United States Pharmacopœia as *Sodii Boras*, Sodium Borate. It occurs in colorless, transparent, shining, monoclinic prisms, which effloresce in dry air. The crystals are odorless, and of a mild, cooling, and somewhat sweetish taste. The effloresced powder has a more pronounced alkaline flavor. Borax dissolves in sixteen parts of cold water, and freely in boiling water. In alcohol it is insoluble. Borax occurs native in Persia and adjacent neighborhoods as a saline efflorescence on the borders of lakes, and in California as a crystalline deposit at the bottom of a small lake. It is also made from other native borates.

Borax is locally bland and constitutionally innocent, and its medicinal virtues seem to reside in the combination of feeble alkalinity with a fair degree of antiseptic power derived from its acid radical. Borax works well as a mild detergent alkali in skin diseases or catarrhs, and ulcerations of mucous membranes, particularly of the mouth. A lump held in the mouth and slowly sucked seems to excite the secretions of pharynx and larynx, and in case of huskiness from dry catarrh of these parts temporarily restores something of the natural quality to the voice—an important matter to a singer or speaker affected with a cold. Internally, borax may be used as a feeble alkali, and it has been accredited also with a power to promote menstruation, correct dysmenorrhœa, and excite uterine contractions—a power which until better substantiated than at present should not be trusted in an emergency. Borax may be given internally in doses of from 1 to 3 gm. (gr. xv. to xlv.), and, externally, may be applied in lotions ranging from one to six per cent. in strength (limit of solubility in water), or in ointment of thirty-per-cent. strength. Borax has been experimented with, among a host of other substances, for the purposes of "antiseptic surgery," and has been found experimentally to prevent the development of microzymes in aqueous solution of from one-half to one-per-cent. strength.[1]

What is practically a soluble form of borax is the *tetraborate* that forms when borax and boric acid are boiled together in water. Sodium tetraborate makes a fine white powder, of greasy feel, which is freely soluble in water. It may be used locally for the purposes of borax, and is convenient for the making of antiseptic borate solutions. Solutions ranging in strength from two to fifty per cent. have been used.[1]

Sodium Acetate: $NaC_2H_3O_2.3H_2O$.—The salt is official in the United States Pharmacopœia as *Sodii Acetas*, Sodium Acetate. It occurs in large, colorless, transparent monoclinic prisms, efflorescent in dry air. It is odorless, with a bitter, saline taste; dissolves in 1.4 parts of cold water, and freely in boiling water; in 30 parts of cold alcohol and in 2 parts of boiling water. It is rarely used in medicine. Its purpose would be as a constitutional sodic alkali, its acid, as in the case of other alkaline acetates, undergoing conversion, in the blood, to carbonic. It may be administered in doses of from 2 to 4 gm. (gr. xxx. to lx.).

Potassio-sodic Tartrate. (See under *Potassium*.)

Normal Sodium Sulphate: $Na_2SO_4.10H_2O$.—This salt, commonly called *Glauber's Salt*, is official in the United States Pharmacopœia as *Sodii Sulphas*, Sodium Sulphate. It occurs in large, colorless, transparent, monoclinic prisms, rapidly efflorescing on exposure to air, and ultimately falling into a white powder. It is odorless, with a cooling but bitter saline taste. It dissolves in 2.8 parts of cold water (15° C. = 59° F.); in about 0.25 part at 34° C. (93.2° F.), and in 0.47 part of boiling water. It dissolves also in glycerin, but is insoluble in alcohol. The salt should be kept in well-stoppered bottles. Sodium sulphate is formed as a by-product in the manufacture of many chemicals. It is a salt of low diffusion power, and hence in full dose, in comparatively strong solution, is a purgative. As such it is powerful in action, like the other alkaline sulphates, producing watery stools, with nausea and griping. From its sickening taste it has been almost wholly superseded by the less disagreeable magnesium sulphate (Epsom salt). From 15 to 30 gm. (℥ ss.–i.) is a full purgative dose, to be taken in aqueous solution, aromatized or slightly acidified to disguise the nauseous bitter taste of the salt. Sodium sulphate is a purgative ingredient of many mineral waters.

(*Di-*) *Sodium* (*Ortho-*) *Phosphate*: $Na_2HPO_4.12H_2O$.—This salt, the common tribasic phosphate, so-called, or *tasteless purging salt*, is official in the United States Pharmacopœia as *Sodii Phosphas*, Sodium Phosphate. It occurs in large, colorless, transparent, monoclinic prisms, which, on exposure to air, effloresce rapidly and become opaque, losing five per cent. of their water of crystallization. The salt is odorless, with a cooling, saline, and slightly alkaline taste. It dissolves in 5.8 parts of cold water and in about 1.5 parts of boiling water. It is insoluble in alcohol. Sodium phosphate is made from the calcium phosphate of calcined bone, by decomposition by sulphuric acid. It should be kept in well-stoppered bottles in a cool place.

Sodium phosphate is a bland salt, of low diffusion power, whose prominent physiological properties are to purge mildly, and, as animal experimentation has shown,[2] to excite quite notably the secretion of bile. At the same time it is feebly alkaline, and possessed of a clean, non-nauseous, salty taste, quite like that of common salt. Therapeutically this phosphate may be used for the general purposes of the milder saline purges, and, more specially, has also proved of avail, even in non-purgative doses, to correct bowel derangements associated with acidity and assumed sluggishness of the liver. From its mildness and not unpleasant taste it is particularly convenient for giving to young children. Mixed with foods, such as soup, in lieu of common salt, it may be administered in moderate quantity without suspicion. As a purge the dose for an adult is about 30 gm. (℥ i.); but for corrective purposes, much less—even so little as 0.65 gm (gr. x.)—given a number of times through the day, may suffice.

Normal Sodium Pyrophosphate: $Na_4P_2O_7.10H_2O$.—The salt is official in the United States Pharmacopœia as *Sodii Pyrophosphas*, Sodium Pyrophosphate. It is not used in medicine, and is official for pharmaceutical purposes only to prepare ferric pyrophosphate.

Sodium Nitrate: $NaNO_3$.—The salt is official in the United States Pharmacopœia as *Sodii Nitras*, Sodium Nitrate. It occurs in colorless, transparent, rhombohedral crystals, which deliquesce in moist air. It is odorless, with a cooling, saline, slightly bitter taste. It dissolves in 1.3 parts of cold water and in 0.6 part of boiling water. It is slightly soluble only in cold alcohol, but dissolves in 40 parts of boiling alcohol. It should be kept in well stoppered bottles. Sodium nitrate is the salt called *cubic nitre*, and is obtained from South America, where it occurs native. It is a salt of high diffusion power, and in its physiological relations closely resembles ordinary nitre (potassium nitrate), except that it is, of course, devoid of the characteristic properties of a potassium salt as such. Its use in medicine has so far been an empirical employment in dysentery, in which disease 30 gm. (℥ i.) of the salt has been given divided in frequent doses throughout the day, in dilute aqueous solution. It is not a standard medicine.

Sodium Chlorate: $NaClO_3$.—The salt is official in the United States Pharmacopœia as *Sodii Chloras*, Sodium Chlorate. It occurs in colorless, transparent tetrahedrons of the regular system, permanent in dry air. It is odorless, with a cooling saline taste. It dissolves in 1.1 parts of cold water, and readily in boiling water. It is sparingly soluble only in cold alcohol, and dissolves in about 40 parts of boiling alcohol. If mixed with organic substances or with readily oxidizable chemicals, such as sulphur or phosphorus, trituration or concussion may cause a dangerous explosion, as in the case of the allied salt potassium chlorate. Sodium chlorate should be kept in glass-stoppered bottles. Sodium chlorate has the peculiar medicinal properties of the potassic salt of the same acid, except in regard to the effects of potassium compounds as such. It is important only because of its excess of solubility as compared with potassium chlorate. The medicinal uses are the same as those of the latter-named salt, which see under *Potassium*.

SODIUM DITHIOSALICYLATE.—This is the sodium salt of an acid formed by the reaction that occurs when salicylic acid and sulphur chloride are mixed together in molecular proportions at a temperature of 120° to 150° C. A large isomeric series is possible, but only two are utilized, the sodium salts of which are known as sodium dithiosalicylate I., and sodium dithiosalicylate II. The acids themselves are not employed for any therapeutic purposes, the sodium salts only being used. No. I. has not been used to any extent except in veterinary practice, in which two-and-a-half and five-per-cent. solutions are used in the treatment of foot-and-mouth disease. No. II. is the salt usually employed. It is a grayish-white powder, very hygroscopic, and entirely soluble in water. On the addition of acids a precipitate of yellow viscid drops is formed consisting of dithiosalicylic acid.

This salt is said to be superior to the salicylates in the treatment of acute and gonorrhœal rheumatism. It is given in doses of three grains, twice a day in mild cases, and more frequently when the attack is severe.

Beaumont Small.

SODIUM OLEATE. See *Eunatrol*.

SODIUM PARA-FLUORO-BENZOATE is a white powder soluble in water and used in tuberculosis in dose of 0.5 gm. (gr. viij.) three times a day. *W. A. Bastedo.*

SODIUM PERSULPHATE. See *Persodine*.

SODIUM SULFORICINATE. See *Polysolveol*.

SOILS IN THEIR RELATION TO HEALTH.—Under this heading we will consider, along with the soil more strictly speaking (that is, the débris of various kinds of rocks and the organic matter from animal and vegetable life forming what is ordinarily called soil), the influence exercised by vegetation.

Soils influence health: (1) Directly, by their component parts and immediate products being taken into the organism; (2) indirectly, by their influence in modifying other surrounding conditions.

(1) The direct influence of soils above alluded to may be exerted (*a*) chemically; (*b*) by introducing pathogenic micro-organisms; (*c*) by acting mechanically on the tissues.

(*a*) Gases and particles of organic matter taken into the organism in various states of chemical change may act by lessening its vitality or by introducing toxic material. The commonest example of this will be found in what are called "made soils." Holes and depressions in the surface of the soil are frequently filled up by street scrapings, garbage, bodies of dead animals, and other refuse, mixed, it may be, with earth, ashes, etc. These after a time are covered with grasses or other forms of vegetation, and eventually may become portions of streets and building sites. In the latter case it will readily be seen how noxious gases may be generated and carried up by the ascensional air of the houses built in and over such sites. Soil so made may also be ground up into dust and inhaled. The same is true in regard to various forms of animal and vegetable organic matter, scattered upon the surface of the ground, especially in our roads and streets.

In the case of houses built on made soil, or soil rich in organic matter, the cellar walls should be made impermeable to gases by the use of cement or other impervious material. A ventilated air space around the foundation wall will be serviceable in this regard, as well as for securing dryness of the walls. All cellar floors should be built of a sufficient depth of concrete or other similar material.

In those soils which contain a large amount of organic matter, the danger will be increased if they are underlaid with a stratum of impermeable marl, clay, or rock. The decomposing material will be retained in the soil. The writer placed on record, in the previous edition of THE REFERENCE HANDBOOK, in the article on *Sewage Disposal*, a remarkable instance of this in connection with the yard of one of our public schools, and also another instance in which filth had travelled laterally one hundred and forty feet over a substratum, saturating the earth in its course.

(*b*) With regard to *pathogenic micro-organisms* contained in the soil and taken from it directly into the organism, there has been and still is much speculative discussion among bacteriologists, but it may be looked upon as quite certain that some diseases are produced in this way.

It has been pretty well established that the germs of *typhoid fever* may be introduced by this method. The writer was one of a committee charged with investigating the causes of the spread of an endemic of typhoid fever in a small village. By a process of exclusion the committee came to the conclusion that some of the cases were due to the germs from typhoid washings drying upon the soil, being wafted in the dust, and inhaled by those who were attacked.

It is the generally received opinion that *tetanus* is caused by the germs finding their way from the soil into wounds and abrasions. It is also supposed by some that *malignant œdema* is caused in the same manner.

Anthrax, as has been established by frequent observations, is taken from the soil of pasture lands by cattle grazing upon them, and there are numerous instances where men have been attacked from the germs on the surface of the soil or from streams running through these pasture lands. We have not been able to collect data which would enable us to form an absolute decision, but there is no reason to doubt that with carelessness the anthrax germs may be taken into the system from the soil by man as well as by other animals.

By some, *diarrhœa* and *dysentery* are believed to be caused by the dust of infected soil. Dr. E. W. Hope,[1] of Liverpool, is quoted by Harrington as having made some important investigations in this connection. It has been noticed by many observers that a period of long-continued dry hot weather, followed by heavy rains, has been succeeded by endemics of diarrhœa and dysentery among children and others. This has been interpreted differently by different observers, as will be noticed hereafter, but Hope states that the highest death rate from these causes, during a period of twenty years, "occurred in the year whose summer had the least rainfall, and the lowest in that in which the summer rain was greatest in amount, and that the fourteen years with average dry summers, in which the mean June to September rainfall was 10.9 inches, averaged about fifty per cent. more mortality during the quarter than the six average wet summers with a mean rainfall of 13.8 for the corresponding period." Hope believed that the absence of showers allowed an accumulation of dust and filth in the streets, roofs, and elsewhere, and that this floating in the atmosphere was the cause of the increased disease and mortality.

So general is the opinion as to the germs of *tuberculosis* being carried from the soil into the human organism through the respiratory passages and other channels, that it is now enacted in most communities that spitting in streets and other public places shall be prohibited. A case came under the notice of the courts in Toronto in connection with our public schools: A lad who had scrofulous sores was excluded from school, and the action of the school authorities in thus excluding him was upheld by the court, one of the reasons being the probability of the germs being conveyed in the dust of the school-room and premises into the lungs of the other scholars.

Much experimentation and discussion are going on regarding the conduct of many other pathogenic bacteria in the soil and the influence of the soil upon them. These cover too wide a territory and the conclusions are still too uncertain to be profitably taken up in this article.

(*c*) *Mechanical irritations* of certain tracts of the organism are produced by particles of the soil taken in from the air or mixed with drinking-water or other media. Sharp particles in the form of dust inhaled into the respiratory passages give rise to *bronchitic affections*; those blown into the eyes cause *conjunctivitis*. The action of such dust on the respiratory passages is well known where it has been caused in connection with the soil of mines and also in the prosecution of some trade or employment such as stone-cutting, grinding of agricultural implements, etc. When similar effects arise from the natural disintegration of the soil it is more difficult to trace them to this specific cause, inasmuch as it is accompanied by other influences.

The inhalation of coal dust and its deposit in the lungs of miners give rise to the disease known as *anthracosis*.

The mechanical irritation of the mucous membrane of the intestines from sand conveyed in drinking-water is well known, and is more properly considered in connection with the subject of water.

2. (*a*) The *ground water* is very largely influenced by the structure of the soil for receiving, holding, and retaining water, and not only by the structure of the superjacent soil but also by that of the subsoil, and by the configuration of both the soil and the subsoil. It will readily be seen that sandy or gravelly soil will be best adapted for receiving water and allowing it to run through it, and that such percolation of the water would be lessened if it had beneath it an impermeable subsoil, as of clay, marl, or shale, with a flat or concave surface.

Clays and marls are least adapted to allow water to pass through them, and hence retain their dampness for a greater length of time.

These conditions of soil in regard to the water in them influence health in various ways. In the first place, habitually wet soils act by increasing the humidity and coldness of the air at their surfaces, and it has been found by long experience and observation that such soils are conducive to *rheumatism, diphtheria*, and *tuberculosis*.

With regard to the last-named disease, statistics were collected by Dr. Henry I. Bowditch,[2] showing that the disease is much increased by dampness of the soil, and is notably lessened by drainage. Similar observations were made independently by Dr. Buchanan in England.

While the Klebs-Loeffler bacillus of *diphtheria* is aërobic and does not flourish in water, it has nevertheless been a matter of repeated observation that diphtheria is more prevalent in the presence of cold, wet soils. Whether this may not be due to a condition of the respiratory mucous membrane produced by such soils, is a suggestion.

We have spoken above of the condition of a concave, impermeable subsoil underlying a more porous structure. To depressions of this kind in an exaggerated form the term "punch bowl" has been applied, and such situations are particularly unhealthy. The condition of a stagnant body of water filling the interspaces of the soil here comes into play.

By similar conditions on a more extended scale marshes are formed, and in addition to the insanitary effects already alluded to they become breeding-places for mosquitoes, and consequently under suitable conditions give rise to *malarial affections, yellow fever*, and, it may be, other diseases.

The bad effects of damp soils on habitations may be lessened by the use of weeping drains so constructed and protected as to prevent the introduction of gases through them when there is no moisture in the soil which they are supposed to drain. Air spaces around the foundation walls have been alluded to when speaking of the means for preventing polluted air and noxious gases gaining entrance into houses. A damp proof course of slate or similar material should also be interposed through the whole thickness of the wall at or above the level of the surface of the ground. Unless such precautions be adopted dampness is likely to strike through and up the walls.

The influence of wet soils in interfering with outdoor living and exercise will be apparent.

(*b*) Before leaving the subject of the influence of soil upon water we must not lose sight of the fact that *water supplies* receive from the soil substances which have a decided influence upon health, both from the chemical and from the bacteriological standpoint. In this connection there is one aspect in which loose soils may, from accident or carelessness, become detrimental to health, and that is the ease with which they will allow pathogenic bacteria, such as the bacilli of *typhoid* and of *cholera*, to be carried for a considerable distance through their interspaces into wells and watercourses. It is highly probable that the colon bacillus is carried in the same way, giving rise to *diarrhœa* and *dysentery*. It has often been noticed that typhoid is very prevalent at that season of the year when the level of water in wells becomes low, an indication of the washing of bacteria into the wells. Instances of contamination in this way from and over the surface of the soil are also on record and must be laid to the account of the more impervious soils.

Soils rich in organic matter will, of course, yield much of this latter to the waters percolating through them. Some of these must contain toxic material, while all of them are more apt to serve as culture media for the growth of micro-organisms.

The chemical additions received by water from the soil are various. The analysis of our mineral waters is abundant evidence of this, and for this part of the subject the reader is referred to the article entitled *Water* and to the articles which treat of the different mineral springs. The prevalence of *calculus, goitre, and cretinism* in certain districts has been attributed to the presence of limestone formations and similar conditions of soil, but the evidence is very conflicting and does not seem to warrant the assumption.

Some observers consider that the absence of minerals in drinking-water is injurious, and as proof of this have cited the less hardy condition of French recruits coming from districts in which rain water is almost exclusively used for drinking purposes.

It has also been concluded, from analyses of river waters made before and after flowing through certain mining districts, that mineral additions taken up from the soil are sometimes of service in lessening the amounts of organic impurities.

(*c*) The *ground air* also is influenced by the structure and consequent porosity of the soil. The movement of the air will follow the movement of the water, and in addition will be influenced by barometric pressure, by the action of winds, and by temperature. While these forces will influence the movement of the air, it will be acted upon in respect to its humidity by the capacity of the soil particles for holding water by the force of attraction, and in respect to its chemical composition it will be modified by the chemical constituents of the soil. In this way, for example, the relative amounts of oxygen and of carbon dioxide will be modified.

It will readily be seen how great a difference in this respect there will be between the ground air, and consequently the air close to the surface of the soil, in arid, sandy soils, and that in soils rich in humus. For example, in and above a soil which is rich in humus, and which therefore contains large quantities of organic matter, the air will, other things being equal, be poorer in oxygen. On the other hand, it is very reasonable to suppose that the absence of such organic matter is one of the causes of the suitability, for tuberculous patients, of some of the arid health resorts, such as certain districts of Arizona. That other factors also play a part in rendering these resorts so beneficial will of course be apparent to the student of climatology.

The prevalence of diarrhœa and dysentery after a period of long-continued dry weather has been referred to in connection with the observations of Dr. Hope, who attributed this prevalence to some "infective agent . . . blown about in the dust of the air." It has also been stated that others have considered it to be due to the accumulated infective material being carried into depleted wells. By others again it has been attributed to the ground air, laden with this "infective agent" during a long period of inaction, being suddenly driven out by a downpour of rain, which, by providing moisture, favored at the same time a certain amount of decomposition and germ growth.

(*d*) The *temperature* of the air, besides being influenced by altitude, is largely modified by certain characters of the soil. The influences of the ground air and ground water on the temperature have been alluded to. The color and structure of the soil play an important part in determining to what extent the rays of the sun shall be reflected and to what extent they shall be absorbed by the latter. Thus, for example, soft loamy soils, and those containing a good deal of humus of a dark color, have a much greater capacity for absorbing heat and then parting with it later when the air above them becomes cooler. Hence the temperature in such districts is more equable, and the changes will be less rapid. The direction of the slope of the soil also acts by reflecting the rays of the sun more or less perpendicularly. If the ground slopes in a southerly direction, the rays are reflected more perpendicularly and consequently the temperature is increased. The movements of the air will, as a consequence, be affected by the same conditions which modify the temperature on the surface of the soil.

(*e*) *Insolation*, while largely dependent upon altitude and other associated atmospheric conditions, will also be modified by the influence exerted by the soil. Reflection of the rays of the sun, just now alluded to, is one of these factors. Another is the absence or presence of dust, which is shown to be largely dependent upon the condition of the soil. This absence of dust, very noticeable in some districts, was brought very forcibly under the notice of the writer in the district of Muskoka. Having occasion to ascend to an open attic floor in a cottage in Muskoka, after a year's absence, he was surprised to find that it was almost entirely free from the dust which would have accumulated in a similar position in most other districts, and especially in our cities or in the vicinity of country roads. The condition observed in the case of the cottage is to be attributed to three factors: that there is very little loose surface soil, the ground being composed principally of rock; that there are no roadways nor wagon roads in the vicinity of this cottage, travelling being effected in boats; and that the soil in the neighborhood is covered with trees and mosses. These conditions make such localities very desirable for the treatment of diseases of the respiratory organs.

(*f*) The influences of the *configuration* of soils have been alluded to in some of their aspects, such as slope and direction of slope both of the soil and of the subsoil. Some other influences under this head remain to be considered.

Valleys and *ravines* have an influence on temperature and also in the determination of the direction of the wind. The positions of the ends of valleys influence their temperature and the character of the wind blowing through them. As an example of the former, the writer has been told by botanists that the valley of the Desjarnins Canal, near Hamilton, Ontario, contains plants which on open ground are not to be found farther north than the isothermal line of Virginia.

The question of *altitude* belongs to the article on *Climate* (*q.v.*), but the altitude of a particular locality in relation to surrounding localities—whether situated on hill, valley, or plain—will have a determining effect on its temperature, humidity, and immediate atmosphere. An elevated spot may be unhealthy by relative depression.

A plain situated at the foot of a range of hills will be influenced by the circumstance whether it is on the north or the south side of the range. Vegetation is also likely to be influenced by such situation.

(g) The influence of *vegetation* must be further considered. It will depend upon the quantity and kind of vegetation. Low scrub and brush-wood are injurious by preventing a free circulation of air on the surface of the soil, and by favoring the accumulation of organic deposit which is likely to decompose slowly and to vitiate the air. Such vegetation should not be disturbed during the existence of a camp in its immediate neighborhood, inasmuch as this removal tends for the time being to increase the unhealthy condition of the atmosphere by the rapid liberation of the vitiated air. This kind of vegetation is also a harboring place for the lower forms of insect life, including mosquitoes, the injurious action of which has already been considered.

The tendency of forests is to equalize temperature, cooling the atmosphere by evaporation from their leaves during hot weather, and also by shielding the ground from the rays of the sun. They also tend to keep up a more equable supply of water in the streams of the locality. Evergreen trees are supposed to have an additional beneficial effect by the exhalation of resinous vapors. Belts of trees are sometimes of service in sheltering localities from bleak winds, and have been supposed to be of service in warding off malaria. In former days rows of sunflowers were planted for this latter purpose of shielding a locality against the malarial "miasm," as it was termed. According to our present knowledge, it may be that these effects were due to these trees and plants forming barriers or receiving-places for the winged bearers of infection.

To the above remarks regarding the health of forests there are exceptions. In some places the influences described keep the soil in a permanently wet condition; as, for example, in the tamarac and mangrove swamps, of temperate and tropical regions respectively. Again, in other forests, through lack of sun and air no opportunity is afforded for the disposal of the decomposing vegetation, which is sometimes very luxuriant.

Wm. Oldright.

SOLVEOL is a neutral solution of cresol in aqueous sodium cresylate. It contains 23.6 per cent. of cresol.

W. A. Bastedo.

SOMNAL.—Introduced as an hypnotic by Radlauer, of Berlin, in 1889. He described it as a true chemical compound formed by the direct combination of chloral alcoholate with urethane.

It is properly a clear, colorless crystalline powder, with a hot burning taste, and very deliquescent, but is supplied in the form of a liquid on account of its instability. It is an alcoholic solution, one part in three. It has also been described as a solution of chloral hydrate and urethane in alcohol.

It is used solely as an hypnotic, the dose being from twenty to thirty minims for adults. *Beaumont Small.*

SOUTH DAKOTA HOT SPRINGS.—Fall River County, South Dakota.

Post-Office.—Hot Springs. Numerous hotels and cottages.

Access.—Viâ Freemont, Elkhorn, and Missouri Valley Railroad (branch of the Chicago and Northwestern system), or viâ the Chicago, Burlington, and Quincy Railroad (Burlington route) direct to Hot Springs, arriving at the same depot by either route.

This attractive new spa is located in the heart of the Black Hills, at an elevation of 3,400 feet above the sea level. Hot Springs is the county seat of Fall River County, and is located about seventy miles south of Deadwood. The town has a permanent population of about 1,500 and a summer population of 3,000. Its proximity to extensive pine forests, in addition to the favorable features of location above mentioned, assists in preserving a mild and agreeable climate, and has brought the resort into much favor with persons afflicted with hay fever, asthma, and incipient phthisis.

The advantages of Hot Springs as a health resort are numerous. First, as to topographical features. The scenery in and adjacent to the place is varied and delightful. The lofty pine-clad hills, grand canyons, rippling streams, and beautiful falls of the Minnekahta and Cheyenne, make up a group of attractions difficult to excel. Second, as to climate. By reason of certain peculiar circumstances of location this resort is favored by very mild, equable atmospheric conditions. Summer days are followed by evenings of delicious coolness, while the autumns are unusually pleasant. During the winter months the temperature has observed an average of 42° F. above zero for the last four years. Situated in the Minnekahta Valley and sheltered on all sides by heavily timbered hills, this resort is almost perfectly exempt from cold winds and sudden changes of temperature. The winter temperature in the valley is from 20° to 25° F. higher than it is in localities only a dozen miles distant. It is said that the protection afforded by the hills is supplemented in no small degree by the millions of gallons of hot water flowing through the valley. During the winter of 1892-93 Dr. C. W. Hargens, of Hot Springs, kept a record of the temperature for five months, beginning with December 1st and ending with April 1st. This was the coldest winter this country has had for many years. We make the following extracts from his notes:

December, 1892. Snowed once; fall of snow three-quarters of an inch. Five cloudy days.

January, 1893. Three cloudy days. No snow during the month; average temperature for the month, 40° F. (for the last two weeks of the month it was 50.2° F.).

February, 1893. One day and a half cloudy. Snowed four times, with total precipitation nine-sixteenths of an inch.

March, 1893. Two and one-half days cloudy. Snowed twice. Total precipitation, two-fifths of an inch. Average daily temperature, 50.3° F.

April, 1893. No snow. No storms of any kind. Mild, pleasant weather throughout the month.

The visitor will find excellent accommodations. The largest hotel, the Evans, is constructed and equipped throughout in accordance with the latest and most approved methods. Other excellent hotels are the Gillespie, the Hot Springs, the Catholicon, the Davis, and the Parrott House. Cottages are also at hand for those who desire them. The hills afford attractive spots for camping out. Adjoining the Evans House is the Evans Sanitarium, containing sixty bathrooms and embracing all varieties of baths. The Stewart Sanitarium, recently completed, also affords falcilities for all kinds of bathing. The Catholicon Sanitarium, now under construction, will add another to the list of the sanitaria of Hot Springs. The springs at this resort are eight in number. The name, the "Minnekahta," is given to a great Indian spring, the word being a synonym for health, pleasure, and recreation. It is said that the waters of this spring were in use by the Sioux and other tribes long before the approach of civilization. The natural temperature of this spring is 98° F. It furnishes the drinking fountain of the Evans House, the Evans bath house, and the Minnekahta bathhouse. An analysis by Prof. Charles B. Gibson, of Chicago, resulted as follows: One United States gallon contains (solids): Magnesium sulphate, gr. 4.32; sodium sulphate and potassium sulphate, gr. 25.62; sodium chloride and potassium chloride, gr. 13.79; calcium sulphate, gr. 16.32; silica, gr. 2.46, and a trace of iron peroxide. Total, 62.51 grains. The waters are perfectly clear, have a decidedly alkaline reaction, and contain no organic matter.

A second spring, known as the Mammoth Mineral

Spring, furnishes a water which is still richer in solid constituents. The analysis shows that one United States gallon contains (solids): Sodium sulphate, gr. 23.26; potassium sulphate, gr. 5.63; calcium sulphate, gr. 36.11; calcium chloride, gr. 5.59; magnesium chloride, gr. 4.11; magnesium carbonate, gr. 3.51; organic and volatile matter, gr. 12.11; and very small quantities of ammonium chloride, magnesium nitrate, magnesium phosphate, iron sesquioxide, alumina, and silica. Total, 92.71 grains.

The analysis of the water of the third spring, known as the Lakatah Spring, shows that one United States gallon contains (solids): Sodium sulphate, gr. 8.82; potassium sulphate, gr. 3.33; calcium sulphate, gr. 16.29; calcium chloride, gr. 8.50; magnesium chloride, gr. 3.14; magnesium carbonate, gr. 3.04; organic and volatile matter, gr. 8.05; and very small quantities of ammonium chloride, calcium phosphate, magnesium nitrate, iron sesquioxide, alumina, and silica. Total, 53.79 grains.

According to the report of the National Association of Railway Surgeons, which visited this resort in 1893, "treatment by the Hot Springs water may be said to stimulate all the secretions and organic functions, to promote digestion and assimilation, and to favor tissue metamorphosis and excretion, thereby relieving internal congestions, stimulating blood-making, increasing the appetite, and favoring new and healthy tissue at the expense of the old and inactive." This treatment may therefore be confidently recommended in "gout and rheumatism after the inflammatory stage; in neuralgia, especially when depending upon gout; in metallic or malarial poisoning; in paralysis not of organic origin; in neurasthenia; in the early stages (only) of Bright's disease; in syphilis; in functional diseases of the liver; in dyspepsia, not of organic origin; in catarrhal affections of the respiratory tract; . . . and in chronic skin diseases, especially of the squamous variety."

James K. Crook.

SOZOIODOL.—(Di-iodo-para-phenol-sulphonic acid.) An acid base which was introduced in 1887 as an antiseptic. It contains forty-two per cent. of iodine, twenty per cent. of carbolic acid, and seven per cent. of sulphur. The acid itself is not employed, but it forms salts which possess all the properties of the acid. The potassium and sodium salts are the ones most employed. They resemble one another in physical characters, forming in colorless, well-defined prisms, soluble in water, the potassium compound in fifty parts and the sodium in fourteen.

The use of these compounds is in all those conditions in which iodoform is likely to be proved useful. It is said to be preferable, as it is soluble in water and glycerin, does not decompose when exposed, readily combines with other substances, and is free from irritating action and disagreeable odor. The zinc salt has been specially recommended for gonorrhœal discharges. It is soluble, one part in twenty of water. All the solutions should be freshly prepared and not exposed to the light, as they are decomposed and free iodine is liberated.

The mercurial salt is a lemon-yellow powder, soluble in about five hundred parts of water. It is mainly employed in the treatment of syphilitic affections. It has been recommended as the most suitable form of mercury for hypodermic injections. The injections should be made in the gluteal regions, alternately on the right and on the left side. It causes a little pain, but the local effects are said to be much less than with any other mercurial salt. The dose is one grain and a half, and one injection a week is equal to three of other forms of mercury. The absorption of the drug is rapid, and the gums have to be carefully watched, as its action is very marked.

Beaumont Small.

SOZOL.—(*Paraphenol-sulphonate of aluminum.*) It occurs in brownish granules of a strong astringent taste and faint carbolic odor. It is very soluble in water, glycerin, and alcohol, and forms very stable solutions.

It is not a powerful antiseptic or bactericide, but has been found to be a very serviceable application to wounds, ulcers, etc., as it possesses an astringent action in addition to its antiseptic properties.

Beaumont Small.

SPARKLING CATAWBA SPRINGS.—Catawba County, North Carolina.

Post-Office.—Sparkling Catawba Springs. Hotel and cottages.

Access.—Viâ Western North Carolina Railroad to Hickory, sixty miles west of Saulsbury; thence six miles by carriage to springs.

The location of the Sparkling Catawba Springs is within the shadow of the Blue Ridge Mountains, 1,150 feet above the sea level. This part of the State, known as the "Piedmont Section," has long been famous for its bracing climate, pure air, and uniform temperature. The springs are three in number, and gush from the ground in a shaded valley surrounded by a circular range of timbered hills and within one mile of the banks of the Catawba River. No analysis has been made, but the springs are said to be blue and white sulphur and chalybeate in character. The new hotel and cottages afford comfortable accommodations for about four hundred guests. We are informed by Dr. E. O. Elliott, of the springs, that the waters possess well-marked alterative and tonic properties, and generally increase the appetite, assist the digestion, and promote the assimilation of food. A very complete and comfortable bathing establishment is at hand.

James K. Crook.

SPARTA MINERAL WELLS.—Monroe County, Wisconsin.

Post-Office.—Sparta. Hotel.

Access.—Sparta is a station on the Chicago, Milwaukee, and St. Paul Railroad, two hundred and fifty-five miles from Chicago. Bulletin 32 of the United States Geological Survey reports twelve mineral wells in Sparta, only two of which appear to have been analyzed. We present the following analysis of the Magnetic Well, made by J. M. Hirsh in 1876: One United States gallon contains (solids): Magnesium carbonate, gr. 3.35; iron carbonate, gr. 11.94; and very small quantities of manganese carbonate, calcium carbonate, ammonium carbonate, lithium carbonate, strontium carbonate, barium carbonate, potassium sulphate, sodium sulphate, calcium sulphate, sodium chloride, calcium chloride, sodium phosphate, aluminum phosphate, sodium iodide, and silica. Total, 19.25 grains. This analysis shows an almost pure chalybeate water, the remaining ingredients being all of a secondary character.

James K. Crook.

SPASMS. See *Convulsions.*

SPEARMINT.—*Mentha Viridis. Brown, Garden, Lamb,* or *Mackerel Mint.* "The dried leaves and tops of *Mentha spicata* L. (fam. *Labiatæ*)." U. S. P.

Spearmint is a native of Europe and Asia, and has spread widely through nearly all temperate regions, where it is also cultivated to a large extent, and shows a high degree of variation in characters. It usually covers quite large patches, propagating by slender runners. The quadrangular, slender, frequently purplish stems are prostrate below, one to two or three feet long, and much branched. The drug is thus described:

Sparingly and obscurely hairy, the hairs short and stout, without menthol crystals in their cells; branches quadrangular, slender, usually pale green, rarely purplish; leaves opposite, exstipulate, very shortly petioled, the blades usually less than 5 cm. (2 in.) long and about one-third as broad, lanceolate, or lance ovate, rounded at the base, acuminate and acute, sharply serrate, thickish, and rigid, deep and usually dark green; flower spikes usually appearing clustered at the summit, interrupted, elongated, and acute, about 5–8 mm. ($\frac{1}{5}$–$\frac{1}{3}$ in.) thick; flowers about 3 mm. ($\frac{1}{8}$ in.) long, the calyx tube nearly equally five-toothed, ten-nerved, the corolla light purple, nearly equally four-lobed, the stamens four, nearly equal, rather long; odor characteristic, aromatic, rather heavy; taste characteristic, pungent.

It is readily distinguished from peppermint by the elongated, slender, and acute flower spikes, the relatively longer stamens and style, and the ranker odor. As seen under the microscope, its hairs never exhibit menthol crystals.

The only important constituent of spearmint is about one per cent. of volatile oil, with which there is associated a little tannin. This oil, although quite similar in properties, is very distinct in composition from the closely related peppermint oil. It contains no menthol, nor apparently any other crystalline substance. Its important constituent appears to be carvone (see *Caraway*). Pinene and limonene also exist.

The action and uses of spearmint are almost identical with those of peppermint. It is somewhat milder in action, on account of which it is often preferred for administration to infants.

Powdered spearmint is often given in doses of 1–2 gm. (gr. xv.–xxx.). The infusion is also popular. The best form of administration is the oil (*Oleum Menthæ Viridis*), dose one to five minims, or one of its two preparations. The spirit or essence (*Spiritus Menthæ Viridis*) contains ten per cent. of the oil and one per cent. of spearmint, and the dose is 0.3–1 c.c. (♏v.–xv.). The water (*Aqua Menthæ Viridis*) has a strength of 0.2 per cent. and the dose is 15–60 c.c. (fl. ℥ ss.–ij.). *Henry H. Rusby.*

SPECTACLES—from *spectare*, to view; French, *besicles*,* *lunettes*; German, *Brille*;* Dutch, *bril*;† Italian, *occhiali*; mediæval Latin, *perspecillum*, *conspecillum*, *ocularius*—are first mentioned about the close of the thirteenth century.‡ Seneca mentions the fact that "letters, however minute and indistinct, appear larger and clearer when viewed through a glass globe filled with water."[9]

The first mention of a lens, properly so called, is attributed to the Arabian mathematician Alhazen (*obt.* 1038),[10] who describes the magnifying property of a segment of a sphere of glass.[11] Roger Bacon (*circa* 1267) mentions the magnifying property of convex lenses, and suggests the benefit to be derived from their use by old persons with weak sight.[12] The step from the use of a convex lens, as a magnifier, to the construction of binocular eyeglasses or spectacles, to be worn by presbyopes in reading, implies a considerable development of the optician's art, in the direction of grinding lenses of relatively long focus. The invention of spectacles is variously attributed to Salvino degli Armati, a Florentine (*obt.* 1317),[13] and to Allessandro della Spina, a Dominican friar of Pisa (*obt.* 1313). The use of concave glasses, as a help to myopes in distant vision, must have followed at no very long interval; the date of their first employment is, however, unknown. The necessity for the selection of lenses of different focal length for different persons, as well as for the same person at different periods of life, must also have been very early recognized; but there is no reason for believing that the choice was made in any better way than by trying them at random, until a pair was found which appeared to be suited to the kind of work for which they were to be used.* Certain it is that spectacles had been in use for from two to three centuries before the theory of their action was explained,† and it is only since the middle of the nineteenth century that anything like a complete understanding of the subject has been reached.

Spectacle lenses, as late as the second half of the eighteenth century, were generally, so far as is known, of the plano- or double-convex, or of the plano- or double-concave form.[16] Both the plano-convex and the plano-concave glasses appear to have been mounted, sometimes with the plane surface and sometimes with the curved surface next the eye. Concavo-convex lenses were used to some extent in the eighteenth century, but with varying practice as regards the side turned next the eye.‡[17] Under the name of *periscopic* spectacles, concavo-convex lenses, with the concave surface turned toward the eye, were brought into use by Wollaston (1804).[18] A special construction of double-convex and double-concave spectacle lenses, made by grinding the two surfaces of the glass to cylindrical curves of equal radii, but with crossed axes, was introduced (before 1830) by Galland de Cherveux;[19] such lenses are still manufactured in limited quantity, but, aside from certain inherent defects, they offer no compensating advantage over the several forms of lenses with spherical surfaces; their existence in commerce made it possible, however, to furnish a cylindrical surface, on demand, at a time when plano-cylindrical lenses were not yet readily obtainable. Cylindrical lenses proper, as used for the correction of astigmatism, were first employed by G. Airy, Astronomer Royal (1827),[20] who was himself the subject of compound myopic astigmatism. Airy discussed the relative advantages, in compound astigmatism, of a bicylindrical lens of unequal radii of curvature, and a spherico-cylindrical lens. The common use of cylindrical spectacle lenses dates from the special study of astigmatism by Donders.[21] Since 1884 it has been possible to have spec-

* From the old French form *bericle*, diminutive of *berille*; Latin, *berillus*, *beryllus*; βήρυλλος, the beryl[1]; *cf.* the derivation of "brilliant"—French, *briller*, etc.—from *berrylus*.[2]

† From *berillus*, *beryllus*, βηρυλλος, the beryl; "the colors of the beryl range from blue through soft sea-green [aquamarine] to a pale, honey yellow, and in some cases the stones are entirely colorless";[3] *ocularii vitri aut berillorum*: Guy de Chauliac (1363).[4] The most available material for spectacle lenses, excepting glass, is rock crystal or quartz, and it is highly probable that this mineral, still largely used under the name of pebble, was utilized by the older opticians.

‡ Spectacles, both convex and concave, were in common use by the Chinese before the opening of commerce with Europe. They were made of a transparent stone, of a color like that of a strong infusion of tea, called *schu-chi* (tea-stone), and were tied upon the head by silken cords.[5] Chinese spectacles are now made of rock crystal, and are mounted in thick frames of tortoise shell or of metal, evidently borrowed from old European models.

The common use of some form of magnifying glass by the ancients is wellnigh proved by their perfect workmanship as displayed in the engraving of gems. On the other hand, it appears certain, from the notices on presbyopia and myopia, by Paulus Ægineta (seventh century A.D.),[6] and by later as well as earlier writers, that they had not applied lenses to the relief of persons laboring under these disabilities.

Pliny's description of the visual defect of the Emperor Nero[7] strongly suggests a case of myopia or of compound myopic astigmatism. The statement of Pliny - Nero princeps gladiatorum pugnas spectabat in zmarugdo[8] — taken in connection with what is said of this gem in the same chapter, would seem to be best explained upon the supposition that the emperor possessed a large and highly polished emerald, or gem of like color, most probably of unequal curvature in its two principal diameters, and that he viewed the combatants, in the strong light of the amphitheatre, by reflection from its convex surface. This theory would imply that the use of the gem for this purpose was the result of an observation made by Nero himself, who may, therefore, be accredited with the discovery of an optical device suited to the correction of myopia, or of compound myopic astigmatism; the invention would appear to have died with the inventor.

* Bartisch (1583) protests earnestly against the widely spread abuse of spectacles.[14]

† "Maurolicus, in his treatise '*de lumine et umbra*' (1554), considers the crystalline as the principal instrument of vision, and as transmitting to the optic nerve the images of objects; and he explains why some persons are long-sighted and others short-sighted, according to the less or greater convexity of the surfaces of the crystalline, showing that in the former case the rays have not been converged to a focus when they reach the retina, while in the latter they have been converged before they reach it. He explains, also, how the convergency may be hastened in the long-sighted eye by the use of a convex glass, and delayed in the short-sighted by a concave one. These observations of Maurolicus were not known to Kepler, when it was proposed to him, as a question by his patron, Dietrichstein, in what manner spectacles assisted sight? The first answer he gave, as he tells us in his '*Paralipomena ad Vitellionem*' (1604), was, that convex glasses were of use by making objects appear larger. But his patron observed, that if objects were by them rendered more distinct, because larger, no person would be benefited by concave glasses, since these diminished objects. . . . He now gave a clear account of the effect of lenses, whether within or without the eye, in making the rays of a pencil of light converge or diverge; and explained that convex glasses assist the sight of presbyopic persons by so altering the direction of rays diverging from a near object, that they fall upon the eye as if they had proceeded from a more remote one, that concave glasses benefit the myopic by producing a contrary effect upon rays which diverge from a distant object, making them fall upon the eye as if they proceeded from a near one."[15]

‡ Aside from the misinterpretation of special optical formulæ, caprice has played its part in determining many eccentricities of practice; from the beginning, the business of selling spectacles appears to have been conducted largely under the cloak of mystery, and very often of deliberate misrepresentation.

tacle lenses ground to order with a convex or concave surface of unequal radius of curvature in its several meridians, thus producing, by means of a single curved surface, the effect usually obtained by the combination

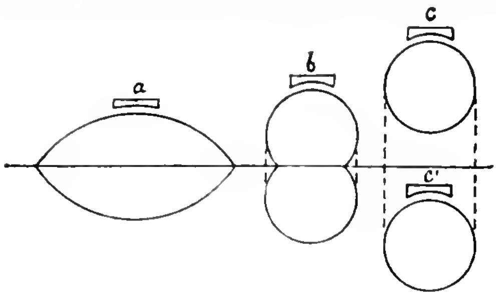

FIG. 4321.

of a cylindrical with a spherical surface.[22] The curved surface of such a convex lens represents a small area cut out from a large surface of revolution corresponding to the rounded rim of a wheel; the concave surfaces produced by this method are such as may be worked upon a

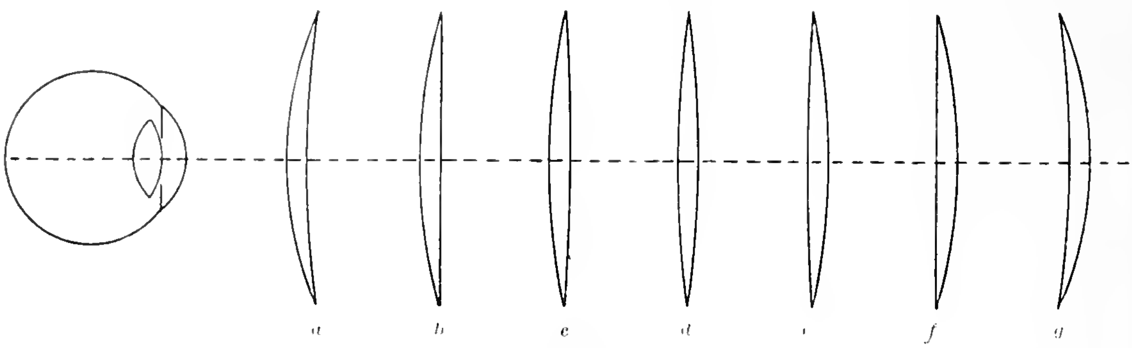

FIG. 4322.

grinding tool having the form of such a wheel.* Prismatic glasses, suggested to Donders by his colleague, Kreeke, as a possible means of re-establishing binocular vision when it has been lost through the deviation of the visual axes in strabismus, were made the subject of spe-

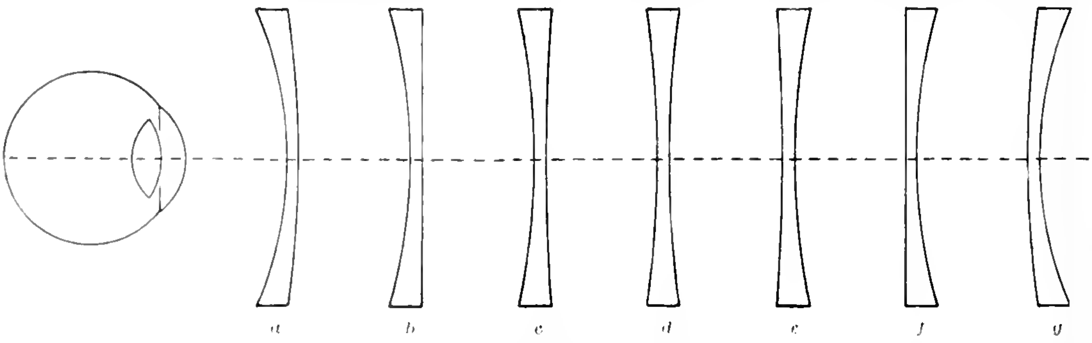

FIG. 4323.

cial study by Donders,[24] and have since held a place among the recognized means of dealing with certain conditions referable to disorders of the external muscular apparatus of the eye. The decentration of ordinary convex or concave lenses, in order to give to the combination of the two spectacle glasses some measure of prismatic effect, was also discussed by Donders.[25] Decentrated convex lenses had already been used in the dissecting spectacles of Brücke,[26] and in the refracting stereoscope of Brewster.[27] Stenopæic spectacles—from στενός, narrow, and ὀπή, a peep-hole—were also employed by Donders,[28] chiefly for the purpose of admitting to the eye such rays only as correspond to a selected limited area of the cornea or crystalline. Like the so-called *panoptic* spectacles of Serre d'Uzès,[29] they are essentially the same thing as the obsolete strabismus goggles (*Schielbrillen—louchettes*). The snow-goggles of the Esquimaux, which cover the entire front of the eyeball, with the exception of a narrow horizontal slit, may be classed with stenopæic spectacles, although designed primarily as protectives against the injurious effects of strong sunlight reflected from the snow.

In very high grades of myopia, and especially in cases of irregular myopic refraction of high degree, the best attainable visual result may often be had by looking through a small circular hole or a slit in a thin opaque card or disc of blackened metal.

The several forms of spectacle lenses, as they have been or may be mounted before the eye, are shown, for convex and concave lenses respectively, in Figs. 4322 and 4323. Of the convex lenses (of positive focus), *a* and *g* (Fig. 4322) are menisci; *b* and *f* are plano-convex; *c* and *e* are double convex, with surfaces of unequal radii of curvature; and *d* is double convex, with surfaces of equal radii. In concave lenses (Fig. 4323) we recognize the corresponding forms: –*a* and –*g*, concavo-convex; –*b* and –*f*, plano-concave; –*c* and –*e*, double concave, with surfaces of unequal radii of curvature; and –*d*, double concave, with surfaces of equal radii. Of these, *g* (positive meniscus, with the concave surface turned toward the eye), and –*a* (negative concavo-convex, with the concave surface toward the eye), are especially designated as

* The entire surface of revolution, as shown in section, takes one of the three forms, Fig. 4321, *a*, *b*, *c*, the last of which is an open ring (anchor-ring, torus); the interior of such a ring gives a surface (*c'*) convex in one principal meridian and concave in the other, and applicable, therefore, to the correction of mixed astigmatism.[23]

periscopic (from περί and σκοπέω) glasses; they offer a certain advantage when the eyes are turned so as to look obliquely and eccentrically through them, the advantage being greater according as the concave surface, as in —*a*, is of shorter radius of curvature.[30] These several forms of lenses, other than the plano-spherical, may be resolved into combinations of two lenses, each with a spherical and a plane surface, placed with their plane surfaces in contact (Fig. 4324, *a*, *b*, *c*, *d*). Inasmuch as a smaller effective area than that bounded by the usual setting is quite sufficient for many of the uses for which spectacles are worn, it is often possible notably to reduce the weight

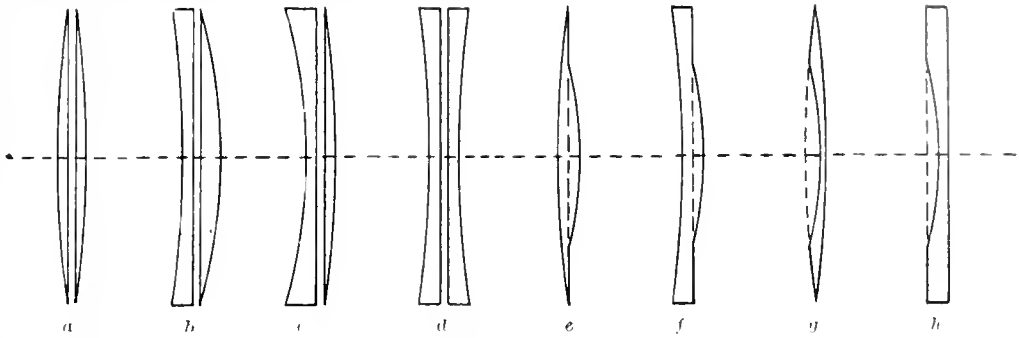

FIG. 4324.

of the glasses, when required to be of very short focus, by the adoption of forms like those shown in Fig. 4324, *e*, *f*, made by cementing a small plano-convex upon a larger plano-convex or plano-concave lens, or *g*, *h*, in which a deep concave surface is ground in a lens of any required configuration.

Cylindrical lenses are found in trade of two forms, namely, plano-convex and plano-concave (Fig. 4325, *a* and *b*); the dotted line represents an element of the cylindrical surface, which is parallel to the axis of the cylinder of which the lens-surface is a segment; they are manufactured by machinery, in different thicknesses, so that any required spherical surface, convex or concave, may be ground to order upon the plane side. The power of a plano-cylindrical lens varies, in its several meridians, from zero, in the meridian corresponding to the axis, to a maximum power (positive or negative) in the meridian at right angles to the axis. In a spherico-cylindrical lens, with both surfaces of the same kind (*i.e.*, convex or concave), the meridian corresponding to the axis of the cylinder is that of least, and that at right angles to this axis is that of the greatest (positive or negative), power. Cylindrical lenses are occasionally prescribed with two cylindrical surfaces of unequal radii of curvature and crossed axes, but the same optical effect is more easily obtained by combining a cylindrical with a spherical surface.*

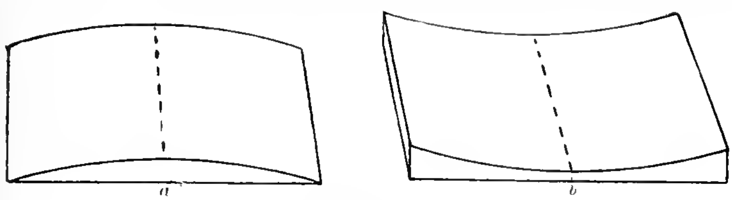

FIG. 4325.

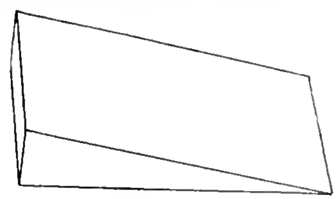

FIG. 4326.

Prismatic glasses with plane surfaces are of the form shown in Fig. 4326; any desired curvature, whether convex or concave spherical, or convex or concave cylindrical, may be given to either surface, or to both surfaces of the prism. A prismatic lens with one surface, or both surfaces, ground to a spherical curvature, is equivalent to a lens cut out from a peripheral zone of a larger spherical lens (Fig. 4327). Some degree of prismatic effect may, therefore, be obtained by the decentration of any convex or concave spectacle lens; such effects are, in fact, not infrequently produced by accident, as a result of carelessness in mounting spectacle glasses.

The stenopæic effect may be embodied in any lens by painting over some part of its surface, next the eye, with an opaque, lustreless, black varnish. A partial opacity of the cornea, or a portion of its surface presenting an abnormal curvature, may be thus excluded, more or less completely, from participation in the formation of the retinal image, with the effect, in some cases, of materially improving the definition of the object.[32]

Tinted glass is occasionally used in the manufacture of both spherical and cylindrical spectacle lenses, which, however, present an unequal density of tint in different parts, dependent on the varying thickness of the glass. In the case of concave glasses, which are thinnest at the centre, this may be an advantage; in the case of convex

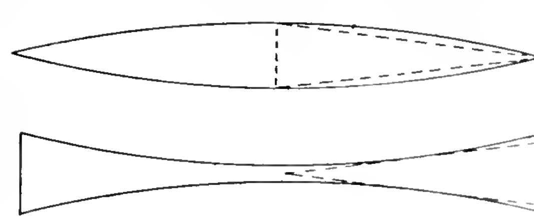

FIG. 4327.

glasses, the inequality of tint may be avoided by cementing a thin plate of tinted glass to the plane surface of a plano-convex lens by means of Canada balsam. A more elaborate device consists in cementing a thin plate of tinted glass between the plane surfaces of two plano-convex lenses, or of a plano-spherical and a plano-cylindrical lens. Amber has been used as a material for spectacle lenses, notably at Königsberg, about the end of the seven-

* Cylindrical lenses with two cylindrical surfaces, with axes at some angle other than a right angle, are sometimes prescribed. Such lenses, as well as bicylindrical lenses with crossed axes, can always be reduced to an optically equivalent combination of a spherical and a cylindrical surface.[31]

teenth century; the transparency of the amber is said to have been increased by heating in a bath of oil or sand.[33]

Tinted glasses are in common use to temper the light which reaches the eye; they are made either with parallel plane surfaces, like window glass, or with concentric curved surfaces, like a watch glass (coquilles). Green was formerly a favorite color, as assimilating the light passing through it to the color of grass and the foliage of trees; blue (the color of the sky) gradually superseded green, and is still often used. The neutral tint, known as London smoke, is, in most cases, to be preferred. Glasses of an amber color, called shooting glasses, are also to be found in the shops, generally ground to a dull surface, with the exception of a small, central area; they are intended to be used in looking at small distant objects in strong sunlight. Amber-colored and, more perfectly, red glasses, by excluding the more refrangible rays of the spectrum, improve the definition of the retinal image in very low grades of myopia; blue reading glasses, on the other hand, may render some slight degree of aid in low grades of hypermetropia and of presbyopia.[34] Tinted glasses should, as a rule, be mounted in large, oval rims, so as to cover the entire front of the orbit; the coquille form of glass affords more perfect protection than a glass with plane surfaces. Darkly tinted (London smoke) coquilles are of great use to persons who are exposed to strong light reflected from sand or from snow, or from the surface of water. Inasmuch as such reflected light is highly polarized, protective spectacles of tourmaline should render valuable service by cutting off the confusing reflected rays, while permitting the unpolarized light, by which objects are actually seen, to pass comparatively unobstructed.[35] London smoke glass, of so dark a tint as to appear black in ordinary light, is used in protective spectacles worn by workmen employed about electric arc lights, and spectacle glasses made up of several layers of glass of different colors have been found especially useful in observing the intensely brilliant scintillations attending the conversion of pig iron into steel by the Bessemer process. A glass smoked in the flame of a candle is a familiar device used in viewing sun spots or a solar eclipse.

All spectacles afford some degree of protection against mechanical injury, and in certain trades it is only by the use of special protectives that the liability to grave accidents to the eyes can be averted. Millers have been long in the habit of wearing large spectacles fitted with thick window glass when employed in the dangerous work of dressing millstones. Protective spectacles of mica[36] are especially to be recommended for miners, quarrymen, stone-cutters, boiler-makers, and others engaged in similar dangerous employments; large spectacles fitted with thick plates of glass or of rock crystal have been found effective as a protection against injury from stray pellets in bird shooting. Goggles of finely woven wire gauze are occasionally used by railway travellers and others as a protection against flying sparks; goggles made of glass bent to a cylindrical curve, and furnished with cushioned rims to fit closely around the margins of the orbits, also masks with glazed openings in front of the eyes, are made in a great variety of forms as protectives in driving automobiles.

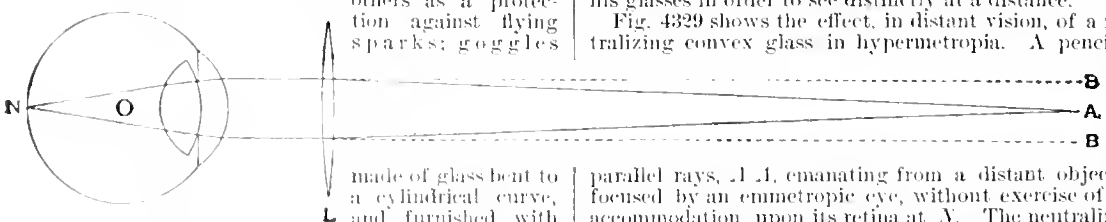

Fig. 4328.

Coquille spectacles and eyeglasses, both colorless and tinted, are made also in the meniscus form (with positive focus) and in the concavo-convex form (with negative focus); as kept in the shops, they range from about +8. dioptries to −8. dioptries. Owing to the shorter radius of curvature of the (concave) surface turned toward the eye, these glasses are more perfectly periscopic than those commonly sold under that name.

The office of spectacles and eyeglasses, other than mere protective and stenopaeic glasses, is, primarily, to supplement impaired accommodation (convex glasses, in presbyopia and in accommodative paresis or paralysis), to relieve the accommodation of an excessive burden by supplementing deficient refraction (convex glasses, in hypermetropia), to correct excessive refraction (concave glasses, in myopia), to correct asymmetrical refraction (convex or concave cylindrical or toric glasses, in astigmatism), and to relieve the external ocular muscles of strain or to overcome moderate grades of diplopia (prismatic glasses). These several effects are, moreover, often variously combined, as in the use of strong convex glasses in reading (by hypermetropes with defective accommodation); of partially correcting concave glasses, or, perhaps, of weak convex glasses, in reading (by myopes with defective accommodation); of glasses of asymmetrical refraction (in compound or mixed astigmatism, and in presbyopia or other accommodative defect occurring in connection with astigmatism); and of decentrated or prismatic glasses with spherical, cylindrical, or toric surfaces.

The action of a convex glass, as used by a presbyope, in reading, is shown in Fig. 4328. Divergent rays emanating from a printed page at *A*, at such distance from the eye, *O*, that the retinal image of the print shall be of sufficient size to admit of its being easily deciphered, are refracted in passing through the lens *L* (whose focal length must be not less than the distance *L A*), and are rendered either less divergent—as if they had originated from some point more distant than *A*—or parallel—as if coming from an infinite distance. When the focal length of the lens *L* is equal to the distance *L A*, the rays constituting the several pencils which enter the eye, *O*, from an object at *A*, are rendered parallel, and a sharply defined retinal image is formed at *N*, without exercise of the accommodation. If the focal length of the lens *L* is greater than the distance *L A*, the rays forming the several pencils emanating from the object at *A* will, after refraction by the lens *L*, be rendered less divergent, as if coming from an object at some distance greater than *L A*, and the eye, *O*, will then be enabled to focus such pencils through the exercise of less of its accommodation than would be required to focus pencils diverging from *A*. The former of these two cases represents the condition of an emmetropic eye in extreme presbyopia, or in total paralysis of accommodation; the second case is that of an emmetropic eye in lower grades of presbyopia, or in a state of weakened accommodation.

The presbyopic eye, when thus adjusted by the convex lens *L* for the reading distance *O A*, is, by the action of the lens, thrown out of adjustment for distinct vision at a distance; a presbyope wearing glasses for reading, or other near work, must therefore remove or look over his glasses in order to see distinctly at a distance.

Fig. 4329 shows the effect, in distant vision, of a neutralizing convex glass in hypermetropia. A pencil of parallel rays, *A A*, emanating from a distant object, is focused by an emmetropic eye, without exercise of the accommodation, upon its retina at *N*. The neutralizing convex lens *L* converts the parallel rays of the pencil into rays of such degree of convergence that the hypermetropic eye, *O*, focuses them accurately at *N′*; the entire accommodation is thus rendered available to meet the requirements of near vision, so that the hypermetropic eye, with its neutralizing glass, becomes virtually emmetropic.

In the case of total presbyopia or paralysis of accommodation in the hypermetropic eye, a lens equal in power to the sum of the two lenses *L* (Fig. 4329) and *L* (Fig. 4328) is required for distinct vision at the reading distance *O A*.

A hypermetrope wearing neutralizing convex glasses sees distinctly, and without conscious effort, at all distances; when, however, he becomes also presbyopic, the neutralizing convex glasses cease to afford sufficient help in reading, and stronger glasses become necessary. These stronger reading glasses are, however, too strong for distinct vision at a distance; hence, an elderly hypermetrope requires, as a rule, two pairs of convex glasses—the one, neutralizing, for distinct vision at a distance, and another pair, of greater power, for reading.

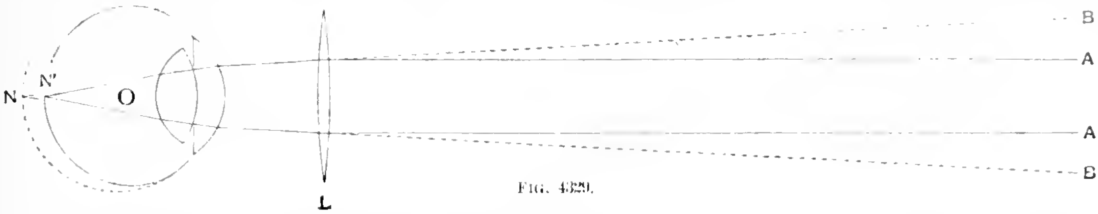

FIG. 4329.

Fig. 4330 shows the use of a neutralizing concave glass, in distant vision, in myopia. The pencil of parallel rays, *A A*, emanating from a distant object, is focused by the myopic, as by the emmetropic, eye at the normal position of the retina at *N*: the actual position of the retina, in the myopic eye, is, however, farther back, at *N'*. The myopic eye, in a state of complete accommodative relaxation, can focus only divergent rays, as from an object at some short distance, *O B*, upon its retina, and, by the exercise of its accommodation, it can also focus rays diverging from some still nearer point, somewhat within the distance of nearest distinct vision (*P*) for an emmetropic eye. The neutralizing concave lens, *L*, converts the parallel rays of the pencil, *A A*, into rays of such degree of divergence as they would have if emanating from *B*, and thus the myopic eye, *O*, is enabled to focus them upon its retina at *N'*. The farthest point of distinct vision (*r*) is thus carried off, by the neutralizing concave glass, to an infinite distance, and the near-point (*p*) is removed to the distance of the near-point in emmetropia.

When the myopic eye becomes restricted in its range of accommodation, as a result of advancing age, the neutralizing concave glasses must either be laid aside in reading or exchanged for weaker concave glasses; in myopia of a low grade it may even become necessary, in reading, to make use of convex glasses, but weaker than those which would be required by an emmetrope of the same age.

A myope wearing neutralizing concave glasses, like the hypermetrope wearing neutralizing convex glasses, sees distinctly at all distances. Only when he becomes presbyopic does he find himself compelled either to lay aside his concave glasses in reading, or to exchange them, temporarily, for weaker concave, or, possibly, for weak convex glasses.

Comparing Figs. 4329 and 4330, it will be seen that the pencil of parallel ray *A A* (Fig. 4329) is of somewhat greater diameter than the pupil, and, conversely, that the pencil *A A* (Fig. 4330) is of less diameter than the pupil. As the areas of the cross-sections of the two pencils are to each other as the squares of their diameters, it follows that there must be a considerable gain in the brightness of the retinal image in the case of hypermetropia corrected by convex glasses, and a loss of illumination in the case of myopia corrected by concave glasses. Thus, hypermetropes wearing convex glasses may see better than emmetropes by moonlight or starlight, and myopes wearing concave glasses see less perfectly under the same conditions; in high grades of myopia the disability from this cause is sometimes so great as to simulate night-blindness (hemeralopia).

Objects viewed through convex glasses appear larger than do the same objects when their images are focused by an exercise of the accommodation, and, conversely, near objects viewed through concave glasses under accommodative tension appear smaller than do the same objects when viewed without exercise of the accommodation. Hence a presbyope using convex glasses in reading sees the print not only clearer than without glasses, but larger than it formerly appeared to him under normal exercise of the accommodation. So, also, a hypermetrope wearing convex glasses sees all objects larger than when he views them without glasses, and a myope using concave glasses in reading sees the print smaller than when he reads without glasses. In uncorrected hypermetropia the actual size of the retinal image is smaller, and in uncorrected myopia it is larger, than in emmetropia.

A convex spectacle lens is increased in effective power by increasing its distance from the eye, and, conversely, a concave lens loses in effective power with every increase in its distance. The correct rule of practice is to mount the glasses as near as possible to the eyes, allowing sufficient room for the play of the eyelashes. A distance of 13 mm. from the vertex of the cornea fulfils this condition in most cases, and at the same time allows the correcting lens to be placed almost exactly at the anterior principal focus of the eye, in which position of the glass the retinal image, whether in hypermetropia or in myopia, becomes practically equal in size to the image of the same object when focused by an emmetropic eye. Whenever a hypermetrope inclines to remove his (convex) glasses to a greater distance from the eye than 13 mm., it may generally be assumed that the glasses are somewhat too weak, and, conversely, when a myope inclines to wear his (concave) glasses at a distance greater than 13 mm. from the eye, it may be assumed that the glasses are somewhat too strong. In presbyopia it is a not uncommon habit of old people to wear their spectacles far down toward the tip of the nose, in order to make a weak glass do the office of a stronger glass in improving the distinctness of the print, and also in increasing its apparent size; in this position of the glasses it is also easy to look over them at distant objects. In aphakia, after an operation for cataract, recourse may be had to the same expedient, as affording a partial substitute for the lost accommodation.

The increase or diminution in the apparent size of objects viewed through a convex or concave spectacle lens is not uniform in all parts of the visual field, but is greater at its periphery than at its centre. Thus, a large object viewed through a spherical convex lens appears more highly magnified in its peripheral than in its central portions, and the same object viewed through a spherical concave lens appears more diminished in its peripheral portions. When the (spherical) lens is accurately centred before the eye, in a plane perpendicular to the line of vision, this distortion of the virtual image is symmetrical; in all other cases it is unsymmetrical.

It has been often remarked that myopes, in selecting concave glasses, are apt to err by making choice of glasses of somewhat excessive power, which cause objects seen through them to appear very sharply outlined. This phenomenon appears to be a result of the chromatic aberration of the eye, causing the object, when viewed through a concave glass under a full correction for the more highly refrangible (blue or violet) rays of the spectrum, to be seen as if bounded by a very narrow red border, instead of by a broader violet fringe, as when the eye is focused for the less refrangible (red) rays. If a distant point of light is viewed by an over-corrected myopic eye through a piece of cobalt-blue glass, the light will appear blue, with a narrow red border; if the eye is under-corrected by its concave glass, the light will appear red, with a broader blue border.

A convex or concave cylindrical spectacle lens elongates or shortens the retinal image in a direction at right angles to its axis, thus giving rise to a change in the apparent shape of the object—a circle appearing elongated or shortened to an

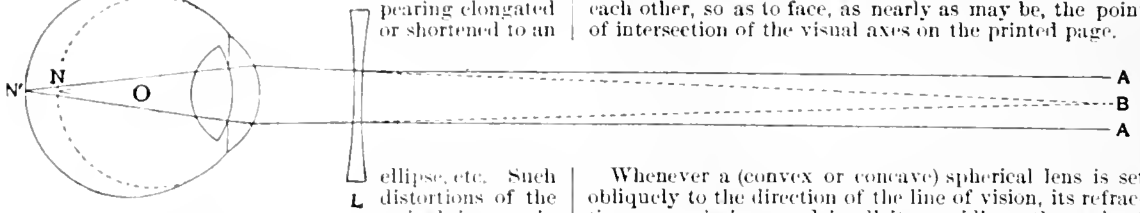

FIG. 4330.

ellipse, etc. Such distortions of the retinal image, in one eye or in both eyes, incident to the correction of astigmatism, or even a difference in the size of the two images caused by unequal spherical glasses, may give rise, in binocular vision, to a great variety of stereoscopical illusions which, until corrected by experience, may be a source of considerable annoyance.

Incidental to the action of convex and concave glasses in modifying the exercise of the accommodation is the effect which they exert upon the associated convergence. Convex glasses, by relieving the accommodation of a part of its burden (in hypermetropia), exert at the same time a positive effect in controlling the correlated convergence; hence, they rank first among the therapeutic agents at our disposal for arresting the development of convergent strabismus, and, in many cases, for its cure. Concave glasses, on the other hand, by increasing the demand made upon the accommodation in near vision, evoke increased action of the recti interni muscles (with correlated relaxation of the recti externi), and thus afford relief in many cases of muscular asthenopia and of crossed diplopia, and even of divergent strabismus (see *Asthenopia*).

Prismatic glasses with plane surfaces (Fig. 4326) may be mounted with their bases toward the nose, in which case they relieve the recti interni muscles of a part of their work in convergence, and are thus of service in certain cases of muscular asthenopia and of crossed diplopia of low grade. Mounted with their bases toward the temples, they are applicable in certain cases of homonymous diplopia dependent on insufficiency of the recti externi muscles. A prismatic glass, mounted with the base of the prism upward or downward, may be used to neutralize the effect of a slight downward or upward deviation of either eye, or the correction may be divided between the two eyes by making use of two prisms, the one mounted with its base upward and the other with its base downward. The deviation which may be thus overcome by a prism is equal to about one-half of the angle included between its two sides—*i.e.*, about 4° with a single prism of 8° angle, or 8° with a prism of 8° angle worn before each eye. Prisms of more than 10° or 12° angle are ordinarily rejected by reason of the conspicuous colored fringes due to chromatic dispersion.

The normal effect of any (convex or concave) spectacle lens is obtained only when the lens is accurately centred in front of the pupil, and the plane of the lens is perpendicular to the direction of the line of vision.* The distance between the centres of the two lenses of a pair of spectacles intended to be worn in distant vision should, therefore, be exactly equal to the interpupillary distance. In the case of reading glasses, the distance between the centres of the two lenses should be a little less than the lesser interpupillary distance when the visual axes are made to converge upon the printed page. In the case of spectacles or eyeglasses to be worn in distant vision, the two lenses should be set in one and the same (vertical) plane, perpendicular to the direction of the (parallel) visual axes, but they should be tipped forward in spectacles which are to be used in reading. In strictness, the lenses of reading spectacles should be also inclined a little toward each other, so as to face, as nearly as may be, the point of intersection of the visual axes on the printed page.

* In a plano-cylindrical lens the centre of the face of the lens is represented by a line, and the condition of accurate centration is fulfilled when this line crosses the centre of the pupil; a lens with plane surfaces, *e.g.*, a simple prismatic glass (Fig. 4326), has no centre; in general, the greater the radius of curvature (*i.e.*, the weaker the lens), the less is the error resulting from imperfect centration or from faulty direction of the plane of the lens.

Whenever a (convex or concave) spherical lens is set obliquely to the direction of the line of vision, its refractive power is increased in all its meridians, the ratio of increase being, however, greatest in the meridian corresponding to the plane of the arc through which the lens is rotated, and least in the meridian corresponding to the axis of rotation. In the case of a (convex or concave) cylindrical lens, rotated about its axis, the increase in refractive power varies from a maximum, in the meridian at right angles to the axis, to zero, in the meridian of the axis. When rotated about a line at right angles to its axis, a (convex or concave) cylindrical lens shows also an increase in refractive power, though in a lesser degree than when it is rotated about its axis. It follows that a tipped spherical lens becomes practically equivalent to a somewhat stronger spherical lens with a cylindrical lens added to it, and that, in the case of a spherico-cylindrical lens, the special effect of the cylindrical surface may be either increased or diminished, according as the compound lens is rotated about one or the other of its principal meridians. A tipped concave spherical lens may be occasionally utilized in distant vision in myopia, with astigmatism of relatively low grade, when the ocular meridian of greatest refraction is vertical or nearly vertical; conversely, a vertically mounted convex spherical lens may be given for reading, when the ocular meridian of greatest refraction is horizontal or approximately horizontal.* Again, in myopia with astigmatism, when

*A familiar instance of such a correction, in myopia, is seen in the not infrequent preference given to a tipped (concave spherical) eyeglass over glasses mounted in a vertical position, in a spectacle frame. So, also, after the extraction of cataract, a spherico-cylindrical lens, with axis horizontal, may be required to raise distant vision to its maximum, although, for reading, a spherical glass may be preferred, by reason of the increased power of the lens in its vertical meridian, incident to the oblique (downward) direction of the visual axes.

If we represent the power of any spherical spectacle lens by D, the angle through which the lens is tilted by ϕ, and the angle whose sine $= \frac{2}{3} \sin \phi$ by ϕ' (assuming the approximate value $\frac{3}{2} = 1.5$ for the refractive index of glass), the effective power of the tilted lens in its horizontal meridian will be represented by—

$$(3 \cos \phi' - 2 \cos \phi)\ D, \ldots\ldots\ldots\ldots [1]$$

and in its vertical meridian by—

$$\frac{1}{\cos^2 \phi}\ (3 \cos \phi' - 2 \cos \phi)\ D; \ldots\ldots\ldots [2]$$

the difference—

$$\left(\frac{1}{\cos^2 \phi} - 1\right) (3 \cos \phi' - 2 \cos \phi)\ D, \ldots\ldots [3]$$

representing the astigmatism of the tilted lens due to the tilting.

The following table shows the computed values of the several coefficients of D, for differences of 5° in the value of ϕ from zero to 45°.

$\phi =$	$3 \cos \phi' - 2 \cos \phi =$	$\frac{1}{\cos^2 \phi}(3 \cos \phi' - 2 \cos \phi) =$	$\left(\frac{1}{\cos^2 \phi} - 1\right)(3 \cos \phi' - 2 \cos \phi) =$
Zero.	1.000	1.000	0.000
5°	1.002	1.010	.008
10°	1.010	1.042	.032

45°	1.232	2.464	1.232
..	......	......	......
90°	2.236	Infinity.	Infinity.

By inspection of the table it will be seen that for every increase of the angle through which the lens is tilted, the astigmatism of the lens the ocular meridian of greatest refraction is approximately horizontal, the wearer of concave spherical glasses may learn the trick of looking obliquely through his glasses, to the right or to the left, in order to improve his acuteness of vision, though at the cost of acquiring an awkward carriage of the head. So, also, a hypermetrope with some measure of astigmatism, when the ocular meridian of greatest refraction is approximately vertical, may get a better correction from his (convex spherical) glasses by looking obliquely through them to one side.

A myope, wearing concave glasses of a power insufficient fully to correct his myopia, may look obliquely to one side, in order to improve his vision for the vertical lines of a distant object, and at the same time contract the opening of the eyelids, in order to improve his vision for horizontal lines; a hypermetrope, wearing convex glasses of insufficient power, is generally able to supplement their effect in distant vision by an exercise of the accommodation.

Spectacle lenses are usually mounted in oval rims, of metal or, in the case of eyeglasses, also of tortoise shell, horn, hard rubber, celluloid, etc. The rims used in mounting convex glasses are generally grooved, so as to grasp the sharp edge of the lens; concave glasses, too, are ground to an edge, and mounted in grooved rims, but it is a not infrequent practice to groove the lens itself, and to sink the rim, which is then made of (steel or gold) wire, in the groove. Convex lenses also are sometimes mounted with the rims sunken, but at the cost of making the lens needlessly thick and heavy. So-called frameless or rimless glasses have the metallic parts attached by means of screws passing through holes drilled in the lenses; concave lenses, with their thick margins, lend themselves better to this construction than do convex lenses.

Caprice has sometimes dictated the wearing of a single eyeglass, carried at the end of a riding-whip, a fan, etc., or worn suspended by a cord: in the latter case the circular glass is held in front of the eye by contracting the orbicularis muscle upon its rim. Binocular glasses may be divided, according to the way in which they are mounted, into three groups—namely, eyeglasses held in the hand (lorgnette—*face à main*); those held in place by means of a spring which pinches the nose (*pince-nez, Kneifer, Zwicker, Klemmer*), and spectacles proper, which are held in place by means of side-pieces passing above and behind the ears (*lunettes à branches, Bügel-brille*). To these three principal types may be added a fourth, still often used in the case of protective goggles, in which the glasses are held in place by means of an elastic band passing around the head.

The several parts of a pair of spectacles are (1) the rims (*cercles*), in which the glasses are mounted; (2) the bridge, or nose-piece (*arcade centrale, Bügel*), by which the rims are connected and supported upon the nose; and (3) the side-pieces (temples, bows, *branches latérales*), by which the spectacles are held in place upon the head. The size of the rims and the length of the bridge should be adjusted to the interpupillary distance, in order that the wearer may look through the centres of the glasses, and to the width of the face, so that the side pieces may touch, but not press against, the sides of the head. In the case of great width of face, larger or longer lenses are required than when the face is narrow.

The bridge should be shaped to fit the nose, and partially to encircle it; noses, however, differ greatly in prominence and in thickness, so that no single type of bridge is suited to all cases. The plain or the braced "hoop" bridge (Figs. 4331 and 4332) is one of the older forms, and is suited to noses of considerable thickness and prominence; the hoop may lie in the same plane with the glasses, or it may be turned forward at any required angle. The so-called "C" bridge (Fig. 4336) is the form most commonly found in the shops and, like the "hoop" bridge, it may be set at any required angle to the plane of the glasses. These forms serve best for reading-spectacles, but for spectacles to be worn in distant vision they often fail to support the glasses at the proper height, or at a sufficient distance from the eyes to avoid contact with the eyelashes. The "saddle" bridge (Fig. 4333), of comparatively recent invention, can be made to fit the greatest variety of noses, and when made of gold can be bent by means of pliers to meet almost any required conditions. The so-called "X" bridge (Fig. 4334), and the "K" bridge (Fig. 4335), are used principally in frames of very light weight; they are, however, of less general applicability than the other forms. The bridge should present a rather broad surface of contact with the nose, and special care should be taken to secure an accurate and comfortable fit. Bridges of the "X" and "K" patterns, when made from very thin wire, are apt to cut the nose. A gold bridge is often to be preferred, even when the other parts of the frame are made of steel, as being more easily moulded to the nose and free from liability to rust. Spectacle frames of tortoise shell were once in common use and have lately reappeared in the shops; when properly fitted to the face they are especially comfortable in reading and sewing.

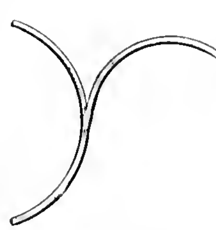

FIG. 4331.

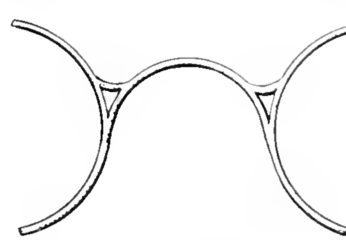

FIG. 4332.

The side-pieces (temples, bows, *branches*) should be slightly curved to fit the sides of the head, and they should be of a length sufficient to reach somewhat beyond the ears. Best of all, for spectacles to be worn constantly, are the hooked temples (Figs. 4333 to 4335) made of thin, elastic wire bent downward in a curve behind the ears.

The several parts of a spectacle frame should be nicely proportioned to each other. In the case of spectacles with straight sides the bridge should be of sufficient stiffness to maintain its shape unaffected by the lateral spring of the side-pieces. Only when hooked sides are used is it admissible to make all parts of the frame of very light weight.

(due to the tilting) increases at a much higher and progressively increasing rate. Thus, for 10° of tilting the increase in the resultant astigmatism of the lens is about four times as great as for 5°; for 20° it is 4.31 times as much as for 10°; for 30° it is 4.94 times as much as for 15°; for 40° it is 6.01 times as much as for 20°; etc. It follows that in any case in which the same spectacles are to be worn both for distant vision and in reading, as in correcting hypermetropic or myopic refraction in persons whose range of accommodation is practically unimpaired, by far the best adjustment is that in which the glasses are tilted forward through an angle equal to one-half of the difference in the direction of the visual line in distant vision and in reading (pantoscopic position).
